<sup>3</sup> Nosol. meth., tom. i. p. 139.

<sup>4</sup> Willan. Art. Strophulus.

also differ in preserving the natural colour of the skin, the greater number, indeed, only show symptoms of inflammation under the influence of external irritation. These papulæ are attended with no prickling sensations, but simply with a violent and incessant sense of itchiness. They occasionally project in so slight a degree, that they appear to be situated rather in the substance than on the surface of the skin. In this form of the disease, the pruritus is more especially complained of by patients when they first lie down, or after they have been in bed some time; it is then so violent as completely to rob them of all chance of repose. The itching may also be excited or exasperated by the contact or friction of the clothes, and by any cause that tends to heat the body, such as meals, exercise, &c. The pruritus intermits occasionally for three or four hours at a time, and now and then is scarcely felt when the patient's attention is very deeply engaged. This variety is entitled *prurigo mitis* by Willan.

Small, thin, circular incrustations, the size of a pin's head, and of a brownish or black colour, which often look wrinkled in the circumference, are always to be seen between the pruriginous papulæ. These minute scabs, which are detached before long, are formed by the drying up of a little blood that has exuded from the summits of the papulæ lacerated by the nails. A number of scratches, the cause of which is evident, and of stains of a brownish-yellow colour, due to the fading of papulæ, may also almost invariably be distinguished. The papulæ in *prurigo mitis* are successively evolved; and the disease, unless attacked by appropriate treatment, may continue for several months.

2d. Prurigo in another instance presents itself with a character of greater severity and obstinacy, when it has been distinguished by the epithet *formicans* by Willan. The papulæ, in this variety, broader and less apparent than in *prurigo mitis*, are attended by an incessant and insupportable pruritus, which is generally remarked to be intense in the same proportion as they appear flatter. They are usually scattered over the entire surface of the body, the face, the feet and the palms of the hands excepted; but they are especially numerous upon the nape of the neck, the lumbar region and outer parts of the thighs. In the evening, and particularly towards three or four o'clock in the morning, the pruritus is increased, and the patient, if he has been asleep, is then promptly awakened. The hands are involuntarily carried to the parts covered with papulæ, and a multitude of distressing sensations are then superadded to the one of pruritus. Some patients feel as if a host of insects were burrowing under the skin, others as if they were devoured by pismires, a circumstance which the epithet of Willan, *formicans*, is intended to recall. Others again feel as if the skin were pierced with red-hot needles. Patients then scratch themselves as if under the influence of rage or despair, and never cease from tearing their skin with their nails, brushes, combs, or any thing they can lay their hands on. The feeling of pruritus, increasing continually, is attended with an impatience and hurry of manner difficult to describe. The patients leap out of bed to walk about quite naked; the muscles of the upper and lower extremities seem in a state of constant and universal contraction, feel hard, and show distinctly and strongly through the skin; when the patients attempt to describe their sufferings, the phrases they make use of are *heat of blood, burning fires, maddening itchiness, &c. &c.*

The apices, and indeed the whole of the papulæ, are before long torn off by the nails. The skin appears covered with small, thin, and black-looking crusts, as in *prurigo mitis*. These incrustations are much more distinct than the papulæ that remain intact; these, having the colour of the integuments generally, are often distinguished with difficulty, on account of their trifling size.

3d. The papular eruption of porrigo is usually more considerable, and attended with severer symptoms among the aged than any other class of patients; hence Willan has established a third variety of the disease, under the title of *prurigo senilis*. The skin consequently appears more rudely scratched in this form of the disease than in the former two; it is also affected with a more copious desquamation. The pruritus is even more unbearable and incessant than in the *prurigo formicans* of children or adults, the external characters of the eruption, however, being precisely the same.

651. The intensity and continuance of the pruritus do not always bear an exact relation to the numbers of papulæ; I have occasionally

seen this symptom excessive, when but a very small number of papillæ could be distinguished on the skin.

Besides the papulæ which characterize prurigo, other and accidental lesions are generally observed, which disappear as soon as the irritation, which has caused them, ceases. Thus, when individuals attacked with prurigo neglect proper attention to cleanliness, pustules, vesicles and furuncles arise amid the papillæ; the skin also presents chaps of greater or less extent, and occasionally acquires a considerable degree of thickness, when the disease is of long standing, especially among the aged, or a furfuraceous desquamation takes place here and there from the trunk and extremities.

Scabies and impetigo may accidentally complicate prurigo; but it is a mistake to suppose with Willan and Bateman, that they may appear as one of the terminations of this disease. Several pathologists have maintained, that the state of the skin in *prurigo senilis* was favourable to the production and propagation of pediculi. (Vide Vocab. sub. *pediculi*.) And Willan even supposed that he had discovered a peculiar insect in one case of the disease; his description, however, of this insect is very imperfect.

Independently of these affections of the skin, *general* prurigo may be complicated with constitutional symptoms. In *prurigo formicans* the eruption of the papulæ is occasionally preceded by headache, general uneasiness, pain at the pit of the stomach, &c. On the other hand, when individuals affected with prurigo are attacked with any acute disease, the papular eruption declines and sometimes even disappears entirely, to recur when convalescence is established.

652. Prurigo may continue a few weeks only, or it may last for several years. During the longer period, very evident remissions and exacerbations are commonly observed. Among women and children, whose skins are fine and delicate, prurigo frequently disappears without leaving any trace of its existence behind it; but when it has affected the thick and dry integument of the aged, the epidermis is continually thrown off under the form of a mealy powder in the vicinity of the papulæ, and the skin presents stains or spots of a yellowish-brown colour intermingled with scratches.

653. The verge of the anus and scrotum in men, and the labia majora in women, are not only occasionally attacked with lichen and eczema, diseases essentially pruriginous, but these parts may be the seat of distinct papular eruptions belonging to prurigo. Such local varieties of prurigo, however, occur much more rarely than is generally imagined; true lichens, and chronic eczema, accompanied with excessive pruritus, have very often been referred to under the title of prurigo.

1st. Prurigo *podicis* is characterized by true papulæ similar to those of prurigo *formicans*. The skin of the verge of the anus and inner parts of the thighs, and buttocks, is rough, uneven, and beset with papulæ of the same colour as the integument that surrounds them, and with a greater number of small blackish scabs, which cover the summit of the papulæ that have been lacerated. These papulæ may be fortuitously mingled with a number of vesicles or small pustules. The itching occasioned by prurigo *podicis* is unbearable, especially during the night. Patients do not often forget themselves in sleep until they have scratched themselves with a kind of fury. This local variety of prurigo is always a long and obstinate disease. After continuing for some months, the symptoms occasionally seem to remit, but they become more violent than ever before long, from some irregularity in diet, &c. Women arrived at the critical period of life are particularly subject to this species of prurigo, and to lichens of the same parts. When the prurigo has been long left to itself, the skin, in a state of incessant irritation, becomes rough, squamous, and of a yellowish-brown colour. Lichen and eczema *impetiginodes* occasionally follow the papular eruption of this variety of prurigo.

2d. Prurigo *scroti* may exist alone or complicated with the prurigo *podicis*. It is characterized by papulæ developed upon the scrotum, and at times even on the penis. When the papulæ are torn with the nails they become extremely painful. Prurigo *pudendi muliebris* is likewise characterized by pruriginous papulæ evolved on the *mons veneris* and *labia majora*. The mucous membrane of the vulva occasionally presents, at the same time, a multitude of small solid elevations which render its surface rough and uneven; in this case there is frequently a true inflammation of the vulva and vagina, accompa-

nied with *intertrigo*. Lorry<sup>1</sup> has given a picture as faithful as it is animated of the symptoms and sufferings produced by prurigo and lichen of the genital organs. "Morbis ille adultos ut plurimum et primum pubertatis florem aggressor aditur, eosque qui, castè viventes, urgenti tamem impetu ad venerem ferrentur; mulieres etiam, sed maturius aditur. Ejus ortus primò mitior est, et pruritus totus continetur. At pruritus illi tum in maribus, tum in fæminis jungitur ardor in venerem inextinguibilis. Mores et præcepta repugnant, coercet virtus vivax, at manus indocilis ad has partes fertur, scalpendoque malum irritatur, et animus ipse in partem operis venit cum artuum tremore et palpitazione. Sedatur vulgò per plurimas horas malum, tuncque omnia tranquilla apparent, at recrudescit per paroxysmos, noctu potissimum afficiens. Sævit autem eò vehementius, quò aut familiariter magis aut proximè cum fæminis mares, aut cum maribus fæminæ vixerint. Nec minores acceperit vires a vino, piperatis, spiritibus, acribus alimentis, potu coffeæ, oleosorum spirituosorum, ita ut noverim viros qui nunquam similibus pruritibus, nisi una ex hisce causis accesserit, quas edocti experientiâ vitabant sedulius. Progrediente malo partes ad aspectum maculosæ, maculis flavis vix supra cutem extantibus distinctæ sunt; scrotum omninò rugosum est, ut et labia pudendorum in fæminis, et tempore paroxysmi prorsus retractum. Erectio penis et libidinis ardens cupido mentem incendunt. Partes illæ non eruptione lichenibus simili afficiuntur, sed epidermis rugosa olet, et alluitur liquore unctioso, non lintea maculante, non digitis adhærente, sed ad sensum lubrico. Incremento malo pruritus enormes fiunt, per paroxysmos et summè violentos, et frequentur rediunt, ita ut nec pudor, nec reverentia regum à scalpendo divertant, et sæpè per intervalla etiam paroxysmorum puncturæ acerrimæ acubus inflammationis per cutem transactis morsu similes, in clamorum adigunt: hinc partes illæ rhagadibus atque fissuris manu factis undiquè hiant. Ardor semper in est, et ad quemvis levissimum incessum exhalat humor olentissimus, fervente intereà œstro venero."

3d. Prurigo *plantaris*. M. Alibert has given an instance of a man, 50 years of age, but vigorous in constitution, who was suddenly attacked with a violent sense of itching in the sole of his foot, which soon acquired such a degree of intensity that even in the street and in company he was compelled to take off his shoe and scratch the part violently till the pruritus was in some sort appeased. A second case of a similar description is quoted by the same author; but in neither of the instances is there any mention of papulæ as the cause of the morbid symptoms, and as violent itching of the sole of the foot may be occasioned by various diseases, the species of prurigo under consideration is inadmissible until it shall have been confirmed by cases much more complete in their details than those we possess.

654. The *anatomical* inquiries that have been made into the seat and nature of prurigo by Alibert and Mouronval have no actual bearing but upon concomitant affections. One of Alibert's patients had died of a suppression of urine and pneumonia; the other presented numerous morbid appearances in the three great splanchnic cavities. In a third case we are informed that the papulæ had shrunk, death having been occasioned by a gastro-intestinal inflammation and an affection of the brain.

655. *Causes*.—Prurigo attacks infants, and the aged especially. It is more common among the poor than the rich, and occurs more frequently among men than women. The disease occasionally appears owing to a residence in low and damp situations, and particularly to a want of proper attention to cleanliness. Other causes have been surmised, the influence of which is more questionable, such as indifferently food, the abuse of spirituous liquors, salted and highly spiced meats, defective or irregular menstruation, vexation of mind, fatigue of body, &c., &c. It has also been observed that prurigo *mitis* generally invaded in the spring or beginning of summer, like lichen simplex, to which this disease, indeed, approximates, whilst prurigo *formicans* made its attacks at all seasons indifferently.

656. *Diagnosis*.—Itching or pruritus in a greater or less degree is a symptom common to almost all the inflammatory affections of the skin, particularly to urticaria, scabies, eczema, strophulus and lichen. Although this sensation has a peculiar character in prurigo, still it cannot be assumed as a pathognomonic symptom of the affection.

The true character of the disease lies in its presenting an eruption of irregularly disseminated papulæ, distinguished by their colour, which is similar to that of the surrounding skin, from the papulæ of lichen and strophulus.

When the papulæ of prurigo have been destroyed by the nails, the true nature of the eruption is made out with great difficulty, the little scabs of this affection differing but very little from those of lichen simplex and scabies; in the neighbourhood of the papulæ that have suffered, however, others that have escaped untouched may very commonly be discovered, and these proclaim the peculiar nature of the eruption. Prurigo is a papular, scabies a vesicular disease. In prurigo the papulæ present the colour of the integuments at large; in scabies the vesicles are transparent on the apices. The summits of the papulæ of prurigo when torn are covered by thin black crusts of dried blood; the vesicles of scabies when they have suffered in the same way are frequently succeeded by small thin and yellowish-coloured scabs. Scabies is readily transmissible from person to person; prurigo is not at all contagious. The pruritus of scabies is by no means a painful sensation; in prurigo it is sharp and burning, and patients labouring under it tear themselves with a kind of cruelty. Prurigo commonly appears on the shoulders, back, neck, loins, chest and limbs in the direction of their extension, very rarely between the fingers, occasionally on the face, and even on the scalp; scabies again occurs between the fingers, in the axillæ, popliteal regions, bends of the arms, and surface of the abdomen. The pruritus of scabies is constant, that of prurigo comes on in paroxysms of greater severity. Prurigo occasionally gets well spontaneously; scabies never terminates in this way, but it is much more under the influence of therapeutic agency than prurigo.

It may happen, indeed, that prurigo is complicated with scabies. Among the solid papulæ of the former the acuminate vesicles of the latter are then distinguished without difficulty. Lichen and the various other inflammatory affections of the skin may in like manner attack individuals labouring under prurigo. Such complicated cases of course require great discrimination in deducing accurate diagnoses.

Local prurigo cannot well be confounded with scabies; but it is more difficult to distinguish it from several other affections, which are themselves accompanied with pruritus of greater or less intensity. 1st. Ascarides in the rectum, hemorrhoidal tumours, slight inflammation or irritation of the great intestines, are all occasional causes of violent itching of the verge of the anus. These complaints differ from prurigo *podicis* by the absence of papulæ, and the presence of other manifest lesions which form no part of this eruptive disease. 2d. The pruritus caused by pediculi *pubis*, by eczema *impetiginodes* *scroti*, &c., need never be confounded with that which depends upon prurigo of these regions: the papulæ characteristic of the latter malady will always prevent mistake; a proper examination of the parts interested, indeed, will constantly enable the practitioner to ascertain whether any violent sensation of pruritus complained of about the anus, scrotum, vulva, &c., depends on the development of the papulæ of prurigo, or is due to another form of inflammation than the papular affecting these parts, to the presence of ascarides in the rectum, &c.

We had an out-patient at the Hôpital de la Charité, twenty-four years of age, in the ninth month of her pregnancy, who for a month had suffered from intolerable pruritus of the genital organs, accompanied, and apparently produced by a cluster of varicose veins upon the left greater labium, as there were no symptoms of any inflammatory affection of the parts implicated. The pruritus was completely removed by a single bleeding. Willan has quoted several analogous cases.

657. *Prognosis*.—Prurigo in children is not generally a very obstinate disease, but it is apt to recur repeatedly. Prurigo *senilis* is a much more serious affection, and often resists the best directed treatment. Tormented by the continual and at times excessive pruritus, patients tear themselves cruelly with their nails; but to the momentary relief thus procured, their enemy speedily returns in such burning and unbearable intensity, that they are frequently driven to acts of despair. The prurigo *podicis*, and prurigo *pudendi muliebris* are commonly very rebellious.

I have several times seen prurigo, with or without pediculi, appear

<sup>1</sup> Lorry. De morbis cutaneis, 4to. p. 449.

as a kind of crisis after measles, or some other more serious disease. Among the aged, living in misery, it frequently coincides with pulmonary catarrh, without, however, appearing to have any influence on the progress or duration of this infirmity.

658. *Treatment*.—The simple or slightly sulphureous bath is of all external remedies, that which proves constantly most beneficial in general prurigo. By this means alone, we very commonly succeed in speedily subduing the prurigo which is induced by filth and wretchedness. The baths ought to be taken tepid or cold; at too high a temperature they are injurious; at any degree under tepid they are very serviceable in prurigo *mitis* and prurigo *senilis*. They ought to be taken regularly every day, and the patient must greatly protract the period of his remaining in the water, even though this should appear to be followed by some temporary increase in the symptoms. Patients seem occasionally to experience more marked relief, by soaking for an hour every day in a bath of some emollient decoction, as of bran. The same means are further useful in preventing relapses of this disease. After the simple or emollient bath has been used for some time, if the eruption still continues, the alkaline bath, such as that of Plombières, or the soap bath frequently produces the best effects. These baths leave no unpleasant odour after their use, like those of sulphureous waters, which are, however, extremely efficacious in many cases, especially among the aged, and those individuals whose general health has suffered from bad or insufficient food. When sulphureous baths appear to increase the irritation of the skin, their action may be diminished by lessening the dose of the sulphuret of potash employed in making them, by adding a quantity of gelatin, or employing the sulphur and the simple bath alternately. This plan of treatment succeeds almost invariably in children affected with prurigo *mitis*.

Sea-water baths, tepid or cold, are employed under the same circumstances as sulphureous baths. Several cures have also been accomplished by means of sulphureous fumigations; the irritation they are apt to excite in the skin, however, frequently compels us to abandon their regular employment, or to combine them with the occasional use of the simple water, vapour, or emollient bath. The sulphureous bath is preferable to any other in the cases of children.

When prurigo is of long standing, or otherwise, when the skin has become rough and thickened, it is sometimes advisable to try the watery-vapour bath from time to time; in general, however, this form of bath is found detrimental to young and plethoric subjects, to children, and especially to the aged. It has been known to cause syncope, which, though not dangerous, perhaps, is still sufficiently distressing to the patient.

It is very seldom that any good is done by the application of the ointments of sulphur or of any of the mercurial preparations, or by lotions of sublimate and lime water, except in those cases that are complicated with scabies.

The pruritus has occasionally seemed to be mitigated by anointing the parts affected with an ointment of hellebore, and of the hydrochlorate of ammonia.

Mercurial washes may be tried with advantage in some cases of prurigo *formicans*, especially when complicated with pediculi. In other instances by merely washing the parts affected with plain cold or tepid water, or with very weak vinegar and water, the greatest relief is procured.

659. Of all the general measures employed in the treatment of prurigo, blood-letting, and diluents, such as whey, weak veal broth, thin gruel, decoction of dog's tooth grass, lemonade, &c., are indisputably the most potent. Bleeding is almost always indicated in youthful and plethoric subjects, and when the disease is attended with distressing insomnia, even in the aged. In females labouring under prurigo, if the catamenia are suppressed, the return of the discharge must be solicited by the application of leeches to the external parts, &c. When the disease invades during pregnancy, should any symptom of plethora be apparent, bleeding must still be had recourse to.

Those persons who have indulged in highly-seasoned food and spirituous liquors, must be restricted for some time to simple vegetable diet, and put upon the use of asses' or goat's milk.

660. Some writers recommend the exhibition of an emetic, and a purge on the invasion of prurigo; others advise decoctions of the burr-dock and potentilla, infusions of wild endive, fumitory, chamo-

mile flowers, &c., or the defecated expressed juice of these plants; and others assure us that they have derived the best effects from the exhibition of sulphur alone. Calomel is also prescribed, combined with the use of the neutral salts, and other more active purgatives. External applications have appeared to me so generally advantageous, that, except in some modified cases, depending on peculiarities of constitution, I recommend the treatment to be confined entirely to these.

661. The varieties of local prurigo themselves present several peculiar indications: 1st. Prurigo *podicis* is in general difficult of cure. When it is severe, it requires imperatively the employment of local bleeding, and even in cases of less intensity, this measure is constantly followed by the most marked temporary amelioration of the symptoms. Emollient cool or cold poultices, hip-baths, suppositories of cacao butter, opiate lavements, compresses dipped in cold water, are all useful in allaying pruritus. After a due perseverance in these measures, and occasionally even from the first, in individuals whose skin is rather irritable, the best effects are derived from gelatino-sulphureous douches. The application of a small quantity of the unguentum nitratis hydrargyri reduced, and of a weak acetic acid wash, is also frequently prescribed with advantage; these means, however, will do harm rather than good, if the integuments around the anus chance to be excoriated, or in a very irritable state.

2d. The same treatment is applicable in cases of prurigo *scroti*, which has now been recommended in prurigo *podicis*. Washes consisting of solutions of sublimate in lime-water, and the mercurial liniments recommended by Willan, are generally less useful than gelatino-sulphureous fomentations, douches and baths.

3d. The treatment of prurigo *pudendi muliebris* should be begun by a bleeding from the foot, if the state of the constitution seem to warrant the practice, by the repeated application of leeches to the vulva, by fomentations and douches of cold water, mixed with the juices of emollient and narcotic plants. Gelatino-sulphureous douches are never to be employed in the earlier stages of the disease; they would but increase the inflammation of the external parts and vagina, which almost always accompanies this variety of prurigo. (a)

(a) Professional advice is more frequently asked for in prurigo or pruritus pudendi than for any other variety of porrigo. It is most common during pregnancy and disappears in general after childbirth. Dr. Dewees (*Diseases of Females*) regarded this disease as aphthæ of the inner surface of the genital parts; an opinion adopted in its full extent by Rigby (*System of Midwifery*), and Churchill (*Diseases of Females*). Dr. C. D. Meigs tells us, on the other hand, in his additions to his translation of the treatise of Colombat de l'Isère on the Diseases and Special Hygiene of Females, that he has not perceived, upon examination, this aphthous condition of the mucous surface. Dr. Ashwell (*Practical Treatise on Diseases of Females*) takes a more extended view of the pathology of prurigo pudendi, in pointing out its connection with some diseases of the uterus and its appendages, as indeed Blundel had done before him, and also of affections of the urinary bladder and its meatus. Dr. Ashwell has, "on some occasions, admitted patients into the ward for some supposed affection of the vulva, which has turned out to be pruritus from disease of the bladder."

The treatment will of course vary with the general health and state of the uterine system. After suitable purging with laxatives, the use of sedatives sometimes allays the irritation. Of the local remedies, the one most thought of in this country, and more successful, perhaps, than any one other, is borax (sub-borate of soda) in solution of water and alcohol applied freely and frequently to the parts affected. Dr. Meigs (*op. cit.*) says that he has rarely had occasion to order any thing more than the following formula, viz:

R. Sodæ borat. ʒss;  
Morphæ sulphat. gr. vi;  
Aq. rosæ destillat. ʒviii.  
M. Ft. solutio.

He directs the person to apply it thrice a day to the affected parts, by means of a bit of sponge or a piece of linen, taking the precaution first to wash the surfaces with tepid water and soap, and to dry them before applying the lotion.

Patients should be cautioned against the use of a seat and bed that are too soft, as these excite and keep up a great degree of heat around the affected parts. During the paroxysms, which almost always occur through the night, patients occasionally succeed in allaying the pruritus that devours them, by applying, without intermission, a succession of cloths wrung out of cold water, to the external organs. Fumigations of sulphur or of cinibar have also been occasionally prescribed with success in very rebellious pruriginous eruptions of the margin of the anus and genital organs. I have, further, oftener than once had recourse to arsenical preparations with advantage in affections of the same description. (a)

#### Historical Notices and particular Cases.

662. It was probably prurigo senilis to which Hippocrates alluded when among the diseases affecting the aged, he mentions an *itchy state* of the whole body.<sup>1</sup>

The definition which Dietrich<sup>2</sup> has given of *cnesmos*, after Galen, is obscure, and applicable to several other pruriginous diseases (lichen, urticaria, strophulus). The definition of Mercurialis,<sup>3</sup> although more precise, still presents us with as many of the characters of lichen as of those that belong to prurigo. Hafenreffer<sup>4</sup> subsequently proposed to distinguish *pruritus* into *general* and *local*. But it must still be

I have found the borax solution to cure some cases, and that of the chloride of lime or of soda others. Hydrocyanic acid in adequate dilution as a wash, has been highly extolled in this disease, or as in the following lotion: R. Liq. potass. f3ij; Acid. hydrocyan. dilut. f3i; Emuls. amygd. amer. f3viii.—M. Iodine is used both topically and generally. Penciling the affected parts with a weak solution of nitrate of silver, (2 grs. to the ounce of water and 2 minims of nitric acid,) is sometimes beneficial.

The relief given by lotions of vinegar or of vinegar and water would suggest the use of diluted lemon juice in prurigo *pudendi*, even if we did not know that this latter has entirely carried off prurigo *scroti*.

In this latter affection the interposition of a fold of linen or muslin, as the skirt of the shirt between the sides of the scrotum and the thighs, will often materially abate and sometimes prevent the troublesome itching,—by diminishing the heat of the parts.

(a) Mr. Wilson introduces the subjoined formulæ “recommended by French dermatologists, and quoted by M. Gibert.”

“R. Hydrate of lime, 3ij;  
Subcarbonate of soda;  
Laudanum aa 3ss;  
Lard, 3j. M.

“Anti-pruriginous ointment recommended by Alibert:—

R. Laudanum;  
Sublimed sulphur aa 3ss;  
Oxide of zinc, 3j;  
Oil of almonds, 3j;  
Lard, 3iij. M.

“Ointment employed successfully by Bielt for an obstinate prurigo of the hands:—

R. Cinnabar;  
Laudanum aa 3ij;  
Sublimed sulphur, 3ss;  
Lard, 3v. M.

“Ointment for local prurigo:—

R. Muriate of ammonia, 3j;  
Powder of white hellebore, 3ss;  
Lard, 3iij. M.”

allowed that the true character of *prurigo*, to wit, the existence of pruriginous papulæ of the same colour as the skin, was first pointed out by Willan,<sup>5</sup> whose labours are given by Bateman in a condensed shape, in his Synopsis. The subsequent observations of Alibert,<sup>6</sup> of Chamberet,<sup>7</sup> and of Mouronval,<sup>8</sup> as well as those published by Sommer and Lœscher on prurigo senilis,<sup>9</sup> deserve to be particularly consulted. It is much to be regretted that pathological writers have so often employed the vague terms *bouton*, *spot*, *eruption*, *rash*, &c., to indicate a host of other cutaneous affections, as well as the one that now particularly engages our attention; great pains, too, have been taken to signalize the characters that distinguish prurigo from scabies, whilst little has been said on the difference between prurigo and lichen, a papular disease, with which it has many more points in common. Many cases entitled *prurigo* by M. Mouronval, even appear to me to be true *lichens*, particularly the fifth, that is quoted in his essay, in which he says that “the spots (*boutons*) were red and prominent, or arranged in clusters, so as to form irregularly rounded patches.” A few cases of prurigo may be found detailed in different periodical publications;<sup>10</sup> and a very remarkable one occurs in Mr. Wilkinson’s work,<sup>11</sup> who found the patient seated naked on his bed, and tearing his skin with a comb.

CASE CV.—*Eruption of furuncles and prurigo, after a severe illness.* G. Cuny, aged sixty-five, of vigorous constitution, but apparently living in filth and wretchedness. About seven years ago he was attacked with a putrid fever, for which he became, at four different times, a patient in the Hôpital de la Pitié, having had relapses as often, and never getting completely convalescent. Immediately after this attack he suffered from an eruption of boils, which appeared on almost every part of his body, during a period of four months. No sooner had the boils disappeared than the patient became affected with the cutaneous eruption under which he now labours; the disease, consequently, dates at least six years back.

At the time of its appearance he neither suffered from fever nor from disturbance in any of the functions. A number of small spots (*boutons*) were thrown out simultaneously over the whole of his body, even upon the hairy scalp and eyelids. The eyes also at length shared in the irritation, which did not then spare the palms of the hands and soles of the feet. Ever since its appearance this eruption has not ceased to torment the patient with a feeling of *general heat*, a sensation of burning, and a pruritus which lasts for hours, and even for nights, and obliges him to tear his skin with his nails, which he has been careful not to cut since the commencement of his malady. The nails of his thumbs are, in fact, nearly half an inch long, those of the fingers somewhat shorter. When the pruritus becomes excessive, he relieves himself by digging these claws into the substance of his skin. Unable any longer to contend with the torments he endured, Cuny presented himself for admission into the Hôpital de la Charité. On the 20th of June, 1827, he was in the following state:—

The skin is filthy and looks generally red; over every part of the surface are perceived crusts of dried blood, yellowish stains, and small papulæ; it is, further, furrowed and marked with scratches in all directions. A few untouched papulæ occur on the back, and tops of the shoulders; these are of the size of small pins’ heads, little different in colour from that of the skin, and affected with a violent itchiness. On the same parts, the small of the back, flanks, chest and arms, traces occur of a still greater number of papulæ, which the patient has torn with his nails, and whose summits are covered with a

<sup>3</sup> Oportet tamen ante alia adnotare, quod omnes illi affectus quibus jungitur pruritus, differentes sunt ab hoc pruritu; quia in illis vel tumor, vel exulceratio, vel excoarctatio aliqua apparet, in pruritu nihil horum. Videntur carnes parum mutatae, asperiores quidem aliquo pacto, sed sine tumore insigni, exulceratione et excoarctatione. Præterea in aliis affectibus, qui junctum habent pruritus, à cute semper emanat aliqua sanies: in pruritu nihil emanat, nisi, ut ait Avicenna, quædam corpora furfuracea, atque neque hæc emanant, nisi cutis unguibus deliniatur. (Mercuriali. De morbis cutaneis, lib. ii. cap. 3, p. 62.)

<sup>4</sup> Hafenreffer. De cutis affectibus, lib. i. cap. 14.

little crust of coagulated blood, of different shades of black according to its age, and nearly a line in diameter. The finger passed over the remains of the papulæ detects a hardness in the skin of the points affected. The base of several of the headless papulæ is red, and around some of them a furfuraceous desquamation appears to be going on; this is the case more especially about the lower parts of the loins. On the shoulders, upper parts of the back and arms, a number of slight scabs, of small extent and irregular shapes, are perceived, which in some places assume the appearance of a furfuraceous desquamation. The scabs are yellowish, or of a dirty gray colour; the skin under them is moist, and they appear to be formed by the desiccation of fluids effused from some accidental vesicles. On the front of the chest and shoulders a number of small tubercular indurations are perceived, round or irregular in shape, projecting slightly above the level of the skin, of a rosy red colour, and from one to two or three lines in diameter on the surface. These give the patient no uneasiness.

Amidst these various alterations, the numerous scratches which the patient had inflicted on himself, were easily recognized by the linear sanguineous incrustations which cover such injuries. Several pediculi were likewise discovered on the surface.

The skin on the parts of the body which have not been mentioned was merely hard and dry, and seemed to have lost its natural pliancy; its colour was made up of a mixture of different shades of red, violet and pale yellow, blending one with another. The principal functions seemed to be performed with perfect regularity. (*The cool and tepid bath; decoction of dog's-tooth grass for drink; the three-quarters hospital allowance*). June 24th.—The patient has taken the tepid bath twice, with the effect of cleansing his skin and freeing it from sanguinolent scabs and furfuræ, so that it now appears covered with minute dots, and small excoriated lines, the effects of scratching and tearing the papulæ. The small tuberculated indurations still continue. The sanguinolent scabs of the lower part of the back and loins are succeeded by red points, scarcely perceptible, around which the cuticle appears raised in a furfuraceous ring to the extent of a line; these are so numerous that they run into each other, and the desquamation over the regions mentioned, is nearly general. 26th.—Perseverance in the use of the bath has caused the furfuraceous desquamation to disappear, so that the skin of the back and loins now looks healthy. 29th.—(*V. S. B. ad 3viii; ointment of black hellebore*.) 30th.—The bleeding has appeased the pruritus and smarting notably. July 7th.—The skin has now regained nearly its natural appearance; it is only roughish, dry, and of a deep brown tint—characters which are common in the aged, especially among those who, like Cuny, have laboured hard all their lives. He was dismissed completely cured on the above day.

The patient has since presented himself at the baths of La Charité for the sake of cleanliness. He has suffered no return of his infirmity.

CASE CVI.—*Prurigo pudendi*.—Madame C \* \* \*, twenty-six years of age, was attacked with this disease in the month of February, 1823. This patient's catamenia had never been regular, and although a wife for several years she had not become pregnant. On the upper and inner parts of the thighs, near the greater labia, and upon these parts themselves, were detected a number of distinct papulæ nearly of the same colour as the skin upon which they were evolved. The tops of several other papulæ were covered with small blackish, flattened and very adherent crusts. The skin of the private parts also bore traces of several scratches. The external passages were red and inflamed, and there was some discharge from the vagina. During the day the parts affected were the seat of an incessant pruritus, which grew more severe in the course of the evening, completely interrupted sleep, and, exasperated by the endeavour of the patient to appease it by scratching, only gave place to a painful orgasm, which lasted through a great part of the night. Leeches were applied repeatedly to the vulva; the patient was bled from the foot; and the hip-bath, tepid, and with the addition of a narcotic infusion, was taken every day; a large blister was subsequently applied to the lumbar region; but at the end of two months and a half, during which this plan of treatment was pursued, a merely temporary amelioration was all that had been obtained. I now consulted with M. Dupuytren, and it was agreed to try the effect of the gelatino-sulphureous douche. After the first few days, this application had indeed a wonderful influ-

ence in allaying the irritation. The patient at once recovered her tranquillity and her sleep; and after using the remedy twenty-five times at the temperature of 25° R., for ten or fifteen minutes each time, she obtained a complete cure, as well of the papular affection as of the leucorrhœa which it had occasioned. The menstrual function did not become more regular after this; Madame C. did not fall pregnant; but three years have now elapsed since she recovered her health without any recurrence of the prurigo.

CASE CVII.—*Prurigo of the scrotum and anus*.—Verset, sixty years of age, was admitted a patient at the fourth Dispensary, June the 26th, 1825. Ever since October, 1824, this patient had laboured under a prurigo of the scrotum, upper and anterior parts of the thighs, and margin of the anus, against which he had employed various remedies in vain. June 27th.—On the parts mentioned a number of voluminous papulæ, having the same colour as the skin, which was not inflamed, were very conspicuous. A much larger number, however, had had their heads removed by the nails of the patient, who found it impossible to refrain from scratching every instant. The papulæ in this condition were covered with a small black crust. Although continually tormented by the pruritus, and tasting only broken and unrefreshing slumbers, Verset's general health did not appear to have suffered. I prescribed fomentations of the sulphureous mineral water of Barèges, with two ounces of gelatin dissolved in each pint of the fluid. This prescription was followed by great relief: after it had been continued four or five days, the papulæ appeared shrunk, and the patient enjoyed tranquil and uninterrupted sleep, which he had not known for eight months. (*Same fomentations; tartaric acid drink*.) July 4th.—The patient continues better; he has used some of the fomentation by way of lavement, and the itchiness he had felt in the rectum was alleviated by this means. The scrotum is the only part upon which papulæ can still be traced; by the 4th these had vanished; the pruritus was complained of less and less; and by continuing the same measures, applying fifteen leeches to the verge of the anus, and taking the tepid-bath twice, the prurigo was completely cured on the 8th of October, 1825.

#### PAPULAR INFLAMMATIONS ARTIFICIALLY EXCITED.

663. Vesicular and pustular forms of inflammation are much more frequently and readily produced by artificial excitement than papulæ. I shall, however, give an account of one case in which a papular eruption was produced by the contact of fulminating quicksilver. Mr. North has given several instances in which an eruption was excited by the internal use of the cubebs pepper, which, in some respects, presented the characters of lichen, but in many more those of roseola and urticaria.<sup>1</sup>

CASE CVIII.—*Papular eruption produced by fulminating mercury*. Guillemot, aged thirty-six, was attacked a fortnight ago with a disease on the skin, which he designated by the universal title of tetter (*dartre*). On the 1st of January, 1834, he commenced working in a manufactory of detonating caps for guns, pistols, &c. The principal ingredient in these articles is fulminating mercury, and the air of the manufactory is so much loaded with this substance in fine powder, that fresh workmen are always troubled with repeated fits of sneezing for two or three days after they enter on the business there carried on. Guillemot soon began to complain of a violent sensation of itching in the face; this was followed the next day by an eruption, which continued up to the time of his entering the hôpital de la Charité, but disappeared entirely within eight-and-forty hours after his reception.

On the 3d of March, Guillemot again presented himself at La Charité, having ceased from his work the preceding evening. Upon the skin of the forehead, and back of the neck particularly, there was an eruption of small red points, rather crowded together, prominent, rough, containing no fluid, and fading but little under the pressure of the finger. The skin in the spaces between these papulæ was healthy, and the eruption was attended with a considerable degree of pruritus. A few spots, perfectly similar to those described, were also discovered on the penis. The patient's teeth were black

<sup>1</sup> Arch. gén. de médecine, Juill., 1832.

and loose, and the gums ulcerated; there was no fever, the appetite was good, and the patient slept well. The patient was put upon the use of the nitric acid, and in two days the eruption began to fade; by the fourth day it had totally disappeared. (*The tepid bath.*) The patient again complained of itching on the fifth day; but nothing beyond some yellowish stains could be discovered on the forehead. On the eighth day the patient went out well.

## VIII.—SQUAMÆ. SQUAMOUS INFLAMMATIONS.

Vocab. *Squamæ, Scale.*

664. It is the distinguishing character of the squamous inflammations to appear as red elevations, spots, or blotches, upon which *squamæ*, in other words, laminæ of the cuticle, altered in various degrees, are formed, thrown off, and incessantly renewed.

665. The number of squamous inflammations reckoned is six: Lepra, Psoriasis, Pityriasis, Pellagra, Acrodynia, and Scaly Syphilis. I shall treat of pellagra and acrodynia when speaking of the cutaneous diseases peculiar to certain countries; and the history of squamous syphilis will form part of that of the venereal disease in general. I have, further, separated from the group of pityriasis, two varieties of cutaneous affection described by Willan under the heads pityriasis *versicolor*, and pityriasis *nigra*. These I denominate chloasma, and melema, as I hold that they belong essentially to the class of pigimentary affections.

Mr. Plumbe and Dr. Duffin have proposed to unite the description of lepra to that of psoriasis. To place the distinguishing characters of these two diseases in greater relief, I have continued to describe them separately, although I still acknowledge the striking analogy that exists between their various symptoms. Inflammation of the reticular tissue and papillæ is the first and main feature of squamous affections. The *squamæ* are a secondary phenomenon to which Willan attached too much importance when he assimilated ichthyosis to this class of diseases.

666. In an anatomical point of view, the analogy of the squamous inflammations to the exanthemata is indisputable. In both classes of disease there is sanguineous injection followed by desquamation. In the squamous forms of inflammation, however, the two phenomena continue to co-exist, frequently during a very considerable length of time, whilst in the exanthemata, the redness and desquamation succeed each other, and usually occur but once. Nevertheless, when any of the exanthemata, erythema, for example, passes into the chronic state, it assumes almost the whole of the appearances characteristic of squamous inflammation.

667. Two squamous inflammatory affections, lepra and psoriasis, make their appearance in the shape of small, hard, prominent, and papular-looking elevations, the tops of which soon become covered with *squamæ* of a dull white colour. These elevations unite, and then change into scaly patches of various forms and dimensions, which may either be in small numbers and limited to a single region of the body, or occur disseminated over the whole of its surface. In the latter case, the desquamation is frequently so copious that the bed and clothes of the patient become filled with dry and whitish-looking scales.

The dermis beneath the scaly patches is found red and inflamed, and inveterate squamous affections are always accompanied with chapping and a morbid increase of thickness in the skin.

Squamous inflammations occasionally remained confined to the points which they have first invaded, or they quit these to show themselves on others. They sometimes cause itching, tingling and an unpleasant sensation of heat, phenomena all of which are constantly increased by such causes as tend to raise the external temperature of the body. These sensations are usually very violent in pityriasis. The insensible perspiration appears occasionally to be diminished in the places occupied by the *squamæ*.

668. The various forms of squamous inflammation frequently complicate each other,—a new proof of their analogy. They are rarely combined with any other form of cutaneous affection.

669. Squamous diseases are much more common among the lower classes of society than among the higher. These diseases are observed at all seasons of the year, although they are more apt to make their attacks in the autumn and spring. Women seem more subject to them than men. No one of them is contagious; but numerous instances prove that they are hereditary.

670. It is necessary to distinguish the squamous inflammations properly so called, from the natural epidermic exfoliations that take place from the skin of new-born infants,<sup>1</sup> and of the aged, phenomena which will be mentioned by and by.

The squamous are not liable to be confounded with any of the other forms of cutaneous disease, when their elementary appearances have undergone no change. It is true, indeed, that *squamæ* are observed in the second period of the exanthemata, and of some papular and vesicular diseases, particularly chronic eczema, and lichen *agrius*; but besides the fact, that a few vesicles or papulæ may almost uniformly be detected in the vicinity of these squamous surfaces, which proclaim the nature of the existing inflammation, there are such differences in the whole appearance of these various diseases that it is impossible to mistake the one for the other. To conclude, the squamous phlegmasiæ cannot be confounded with ichthyosis in which the dermis is unaffected with any degree of redness, and the seat of no morbid sensation.

When treating of lepra, psoriasis and pityriasis, I shall take care to point out the particular features that distinguish these diseases severally.

671. The squamous inflammations commonly require several months and sometimes several years of treatment for their cure. They are the more obstinate as they occupy a larger extent of surface, and as they are of longer standing.

672. With regard to treatment, few of the phlegmasiæ have so many points of resemblance as the squamous inflammations; to be satisfied of this it is enough to glance from the treatment of lepra to that of psoriasis.

## LEPRA.

Vocab. *Alphos, Lepra, Leuce, Melas, Dartre surfuracée arrondie.*

673. The word *lepra*, which was long used to signify almost the whole of the chronic diseases of the skin when they had attained a high degree of severity, is now employed in a limited and more determinate sense to designate a chronic inflammation of the integuments, characterized by scaly patches of different dimensions, of a round or orbicular shape, depressed in the centre, surrounded by a red and prominent circle, and either disseminated over the surface of the skin or united into one or more patches of larger size and more irregular shape.

674. *Symptoms.*—Lepra is occasionally seen confined to the elbows and knees. Its orbicular patches generally make their first appearance on the extremities, and usually on the parts below the knees and elbows. In the majority of instances it is developed on both legs or both arms at the same time. It is then apt to extend by the successive formation of new scaly patches along the arms and thighs to the breast and shoulders, and to the lumbar and lateral regions of the abdomen. The patches are often more numerous and prominent on the lower part of the belly than elsewhere. The disease rarely extends to the hands or hairy scalp. The patches that do occur on the head are generally of small size. A few are occasionally seen around the outer angles of the orbits, from whence they spread along the eyebrows to the forehead and temples. The patches are everywhere apt to coalesce by their corresponding edges, but the originally orbicular form of the parts composing these aggregate patches is still proclaimed by the arcs of circles which are seen in their circumference.

<sup>1</sup> Billard. *Mal des Enf. nouveau-nés*, p. 32, 8vo. Paris, 1828.

675. The *lepra vulgaris* of Willan, the *dartre furfuracée arrondie* of Alibert, invades in the shape of small solid elevations, around which numbers of other reddish-coloured, prominent spots, about a line in diameter, of a circular form and firm consistency are evolved. It was undoubtedly this papular appearance which led Willan to imagine that lepra was owing to an induration of the papillæ of the skin.

The summit of these elevations, the appearance of which is frequently successive, smooth in the earlier stages of their existence, become covered some few days after their formation with a small epidermic scale, white, semi-transparent, smooth and polished. This minute spangle-like scale is detached before long, and its fall is announced by a feeling of tingling or pruritus. The small space of skin which it covered is now found red and is rough to the touch. In the centre of the inner surface of the scale which is thrown off, a minute eminence may be perceived, less consistent than the other parts and which appears to have been lodged in a slight depression of the skin; it is even observed to be tinged with blood when violence has been employed in removing the scale.

These small scaly spots, after having thus shed their covering once, enlarge in rather a rapid manner, until they measure an inch and even more in diameter, but *always preserving a circular shape*. They are speedily again covered with squamæ, which are dry, glistening, somewhat opalescent, tough, and of a pearl-gray or pale yellow tint. They are bounded by a rosy, or purplish and *slightly elevated* margin, so that the centre of each patch appears somewhat *depressed*. The squamæ, which almost always adhere very firmly to the skin, are by no means evenly and regularly spread over the surface of the leprous patches, which are never seen covered by a single scale. The squamæ are superposed, especially in the circumference of the patches, and become thicker and thicker so as to form prominent layers. The exposed parts of the squamæ often acquire a whitish tinge; they are detached partially and irregularly. After their fall the small orbicular surfaces of the skin which they had covered, look red and shining, and rise above the level of the healthy parts which surround them. If the leprous patches are recent, the corion does not present lines in correspondence with those of the cuticle; but impressions of this kind are observed on the patches of older standing. In the latter case, indeed, they occasionally present a furrowed appearance, from an increase in the naturally superficial wrinkles of the skin, which are found in correspondence with smaller slight projecting lines situated on the inner surface of the squamæ.

After being freed from scales naturally, or by art, the surface of leprous patches is speedily covered by a fresh formation of squamæ, so that in the course of a few months or several years the parts affected may have presented a greater or smaller number of successive desquamations.

The spontaneous or artificial cure of the orbicular patches of lepra begins in the centre, and extends towards the circumference. After the detachment of the squamæ from the patches, the skin, when they are not renewed, first acquires a grayish tint with a shade of yellow; at a later period the ring which bounds the patches is narrowed progressively from within outwards, the circle breaks at length in one or more places, and the spot subsequently disappears entirely.

Upon some regions and in particular individuals, the squamous patches of lepra remain of inconsiderable size, never exceeding a few lines in diameter; they also increase very slowly and are but little prominent, rarely run into one another, are developed almost exclusively on the extremities, and differ from the patches of *lepra vulgaris* by the whiteness and small size of the squamæ that are formed. This constitutes the variety entitled *lepra alphoides* by Willan. It is more commonly observed among children than adults or the aged, and is not easily distinguished from psoriasis *guttata*. Further, the scaly and orbicular patches of lepra may present a particular appearance, produced by the confluence of the primary spots or scaly rounds. They then extend over large surfaces, and are often symmetrically disposed on the two sides of the body.

I have, moreover, observed lepra under another form, that, namely, of arcs of circles a few lines in diameter, red, prominent, devoid of scales and bounding surfaces of various extent, occasionally as much as five or six inches across, the skin of which had either a yellowish

cast, or appeared perfectly healthy. This variety, in its progress at least, has the most striking analogy with the centrifugal palmar psoriasis. Although most commonly encountered on the trunk, I have met with this variety of lepra exclusively on the lower part of one forearm and hand, on the anterior and posterior aspects of which it formed a kind of irregularly circular wreath.

When lepra is long neglected, or when it extends to the fingers, the disease may at length reach the matrices of the nails. These appendages then become thick, rough, opaque, of a dirty yellow colour, and crooked at their ends, whilst their roots are thickened, and look as if they were formed of many distinct and superposed layers.

Lepra is very seldom seen exclusively on the hairy scalp. When it is, the squamæ are commonly yellow and furfureous; they have none of the glistening micaceous appearance which they present on the knees and elbows.

When the number of squamous patches is not very considerable, and they are not highly inflamed, lepra is attended with no morbid sensation, unless it be some slight degree of itching when the temperature of the surface is increased by exercise and the warmth of a bed. This sensation, according to Mr. Plumbe, is caused by the detachment of the circumference of the squamæ, which is affected by the swelling of the areola surrounding the patches. It is certain that sensations of tingling and pruritus are no longer perceived by patients labouring under lepra, when no new scales are formed beneath those that already exist, and that the disease is then tending to recovery.

When the patches of lepra are inflamed and extensively diffused over the surface of the body, they may be attended with pain and a feeling of tension in the skin of the extremities. The inflammation has been seen running to such a height, that it impeded the motions of the joints, and obliged patients to keep their beds, every movement of the body producing deep chaps and a very singular crackling noise.

The influence of lepra does not seem to extend beyond the parts of the skin which are immediately attacked; the disease appears to be essentially local. If several authors could be named who, in describing this affection as symptomatic, have specified different other morbid phenomena, especially an alteration of the voice, it is owing to their having confounded lepra with the Greek elephantiasis, and regarded two diseases every way distinct as varieties of the same affection.

676. *Observations on Structure*.—The whole of the tissues which enter into the formation of the skin, do not appear to be alike affected in lepra. It has been conjectured that the vessels secreting the epidermis labour under a chronic irritation, the effect of which is to render the production of this substance more copious than natural; but as this hypothesis offers no explanation of the orbicular form of the patches, some pathologists have supposed that the superficial vessels of the skin were disposed in small concentric circles; others have maintained that the circular arrangement of the squamæ was a natural consequence of their development under the form of a round elevation, the inflammation in spreading still retaining its primary form.

I have ascertained that the papillæ are more largely developed on the leprous patches than on the healthy skin.

677. *Causes*.—Lepra is common to both sexes, and occurs at all ages; I have not myself met with the disease in infants at the breast, but I have had frequent occasion to see it after the period of the first dentition. Mr. Wilson assures us, that it is observed more frequently at the present day in England than it used to be formerly; but it is very possible that the disease was long misunderstood or imperfectly described under other names. Heberden in particular was probably mistaken when he said, that lepra was very rare in England,—“*de vero scorbuto et lepra nihil habeo quod dicam, nam alter rarissimus est in urbibus, altera in Angliâ penè ignota*,” unless, indeed, by *lepra* he intended to refer to elephantiasis, a suspicion which seems to acquire confirmation from the fact that several French practitioners, entertaining confused notions of the nature of lepra, forgetting the characters which had been anciently assigned to the disease, and confounding it with elephantiasis, (the *lepra* of the middle ages,) have also said, that lepra was only seen in some of the southern

departments of France, whilst it is certain that in the hospitals of *La Charité*, *St. Louis* and *Les Enfants Malades*, a considerable number of individuals are every year seen labouring under this form of squamous inflammation, which I have also encountered in all classes of society. Almost all that has appeared of late in France on the origin, propagation and disappearance of *lepra* in different quarters of the globe, has been advanced upon the strength of statements borrowed from writers who have confounded *lepra* with Greek or Arabian elephantiasis, or with other diseases not less distinct. (a)

The causes of *lepra* are for the most part very obscure, or altogether inappreciable. The disease is not contagious; patients labouring under it are not kept isolated in our hospitals, and husband and wife continue to cohabit without the one infecting the other. Like several other diseases of the skin, whose term of duration is much shorter (*roseola*, *urticaria*, &c.), *lepra* appears to be occasionally produced by the abuse, and even by the simple use of stimulating food and spirituous liquors. Bateman was acquainted with an individual in whom spiced food and a small quantity of spirits never failed to produce the disease. In the same way, it has been known to follow the ingestion of different poisonous substances, the salts of copper, for instance, and the abuse of acids. It has now and then appeared to be induced by the habitual use of game, salted and highly-seasoned food, fish, shell fish, &c., or to be engendered by the united influence of affliction and poverty. Willan was of opinion that *lepra* was principally caused by exposure to cold and moisture, and by the action of certain dry and powdery substances upon the skin: but Bateman has remarked, with justice, that bakers, and persons employed in dusty workshops are rarely affected with this disease, whilst it is frequently observed among females, and those classes of society in which personal cleanliness is an object of the most particular attention. In some cases, *lepra* has been seen occurring after violent and long-continued exercise. Many instances of hereditary *lepra* have been recorded. To recapitulate, it is impossible not to perceive that much obscurity still remains in regard to the number and nature of the causes capable of producing this disease.

678. *Diagnosis*.—The diagnosis of *lepra*, even at the present day, remains one of the most important points of its history, on account of the confusion at which I have hinted; and yet it is indisputably one of the diseases of the skin whose characters are the most remarkable. In many particulars it differs from all the chronic inflammatory affections of the skin, even from those that show themselves like it under the squamous form. In psoriasis the epidermis is, indeed, as in *lepra*, more or less rough, scaly in a greater or less degree; but the form of the squamous patches is much less regular, their edges are less raised, inflamed in a minor degree, and their contour is by no means so pre-

(a) Dr. Green (*A Practical Compendium of the Diseases of the Skin*, &c.) in confirmation of the opinion of Mr. J. Wilson in the text, says:—"Few are aware how very commonly scaly leprosy prevails in London; those who are affected with it, and indeed with any cutaneous affection, generally concealing the circumstance even from their most intimate friends, as if there were something disgraceful attached to this class of complaints. Individuals in every class of society are, however, subject to most of these, and to *lepra* in particular. The disease I find one of every-day occurrence, and by no means so intractable as I used at first to believe it, or as is supposed. Most slight cases will get well readily under the use of the sulphur fumigations, assisted by very gentle medicines; others require greater perseverance, and the administration of medicines of a more active kind, among the number of which I believe the preparations of arsenic to deserve the preference. I never had but three cases of leprosy, which, by their obstinacy disheartened both myself and patients; one was that of a gentleman who took the sulphur fume bath upwards of a hundred times, without deriving much or any permanent good from it. Another gentleman, after a trial to the same extent of this means, and a similar result, went to India, and I heard no more of him. The third is a medical gentleman, who has had the disease from puberty, and is now fifty years of age. He too has taken more than a hundred fumigations, though very irregularly, and considers himself incurable of the disease in question; otherwise he is in fair health."

cisely circular as that of the patches of *lepra*. Lastly, in inveterate psoriasis, the skin beneath the scaly patches is frequently traversed by deep fissures, and is in general much more sensitive and irritable than in *lepra*. Still there exists one variety of psoriasis, the psor. *guttata*, which has so many and such great analogies to *lepra*, that it constitutes, as it were, a form of disease intermediate between this affection and the other varieties of psoriasis. The scaly patches of psoriasis *guttata* are in fact isolated and distinct like those of *lepra*, but they are smaller in size, being rarely more than two or three lines in diameter, and their circumference is less regular and less prominent.

In some inveterate cases of *lepra*, even when the orbicular patches are blended together by their corresponding edges, it is still possible to distinguish the disease from certain psoriasis; with a little attention, a few halves or quarters of circles may be distinguished projecting from the circumference, or in the midst of the agglomerated patches.

Certain circumscribed lichens which get well from the centre towards the circumference of the patches are also to be carefully distinguished from *lepra*, the arcs of whose patches, always redder, more prominent, and more regularly defined on their convex edges, never exhibit true papulæ on their surface.

Syphilitic tubercles of a flattened form and arranged exactly side by side, so as to form perfect circles in the centre of which the skin is occasionally healthy, might be taken at the first glance for large rings of *lepra vulgaris* on the way to recovery; but mistake becomes impossible when it is seen that the squamæ, when any occur on the tubercles, do not form a continuous circle; they are thin hard lamellæ, always of smaller size than the induration on whose summit they are fixed.

The dryness and roughness of the skin, so remarkable in *lepra*, are not perceived in squamous syphilis, the thin and grayish squamæ of which, when they are old, crown small copper-coloured elevations, and are almost as soft to the touch and as pliant as the other parts of the skin. Further, the blotches that occur after a syphilitic infection usually grow pale and get well under the influence of mercurial medicines; their disappearance, moreover, is attended with this peculiarity, that they generally begin to heal off from the circumference, whilst the orbicular patches of *lepra* recover from the centre towards the circumference.

Psoriasis and pityriasis of the hairy scalp present disseminated furfuraceous squamæ, not scaly patches with regularly circumscribed edges. It might be thought difficult to confound the squamæ of *lepra* with the crusts formed by the desiccation of the fluids excreted from surfaces affected with vesicular and pustular inflammations: yet Willan observes that *lepra* has occasionally been mistaken for *impetigo figurata* vel *annularis*, or rather for the scaly state of the skin consecutive to the fall of their incrustations.

*Lepra* has been confounded with ichthyosis by Plenck and Chia-rugi. After the middle ages the title of *lepra* was often given to two diseases as different as possible from the one we are more immediately engaged in describing,—Greek elephantiasis and Arabian elephantiasis.

Leprous patches that have been freed from squamæ by the action of baths, lotions and unguents, are more difficult of distinction; it is, however, generally sufficient to question the patients narrowly, to discover that the circular red patches, healed up or not in their centres, and the red rings and half rings, that appear upon the skin, were originally covered with squamæ; besides they speedily again become crusted with scales when left to themselves.

679. *Prognosis*.—Among the aged, *lepra* is almost always incurable, or at least is so rarely cured completely that it is often advisable not to persevere too long in endeavours to obtain such a consummation. The disease seldom gets well spontaneously; it almost always proves very rebellious to every kind of treatment; the patches often follow each other in succession on one region, whilst they disappear on another. The hereditary forms of the disease are the most obstinate of any. The disease never degenerates into cancer, as has been affirmed by several authors.

680. *Treatment*.—An infinite number of remedial measures have been proposed in reference to *lepra*. These means are observed to act much more powerfully in summer than at any other season. I have

seen a certain number of cases of lepra, in which the eruption made its appearance during the autumn, to vanish spontaneously with the following spring.

Individuals whose constitution has been severely tried or broken, as well as those who show symptoms of plethora, require to undergo some preparation, directed with a view to bringing the system into a state more favourable to the success of the treatment: it may be commenced at once when the habit of the patient presents no peculiar indication.

1st. *External remedies.*—When lepra is of recent date, and extends over a large surface of the body, when the patches are affected with a painful pruritus, and the motions of the joints are impeded, the disease will be aggravated by sea bathing, by frictions or lotions with the preparations of sulphur, &c., which have been far too indiscriminately recommended in the treatment of diseases of the skin: blood-letting, on the contrary, and anointing the parts affected with cream, fresh butter, or sweet lard, give speedy relief. The vapour-bath, and the emollient or gelatinous bath may be employed as a principal or accessory means. The simple vapour-bath, occasionally proves sufficient of itself to cure recent lepra.

When the squamous patches are but very slightly inflamed, or of old standing, recourse is usually had to topical applications of a more or less exciting kind; before using these, however, it is always proper to cleanse the skin by means of fomentations, the tepid-bath, and gentle frictions, in case the scales adhere very firmly or lie in very thick layers. The use of stimulating washes, such as those composed of a mixture of spirits and water, or a solution of the sulphuret of potash, favours the removal of the scales, and often gives a favourable tendency to the progress of the patches. When the squamæ are detached, a little of the white pitch, tar, or weak nitrate of mercury ointment, may be rubbed over the affected parts, before the patient retires to rest for the night; next morning the skin must be washed with tepid water, or a weak saponaceous solution. By means of these topical applications, continued for several months, we occasionally succeed in restoring its natural texture to the skin, even after a course of internal medicines had been tried and failed. I have, however, obtained a still greater number of cures by the inunction of an ointment of the white precipitate, a drachm of white precipitate to an ounce of hog's lard; a drachm or even a drachm and a half of this mixture may be rubbed in every day without any risk of exciting salivation; this is the external application I am in the habit of prescribing in the greater number of cases of lepra.

Sulphureous water baths and fomentations are often successfully employed under similar circumstances. The waters of Barèges, Cauterets, Bagnères, Bagnoles, Enghien, &c., in France, and those of Bath, Harrowgate, Leamington, Crofton, &c., in England, are frequently recommended. The sulphur vapour-bath generally fails to do any good, although its virtues have been often extolled; a certain number of complete cures have nevertheless been obtained by this means. The acid vapour-bath, the natural or artificial sea-water-bath, the alkaline bath, and the waters of Plombières have been employed with greater success. The sea-water-bath, especially, is much recommended in England, and it occasionally produces so much excitement of the skin, that it is found necessary to dilute the sea with river water. The simple vapour bath, commonly recommended with the view of freeing the skin from squamæ, is frequently found to modify the state of the surface advantageously. The tepid-bath is also effectual in removing squamæ and in keeping the skin clean.

When leprous patches are few in number, and of very old standing, they are sometimes successfully treated by the repeated application of small blisters, and by the use of superficial escharotics, such as dilute muriatic acid, or the acid nitrate of mercury.<sup>1</sup> Some inconclusive trials have been made of the acetate and phosphate of mercury, and of the sulphate and deutoxide of antimony, in lepra; more evidently good effects have followed the application of the iodide of sulphur, in the proportion of twelve grains to the ounce of lard. It is frequently only after numerous trials, that the application best suited

to the particular case can be ascertained. My own practice is to begin with the white precipitate ointment, or with that of the proto-chloride of mercury, unless in those cases where the disease is of very long standing, when I try the iodide of sulphur in preference.

2d. *Internal remedies.*—The decoction of dulcamara in the proportion of half, and then a whole ounce, and even of two ounces to the pint of water, has been recommended by many practitioners, and more particularly by Dr. Crichton, as very efficacious in lepra. I have prescribed it several times with success; but I have seen this medicine, when given in somewhat large doses, produce vertigo, without, in every instance, appearing to exert any very sensible influence on this squamous inflammation of the skin. The extract of dulcamara is much less energetic in its action than the decoction. The dulcamara may succeed in the slighter cases of lepra, affecting young and healthily constituted individuals. I am in the habit of using the white precipitate ointment externally, at the same time that the dulcamara is taken internally.

Cases of lepra, which had resisted every other medicinal means attempted, have been cured in the course of six weeks, by the exhibition of purgatives, combined with the tepid or vapour-bath. Calomel combined with jalap or rhubarb, so as to produce one or two liquid evacuations daily, appears to be the form of purgative best adapted to these peculiar cases; when taken alone, calomel is apt to be absorbed into the system, and to cause pyalism. In some cases of obstinate lepra, and in robust individuals, I have had recourse to purgatives of a more active description.

The tincture of cantharides, administered internally in some mucilaginous drink, in doses gradually increased from five to ten, fifteen, twenty or thirty drops, occasionally causes the rapid disappearance of lepra, especially when the disease is of limited extent, and not very severe in its character. This medicine has been carried the length of sixty and even eighty drops, due regard being had to the state of the digestive organs; such doses of course require to be very prudently administered; but of all the energetic and dangerous remedies that have been used in the treatment of lepra, the tincture of cantharides is, perhaps, that which has the most remarkable influence on the disease. The great objection to its employment is its liability to excite inflammation in the digestive organs and urinary passages, especially among females, which necessitates the immediate suspension, and occasionally even the entire abandonment of the medicine.

When lepra is of long standing and extensive, and has been fruitlessly treated in a variety of ways, we must then either be content to pursue palliative measures, regulate the diet, &c., or else resort to arsenical preparations, as the state of the general health, and the knowledge we possess of the diseases the patient has already laboured under, may incline us. As lepra, however, exerts no evident ill effects on the constitution, and the inconvenience it occasions being either extremely trifling or very endurable, it will probably be found advisable in the majority of instances to confine the treatment to that which is merely palliative, unless the patient positively insists on some more active system being followed. In the latter case, the use of Fowler's arsenical solution may be begun in doses of four or five drops daily, and the quantity gradually increased to fifteen drops, to be taken at four different times in the course of the four-and-twenty hours, and continued for several months. Some practitioners have not scrupled to carry this medicine the length of fifty and sixty drops daily. I have already quoted several cases, from the works of Girdlestone, Willan, Bateman, Plumbe, and others, which demonstrate the excellent effects of this medicine in lepra. (§ 188.) I have myself obtained similar good effects in many cases; but I have often, also, in spite of all my care to graduate the doses of the medicine, seen it excite great disturbance in the functions of digestion; it therefore requires to be administered with the greatest caution; and if, after being taken for a few days, patients begin to complain of a feeling of tension, of stiffness and puffing in the face, and of heat and prickling in the throat, these phenomena, even when unaccompanied with evident derangement of the functions of the stomach, proclaim that the medicine has been given in too large doses, and warn us that these must be diminished. If, in addition, the tongue become red on its tip and edges, if thirst be complained of, the features look slightly erythematous, and the secretion of saliva be augmented, the further

<sup>1</sup> Instead of applying caustics directly to the affected parts, I have been assured, in conversation with a gentleman whose name is unknown to me, that if the nitrate of silver be applied circularly around the leprous spots, they very speedily disappear.—R. W.

use of the arsenical solution must be immediately suspended. Lastly, the medicine must be entirely abandoned if such symptoms as nausea, vomiting and vertigo, accompanied with cough and pain in the epigastrium, supervene. All these unpleasant phenomena usually subside upon the mere suspension of the arsenical solution, without our being obliged to combat them by blood-letting, which may, however, become necessary. The less active arsenical solutions of Valangin, Pearson and Lefèvre, and the arsenical pills of the Edinburgh pharmacopœia, have the same advantages and inconveniences as the common Fowler's solution, and require the same watching and the same reserve in their administration.

The pertinacity of lepra, its resistance to the most active remedial means, and the hope of substituting for these other medicines more certain in their effects or less dangerous at least in their action, have given rise to an infinity of experiments, the results of which I shall now endeavour to recapitulate.

Tar, in the dose of eight, ten or twelve grains and more, and terebinthinate pills, in doses of fifteen, twenty-four and thirty-six grains, have been tried in lepra, with very various and very uncertain results.

The sulphuret, and other preparations of *antimony*, have occasionally appeared to produce an improvement in the state of the skin, but never any remarkable cure of this disease.

The advantages of *mercurial* medicines have been exaggerated, particularly by Wilson. A watery or spirituous solution of the sublimate in minute doses, is of all these preparations that whose efficacy is the least subject to dispute. Calomel, in purgative doses, as has already been said, is often useful in lepra *vulgaris*; but it so readily excites salivation, that its action requires to be narrowly watched.

The decoction of *daphne mezereum*, employed by Pearson in several cases of lepra, frequently produces a temporary improvement, never a complete cure; its effects, however, are more apparent than those of *sarsaparilla*. The *daphne mezereum* may excite vomiting, hypercatharsis, and inflammation of the stomach and pharynx. The medicine is less energetic under the form of a syrup; some practitioners are in the habit of prescribing it in combination with arsenical preparations.

The *liquor potassæ* of the Berlin pharmacopœia in doses of from twenty to thirty drops; the watery extract of *white hellebore* in doses of from two to four grains; various preparations of the *ranunculi*, of the *rhûs radicans*, and *rhûs toxicodendron*, have occasionally proved of signal advantage in lepra, when the disease was extensive, and attended with high inflammation, but unaccompanied with notable derangement among the digestive functions. The effects of such medicines, of course, require to be carefully watched.

Experiments, made subsequently to those of Dr. Lettsom, are far from confirming the benefits he believed he had derived from the decoction of the bark of the *ulmus pyramidalis*, a medicine of a much less formidable character than any of those just signalized. Much still remains to be done in regard to the treatment of lepra. A quiet and regular life, a diet of white meats, fresh vegetables, ripe and watery fruits, milk, &c., assist the action of the different medicines I have mentioned, all of which we are often obliged to try, one after another, in a disease so obstinate in its characters. (a)

(a) Plumbe lays great and deserved stress on the dependence of lepra on constitutional causes; but as urgent are some, at least, of his predecessors in saying that this origin and connection have been much overlooked. Alibert I might cite, among others, as pointing out expressly, in some of his cases, the occurrence of the disease after strong mental emotions, and particularly fear and anxiety. This author gives the history of a patient at the St. Louis Hospital, who unexpectedly saw his former master, a member of the Parliament of Paris, dragged to the scaffold, during the horrors of the Revolution; and who was so terrified at the sight, that a furfuraceous eruption broke out suddenly on the whole cutaneous surface. This affection assumed the true character of lepra, or, as Alibert termed it, *dartre furfuracée*. In another case, described by him, the disease originated from depression of spirits, caused by the imprisonment of a friend, and increased afterwards by a loss of the situation which he himself held. Biett also assigns mental affections as one of the most common causes.

The class of persons, says Plumbe, who appear to be most subject

### Historical Notices and particular Cases.

681. The word *lepra* is nowhere well defined in the collection of the Hippocratic writings.<sup>1</sup> It, however, occurs in a less vague accep-

to lepra, are those minds that are anxiously occupied by the cares of business or study, or who are accustomed to bodily exertion beyond what their strength enables them to bear. He is too exclusive in his opinion, that lepra is always caused by debility either direct or indirect, and requires uniformly nutritive and stimulating diet. In his general proposition, however, we can all join, viz., that attention to the general health, and the invigoration of the constitution, are the chief means by which the cure is brought about.

As respects a more specific cause in certain venereal indulgences, the observations of Plumbe merit serious attention. "If any fact were necessary," he tells us, "in addition to those I have adduced, that debility of circulation and system were the causes of lepra, I might allege that in young men, as confessed to me often, the practice of masturbation has been followed, and that to a very great extent, in the very worst cases which have come under my notice." He adds "the lepers of whom we read, therefore, as excommunicated from their species, and remarkable for their disgusting salaciousness, have been probably the victims of the vice alluded to—the effect has been mistaken for the cause."

On the score of *treatment* of lepra, little essentially new can be added to the conditions and details so well laid down in the text. A preference is indicated by M. Rayer for the iodide of sulphur among the external remedies. It is the favourite one of M. Biett in several diseases of the skin, including lepra. The proportion of the iodide may be increased from 12 to 30 grains to the ounce of lard. M. Biett has also used with marked success, the iodide of ammonium in the proportion of ʒs to ʒss with ʒi of adeps; the weaker ointment being used when the disease is recent, and the stronger when it is chronic. As the iodide is decomposed by exposure to the air, the ointment should be kept in stopped bottles. For details, as to the mode of employing this preparation and on the treatment generally of lepra and psoriasis, illustrated by cases, the reader is referred to an instructive paper by Dr. Pennock in the *American Journal of the Medical Sciences*, vol. xv. M. Gibert speaks favourably of the ointments of anthracokali and foligokali, two new medicines of whose use mention has been more fully made in a note at pp. 201–2 of this work.

"M. Lemery, of St. Louis, has lately recalled the attention of practitioners to an old, but valuable application, in leprous affections—namely *tar*. Finding, however, that this remedy was objectionable on account of its colour and odour, he had recourse to one of the products of tar, *concrete naphthaline*, which afforded him the most successful results. The preparation which he employs is an ointment, composed of

Naphthaline two to four parts.

Lard thirty parts.

M.

This he applies to the diseased skin, on folds of linen, night and morning. The ointment is highly stimulating, and has a powerful smell, which quickly passes away. By means of the naphthaline ointment, M. Lemery succeeded in curing eight patients out of fourteen, in from five weeks to three months."

Dr. A. T. Thomson (*Commentaries on Diseases of the Skin*), Wilson states that he has found no combination of mercury equal to that with iodine, in the treatment of lepra. "The biniodide, in doses of a sixth to a fourth of a grain, seems to exert almost a specific influence upon the morbid state of the skin; and when given at the same time as the iodide of arsenic, and aided by blood-letting, it has rarely failed in rapidly and permanently curing the most inveterate cases of the disease. As the acrimony of the preparation has sometimes greatly disturbed the alimentary canal, I have usually combined it, either with opium or conium, and I have always carefully avoided pushing it to pyalism. Candour obliges me to admit, that as I have usually prescribed the biniodide in conjunction with the iodide of arsenic, it

<sup>1</sup> De affectibus. Intérp. Van der Linden, tom. 11, p. 182.—Prorrh. l. 11, pp. 521 et 522.

tation in the *Isagoge*, which is ascribed to Galen.<sup>1</sup> The definition of Paulus Ægineta is more precise.<sup>2</sup> Subsequently, the title

is difficult to say what share the mercurial had in the cures; and, in cases where idiosyncrasy prevented me from employing arsenicals in any form, I have seen the beneficial properties of the biniodide very obviously displayed."

The preparation of arsenic, which is preferred by Dr. Thomson, is the iodide in a dose at first of a tenth of a grain; but in no instance to be increased beyond the third of a grain. Heat of the mouth and fauces, and anxiety at the præcordia with pain at the epigastrium or griping, will indicate a necessity for reducing the dose; and if nausea, cough or salivation supervenes, it should be left off altogether. Iodide of arsenic is incompatible with cinchonia in any form.

Donovan's solution, the triple compound of iodine, arsenic and mercury, has been given with success in lepra, pityriasis and psoriasis. The commonly prescribed dose of half a drachm, is larger than it will be prudent to begin with, in most cases. I prefer the dose of five drops, gradually increased to twenty, twice a day; in some cases even this latter cannot be reached without the patient suffering from nausea and gastric distress. Dr. Graves has, however, administered it to the extent of half a drachm four times a day, for two months with but two interruptions; and Sir Henry Marsh carried it, in the case of a boy twelve years of age, to the extent of half an ounce daily, in divided doses, which only produced very small insalvation.

Mr. Erichsen's remarks (*Med. Gazette*, 1843) on the employment of arsenic in squamous affections of the skin are so clear, and clinically valuable, that I have no hesitation in repeating them on the present occasion.

"Useful, however, as arsenic may be in many diseases of the skin, it is in the treatment of the squamous affections, more particularly of long-standing cases of *lepra* and of inveterate *psoriasis*, that it is incontestably of the greatest service. For it is by no means rare to meet with cases of these diseases, which, obstinately resisting, perhaps for years, milder methods of treatment, will, in the course of a few weeks, yield to the judicious employment of the preparations of this metal, the utility of which in this class of affections is so fully established by most dermatologists, that it is almost needless to insist upon it. It was, indeed, the success that attended the employment of arsenic in the squamous diseases that first led to its introduction into practice as a most valuable remedy in other affections of the skin. But, notwithstanding its utility in this class of diseases (the squamous), it is not admissible in every stage of their progress, nor indeed is it required in the great majority of these cases; far from it; it is only in very extensive and obstinately rebellious forms of these complaints, or when the patient is suffering some very positive inconvenience from the disease, that we should be justified in administering it, and then only in the absence of those circumstances that have already been pointed out as contra-indicating the administration of arsenic in other affections.

"With regard to the stage of *lepra* and *psoriasis* in which the preparations of this metal may be administered, it should be laid down as a rule that they should not be given until the disease had assumed a decidedly chronic, inactive character. So long, indeed, as there is any inflammatory redness, heat, or irritation about the patches, they should never, under any circumstances, be employed, as the stimulus of the arsenic would almost infallibly augment the severity of the disease; besides, during the earlier periods of the complaint, we should probably be able to effect a cure by other and less heroic measures. It is only, then, in very long standing cases of an extensive and indolent squamous disease, in which all other means of treatment that are likely to benefit have been employed without success, that these remedies should be given. And even then, as Rayer justly remarks, as these diseases frequently exert no evident ill effects on the constitution, the inconvenience they occasion being but very trifling, it will be advisable to confine the treatment to a palliative one, unless the patient positively insist on some active measures being adopted, when we should not hesitate to have recourse

*lepra* was given to every disease of the skin, distinguished by a hideous and disgusting appearance, and particularly to the Greek elephantiasis. Willan was the first who restored to the term its original meaning; he has also given good figures, and a very accurate description of the disease which the word was originally used to designate.<sup>3</sup> Bateman has faithfully copied Willan's account of the disease in his *Synopsis*. Dr. Falconer<sup>4</sup> has included impetigo in his account of *lepra*. The remarks of Levacher Lafautrie<sup>5</sup> appear to bear upon a complication of *lepra* with pellagra. Römer and Carminati have published observations in favour of lizard and viper broths (§ 114). Galès, Clarke, and Willan quote several cases of *lepra*, cured by sulphur fumigations (§ 128). Carrère, Crichton, Razon, and Bertrand-Lagrèsie have extolled the *dulcamara* (§ 202). Girdlestone, Willan, Bateman, Duffin,<sup>6</sup> and many others, have particularly recommended arsenical preparations (§ 188). Various cases and observations have been published in different periodical works,<sup>7</sup> and in the dissertations of Bonorden, and of Meckel.<sup>8</sup> Alibert has treated of *lepra*, in his large work, under the title of *dartre squameuse orbiculée*.

CASE CIX.—*Lepra; blood-letting, baths and purgatives.* D \* \* \*, aged twenty-one, sprung of healthy parents, had laboured under *lepra* for two months, when he came to consult me on the 3d of May, 1826. The disease had begun in the shape of small circular scaly

to the employment of the arsenicals, due attention being paid to the temperament of the individual, and to the state of his digestive organs.

"In the majority of cases of *lepra* or *psoriasis*, Fowler's solution will, I think, be found the most useful preparation of arsenic that we can employ. The liquor of the hydriodate of arsenic and mercury has been very successfully exhibited in cases of this description, as has also the iodide of arsenic, either alone, or, if the disease be of a syphilitic nature, in combination with the biniodide of mercury and extract of conium. Instances illustrative of the value of these preparations have been adduced in a former part of this paper. The 'Asiatic pills' were strongly recommended, and, according to Cazenave and Schedel, employed by Bielt with advantage, in cases of *psoriasis inveterata*: they are, however, open to the objection of being less manageable than the other preparations of arsenic.

"When these remedies are about to exercise a beneficial influence in cases of *lepra* and *psoriasis*, it will be observed that an increased action appears to take place in the diseased cutis, which becomes red, inflamed, and irritable; the scaly patches then appear to heal up, either from the centre or the circumference, according to the nature of the affection, whether it be *lepra* or *psoriasis*, and eventually fall off, leaving the subjacent skin red, smooth, shining, and covered by thin epidermic exfoliations, which may usually be readily cleared off by stimulating topical applications, such as the ointments of tar, or of the nitrate or the biniodide of mercury; after which nothing but a red stain will be left in the site of the squamous patch. And this will soon disappear if the remedies be persevered in, which they should always be, until this blotch is entirely and effectually removed; for, until this be accomplished, the disease will be very liable to return: indeed, it is from a want of due attention to this very important circumstance, that the arsenical preparations have been so often accused of affecting merely temporary cures. We must not be content with removing the scales merely, which are secondary phenomena, but we must get rid of the primary lesion, that peculiar inflammatory or congested state of the blood-vessels of the cutis, which, by giving rise to an increased and morbid secretion of the epidermis, is the proximate cause of the scaly diseases."

Mr. Plumbe states, that *dulcamara* has unfortunately failed in his hands, and Mr. Phillips' testimony is scarcely more favourable.

patches on the knee and elbow, and subsequently spread to other parts of the body.

May 3d.—The patches on the knee, eleven in number, were generally circular in shape, and from six to nine lines in diameter; their centres were depressed, covered with thick, hirsute squamæ, and intersected with fine linear fissures; their circumferences were in strong relief with the neighbouring skin. On the leg and thigh a number of squamous patches, circular like the former, but of smaller size, and with centres less depressed, and edges less raised, were conspicuous; these patches, in a word, bore the strongest resemblance to those of psoriasis *guttata*. Interspersed among the squamous patches, several small, solid elevations, the size of a millet-seed, were perceived, the summits of some of which were red; those of others were covered with a small white scale, whilst others were transformed into squamous patches, so that the successive stages of the disease could be readily traced. On the upper extremities, the same gradations in the progress of the patches were conspicuous; those first formed on the elbows being the largest. On the trunk, the patches were few in number, and only occurred on the lumbar region. The patches on the extremities were the seat of a very violent pruritus, when the heat of the surface happened to be increased by any accidental circumstance. In other respects, D \* \* \* was in perfect health. I bled him from the arm to the extent of six ounces, and he took a tepid-bath every other day. The bleeding was followed by a great abatement of the pruritus; and several of the most recently-formed patches became pale, and shrunk in appearance. The venesection was repeated after the lapse of a fortnight, and the baths were continued; I afterwards recommended leeches to be several times applied in the vicinity of the patches that looked most inflamed. In this way I brought about a great diminution in the number and dimensions of the patches, which, for the most part, were now changed into true rings, the integument in their centre having become perfectly healthy. Several doses of purgative medicine were prescribed, as a final measure, at considerable intervals from each other, and the cure was complete after three months and a half of treatment.

CASE CX.—*Lepra of the knees and elbows; blisters and escharotics.* F. B., aged twenty-eight, in other respects healthy, presented himself at the Bureau Central with a number of well-characterized leprous patches on the olecranal regions of the right and left arms, as well as on both knees, a single one on the right foot, and two of small size on the cartilage of the right ear. The disease was of four months' standing, and the patches were scarcely at all inflamed. Within the space of eighteen days, six small flying blisters, the size of the patches upon the olecranal regions, were applied to their surface. The patches of the knee and ear were cauterized with the hydrochloric acid, and this measure had to be repeated many times on several of them. The acid acted so deeply that it left the mark of two circular cicatrices which still proclaim the forms and dimensions of the patches.

CASE CXI.—*Lepra of the scalp; white precipitate salve.* J. V \* \* \*, aged twenty-three, entered the La Charité Hospital on the 17th October, 1833. This young woman was fat and ruddy, and in general good health. In the course of the previous month of May, a number of solid elevations suddenly made their appearance on the scalp. These soon became covered with thin, dry scales, without causing pruritus or smarting. Suffering little inconvenience from this affection, the patient at first tried no means to get rid of it; more lately, however, she had made use of a tisan of saponaria, bathed the parts affected with salt and water, and applied a blister to her neck, but without deriving any benefit from the treatment.

On entering the hospital, the surface of the scalp presented a great number of circular squamous patches varying from half an inch to an inch in diameter, distinctly circumscribed, and of a yellowish colour. These were covered by an agglomeration of small scales, which appeared to be attached to the scalp by one of their extremities, and to lie one over the other. The squamæ did not adhere at all firmly, a little rubbing detached them readily; the integument under them was rosy and dry; on several other places large papular-looking elevations were perceived; the hair had fallen off from some of the patches over others it was finer and thinner than on other parts of the head. On the integument in front of the left ear, two patches occurred; one of them, the size of a shilling, was covered around its circumference

with fine dry white squamæ, whilst its centre was without them, but dry, red, and discoloured. There was no discharge from any part of the affected skin. The patient complained from time to time of a slight degree of smarting in the affected parts. The whole of the rest of the body was free from all trace of any similar affection. The patient was directed to rub a drachm of the white precipitate ointment over the surface of the scalp daily, the hair having been previously clipped short. By this means the squamæ were all removed in the course of three or four days; and those that were formed afresh were white and fine, and only apparent around the circumference of the patches. October 22d.—Four drops of the tincture of cantharides were now prescribed in a mucilaginous mixture. 24th.—Headache, for which bleeding was deemed necessary; five drops of the tinct. cantharid. 25th.—Symptoms of inflammation in the vein which had been opened; twenty-five leeches, and a poultice to the part; the arm to be twice put into a tepid bath. 26th.—The same number of leeches as before, applied to the bend of the arm, gave relief. The tinct. canthar. had been continued in doses of five drops daily, but the patient now complaining of pain and scalding in making water, the further use of the medicine was suspended. The lepra continued to advance nevertheless towards recovery. Squamæ were now only formed here and there, and the colour of the patches was getting daily less and less vivid. A few tepid baths, and the renewed application of the white precipitate salve completed the cure, so that the patient left the hospital on the 10th of December, quite recovered. (a)

(a) *Cases of lepra vulgaris—Sulphur vapour bath, bleeding, and Fowler's solution.*

"A lady, aged twenty-five, came to consult me in the beginning of April, 1832, on account of leprosy, under which she had laboured for the last seven years. When she applied to me, the disease was not confined to any particular region, but extended over the whole of the body, with the exception of the hands, feet, and face. The head had been shaved regularly once a fortnight during the last three years, for the convenience of making applications to the spots. The squamous patches, on the body and limbs, varied in size from that of a crown piece to that of a sixpence; they were all of a very regular round shape, though some of them had run together in different places, and formed broad continuous patches. The edges of the several patches were of a more vivid red, and appeared more raised than their centres, which, for the most part, were covered with thin scales, constantly falling off, but as constantly reproduced. Several of the spots, however, were declining, and presented nearly the same pale colour as the skin at large; the red raised edges which surrounded these, formed simple rings, enclosing patches of apparently healthy integument. Other spots again were on the increase, and appeared as small red elevations, covered with a thin shining scale of similar dimensions. The patient informed me that this process of decline in one part, and of increase in another, had been constantly going on for rather more than the last seven years.

"The patient was otherwise in good health, complaining of nothing except a proneness to occasional headache. She had made trial of all the usual remedial means prescribed in cases of scaly leprosy without success, with the single exception of the sulphur fume baths; and it was with the view of trying the effect of these that I was now consulted.

"This patient began by taking three vapour baths, in order to free the surface in some degree from the thick covering of scales spread over it, and a few doses of aperient medicine as preparatory measures. The sulphur fume baths were only commenced on the 17th of April, one being taken every other day. But the disease was still in too active a state to be benefited by this treatment; in a week, the patient was literally of a uniform and bright scarlet red colour, and very many new spots were brought out, to which her attention was directed. She therefore ceased to take the baths till the 30th, when she again commenced them. By this time, the general redness had disappeared, but the leprous spots were much in the same state as before. May 10th.—The new spots had not maintained the character of the former ones, not having gone on gradually extending, and many of them having even receded entirely. The baths were now taken daily; but

## PSORIASIS.

Vocab. *Dartre, Psoriasis, Scall, Itch* [Dry Scaly Tetter, &c.].

682. Psoriasis is a chronic inflammation of the skin, limited to a single region of the body, or occupying almost its entire surface, appearing primarily under the form of solid elevations, which change

up to the 20th of May, so little progress has been made in the cure, that I bled the patient to fourteen ounces. The blood was natural, but firm in texture.

"30th.—A great improvement had taken place since the bleeding, many of the spots having disappeared, and left red rings, some of which were broken through in different places, the skin in the gaps presenting its natural appearance. June 9th.—Improved, though not to so great an extent as during the interval up to last report. Few entire red patches remained, but the old rings had undergone little variation. To these, with a camel's hair pencil, the patient was directed to apply a little diluted aromatic vinegar every night, and she commenced taking four drops of the arsenical solution, morning and evening, in a cup of barley-water. 19th.—The patient began to complain of a troublesome itchiness of the skin, which very usually occurs in consequence of the excitement occasioned by the heat of the bath and the effects of the sulphur; this, however, did not deter her from continuing the fumigation till the 24th, when the pruritus was so much increased, that they were discontinued for a few days. Having suffered from pains and uneasy sensations in the stomach and bowels also, the arsenical medicine, which had been increased to ten drops twice a day, was likewise left off for a time.

"July 3d.—The patient, being now free from pain in the abdomen, and the pruritus of skin having subsided, resumed the fumigations, together with the medicine. At this date she was greatly better. 13th.—The skin had become much darkened and hardened, from the effects of the sulphur. This state I knew to be the herald of the process of peeling or desquamation which always follows the continued use of the sulphur fume bath, and from which I anticipated the best effects in this case; I therefore advised the sulphur bath to be discontinued for six weeks; and to facilitate the peeling of the skin, I recommended a few water baths, and now and then a vapour bath, to be taken, whilst the arsenical solution was steadily persevered in, so long as no unpleasant constitutional symptoms supervened.

"I did not see this lady again until the end of September, when the whole of the leprous spots had disappeared, except two or three on the abdomen. To these she was advised to apply the aromatic vinegar as before, and still to await the result of the treatment, as desquamation of the cuticle had not yet come to an end.

"This lady visited me again in the April of 1833, with a return of her complaint, but of very trifling extent, showing itself only on the body, and consisting in all of not more than a dozen spots. She was so much convinced that the bleeding had exerted a beneficial influence in the treatment of the year before, that she had had herself bled before visiting me, with the intention of resuming the sulphur fume baths. Eighteen of these, on this occasion, removed every trace of the disease.

"This lady informed me that she had gone on *peeling* during the greater part of the winter, and had lost all vestiges of her complaint, till, on the return of spring, when, as just stated, it showed a disposition to recur.

"Since this trifling attack the patient has remained quite well. On this latter occasion, no medicine whatever was taken.

"CASE 2.—Very nearly at the same time (April, 1832) as the last patient, a lady from Ireland consulted me on the same form of squamous disease—leprosy, and it was an odd coincidence, that this lady, on comparing notes with the one whose case has been just detailed, found that they had both been assailed with the disease about the same period, and were so similarly affected, that the account of the symptoms in the one proved to be a correct detail of those in the other. It is not very usual for lepra to appear on the hairy scalp, but this latter patient, like the former, was so attacked, and had been in the habit of having her head shaved for three or four years, every ten

into squamous patches of different sizes, not depressed in the centre, and of which the edges are irregular and but slightly raised.

683. Four principal varieties of psoriasis are reckoned; these are: 1st. Psoriasis *discreta* (*guttata*, Willan). In this variety numbers of small, distinct elevations, and squamous patches, occur, from two to four lines in diameter, irregularly circumscribed, and of a form and appearance very analogous to that which results when the body is sprinkled with water and the fluid lies in large drops upon its surface; such, indeed, appears to have been the origin of the epithet employed by Willan, to distinguish this variety.

Each of the squamous patches is announced by a small solid, red elevation, the size of a pin's head, the summit of which soon gets covered with a minute dry scale of a dull white colour. These patches are irregularly rounded, slightly prominent, especially towards their centre, and separated from each other by considerable intervals of healthy skin. When the patches are freed from their investing squamæ, the corion appears red and irritable, and if the

days, or once a fortnight, for the convenience of making applications of different kinds to it. The only difference in the cases was that this second patient was twenty-nine years of age, very prone to what she described as feverish heats, and to headaches, and was further of a very constipated habit. The numerous spots and patches were in all particulars alike in both patients, who were both of strong make, and in the enjoyment of fair average health. The first lady took the sulphur fume bath fifty-one times, between the 17th of April and the 13th of July, before the complaint disappeared, and she had a slight return of it the following year. The latter lady had forty-seven fumigations administered, between the 20th of April and the 23d of June, when it was judged unnecessary to continue them longer. After the process of peeling was completed, this lady found herself quite well, and has had no return of her malady up to the present time.

"She was bled, and took medicines similar to those prescribed in the first case, with the addition of an aperient draught most mornings, when she first commenced the use of the fume bath; aperient medicine, indeed, was required from time to time, throughout the whole course of the treatment.

"The arsenical solution, given with the usual precautions, has long and justly held a high reputation in most countries, for its influence over lepra. I am anxious, from my own experience, to attest its beneficial powers in this disease. It is not improbable but that both of the cases detailed would have recovered under the use of the sulphur fumes, without the addition of so powerful a medicine as arsenic; and, indeed, I have known many cases that have been of short standing recover without any assistance from other means, even without the use of bleeding. But in cases of longer standing, I have reason to conclude that both of these adjuncts are advisable, and tend greatly to abridge and facilitate a cure. Leprous patients perspire readily and abundantly whilst in the fumigating bath; in psoriasis, another scaly disease, I have found them to perspire less freely, and still less in general pityriasis, when the scales are much thinner, for the most part smaller, and much more continuous.

"I have selected these two cases of lepra on account of their long standing, and because I think they tend to show the powerful remedial influence possessed by the sulphur fume bath, in this peculiar and generally intractable disease. These cases I also consider as fair specimens of the utility of conjoining internal medicines with the fumigatory method; for although the latter has been upheld as adequate to cure lepra by itself, and I have known many instances of the fact, yet when we have a disease of an acknowledged rebellious character to contend with, it seems to me well to meet it with the whole of the corrective powers we possess."—*Green on Diseases of the Skin*, pp. 152–3.

<sup>1</sup> Dr. Bardsley, in his "Hospital Facts," abstains from detail relative to the medicines given when putting to the test the efficacy of fumigations in the cutaneous diseases.

Of the value of his preparatory treatment there can be no doubt, and although he speaks and his tables show so favourably in regard to the merits of the fumigatory method of treatment, I have reason either to doubt the excellence of the construction of the apparatus employed, or to judge unfavourably of the way in which the fumigations were administered, from the results as shown in the tables. Dr. Bardsley's other statements relative to the fumigatory method deserve the particular consideration of the profession.

whole have been thus cleansed, the disease appears in the shape of rounded spots, from two to four lines across, slightly prominent and of a brownish-red colour. These patches occasionally get well, like those of lepra, from the centre towards the circumference; in this case the middle of the patches presents an accidental depression, and acquires a slightly yellow tint; in proportion as the cure advances, these patches become transformed into segments or small arcs of circles, and after it is accomplished, the skin still presents small stains of a grayish brown, or yellowish cast, in those points that had been possessed by the eruption.

Psoriasis *discreta* is seldom accompanied with much pruritus, even when the body is heated by exercise or any other accidental cause.

The patches of this variety of psoriasis may be confined to the hairy scalp, face, trunk, or extremities, or be disseminated over the whole of these regions, appearing either at once upon all of them, or upon each in succession. Almost always very irregularly disseminated, the patches appear crowded in one situation, and very thinly sown in another; on the extremities they are always observed to be more numerous in the line of extension than in that of flexion. Psoriasis *discreta* makes its attacks most commonly in the spring and autumn, and occasionally disappears spontaneously during summer; it has been known to appear and disappear in this manner for several years in succession. In children it is more quickly evolved than among adults.

2d. Psoriasis *confluens* (*diffusa*, Willan). Instead of being separate and distinct, it much more frequently happens that the primary papulæ of psoriasis are evolved so close together that the squamous patches which succeed them meet and blend by their corresponding edges. As may be imagined, the patches in this instance are of very various sizes and forms. As in psoriasis *discreta*, each of the smaller patches which goes to the composition of the larger clusters, begins in the form of a solid papular-looking eminence, on the top of which a dry scale of a dull-white colour is soon formed. The patches increase in size, become confluent, and compose at length an irregular squamous surface, upon which, however, the original spots may often be distinguished. These large patches are sometimes irregularly intersected by red lines, and here and there show angular portions of integument which are free from squamæ.

Psoriasis is more constantly *confluent* on the limbs than on the trunk; and the patches characteristic of this form of the disease frequently disappear on one district at the same time that the eruption which gives rise to them makes its appearance on another.

The arrangement of the eruption of psoriasis in small distinct circular spots, or in broad confluent patches, is no evidence of diversity in the nature of the disease; it is frequently seen in the shape of psoriasis *discreta* on the body, whilst it has the character of psoriasis *confluens* on the limbs.

Patients labouring under confluent psoriasis of recent date, complain of a considerable degree of pain and pruritus in the affected parts, which is always increased by the warmth of bed, the vicinity of a fire, and any other cause that tends to stimulate, or raise the temperature of the surface.

Psoriasis *confluens* of the forearms and legs is occasionally seen forming a kind of irregular band, and sometimes, but more rarely, a sort of case which includes the affected limb through its entire length. In this instance, instead of the usual micaceous squamæ of psoriasis we occasionally only distinguish an agglomeration of minute furfuraceous scales, the colour of which approaches that of the flour of mustard. When the squamæ, in such cases, have been got rid of by baths, vapour douches, &c., the surface they covered appears smooth, shining, and highly inflamed. (a)

(a) Psoriasis *infantis*, a term applied by Willan to psoriasis *diffusa*, as it is seen in the infant, is thus described by Plumbe.

"The psoriasis of infants is entitled to a separate consideration from the foregoing, on a very important account. There is no question that it has often been mistaken for the consequence of venereal taint on the part of the parents of the child who is the subject of it, and has been, therefore, the means of inflicting much injury and undeserved distress. Dr. Willan, after alluding to one or two unimportant points, in which he states the venereal affection of the skin of infants

3d. Whether this squamous inflammation have appeared under the form of small *distinct* patches (psoriasis *discreta*), or of confluent

to differ from that under consideration, advises 'practitioners not to be too hasty in judging from mere inspection, and never to decide till they are *justified by collateral circumstances*.' It is seen in infants from birth up to three years of age.

"From a very minute and lengthened inquiry into the history of many cases of this disease, I am irresistibly led to the conclusion that it has no connection with any form of venereal disease, except indirectly, *i. e.*, when syphilitic affection may have combined with other causes in reducing the strength of the mother, or otherwise depriving the child of healthy sustenance. A generally healthy performance of the different animal functions, which is often found compatible with constitutional syphilitic disease, is not seen in the cases of infants affected with psoriasis. It is found to occur, moreover, where the parents on neither side can be liable to suspicion.

"Like the psoriasis and lepra of adults, it may continue long after its direct exciting cause has ceased to exist; and when taking place on the skin of unhealthy and poorly nourished children, it frequently continues when a better constitutional condition has been produced. From this circumstance, and the unyielding nature of the disease, it has no doubt sometimes happened that the suspicion alluded to has arisen, where, at the commencement of the eruption, it would not have been entertained; and the treatment which has been adopted under these circumstances has been improper and injurious. In an institution to which I have the honour of belonging, cases without number have come under my notice, where poverty of circumstances existed on the part of the parents in a most extreme degree, evidently operating as the cause of the disease, when from a change to better living, consequent on the parents obtaining employment, the disease has speedily disappeared. Many such cases have been considered and treated as venereal without benefit; but, on the contrary, with aggravation of all the symptoms.

"With respect to the class of society among which infants are chiefly affected with this disease, it may be safely asserted, that it is almost unknown among the rich or affluent, or even those whose circumstances bear them uniformly above the reach of want. It may sometimes occur from bad feeding or neglect, but it is generally the concomitant of poverty, and for the most part only seen in the cellars and confined apartments of the poor and unhappy, where privation of nourishing food and impurity of atmosphere unite their depressing powers.

"When the disease first comes under our notice among the poor, it is characterized by red patches of inflammation on the cheeks, chin, forehead, nates, abdomen, &c. On the face some of the patches are small and irregular, others large, and assuming somewhat of a circular form. Some are covered with a horny scale, which is glossy and smooth to the touch, but which in a few days cracks and exhibits fissures of greater or less length and depth. Some are occupied by portions of scales of morbid cuticle rapidly detaching themselves, while others are forming beneath, which take the same course. The eyes sometimes partake of the inflammation, and generally the mucous membrane of the nose becomes inflamed and thickened, leading to snuffling, difficulty of respiration, and some fluid discharge.

"In the more aggravated cases, the bottoms of the fissures emit a bloody discharge, if situated in the neighbourhood of joints, but not otherwise; and if no great emaciation may have existed at first, the irritation and pain belonging to the disease make it soon apparent, and it generally increases with rapidity till death takes place.

"The most irritable and painful spot which the disease is found to occupy is about the nates or between the legs; the perineum, labiæ, scrotum, &c., also, are not unfrequently the seats of much abrasion and tenderness, apparently produced by the stimulating properties of the urine.

"It seldom happens that if the excretions be examined, a very disordered state of the alimentary canal with the secretions of the liver be not discovered, which may have been either concerned as an original cause, or impeding the restoration of health and strength. Hence small doses of the hydr. c. cretâ, with the occasional use of a brisker purgative, are necessary. Tepid bathing, to the extent of liberating all the hard scales which may have been formed, and allay-

inasses (*psoriasis confluens*), when it has existed during many months, or several years, especially when it can be traced to a hereditary taint, or attacks individuals of shattered constitution, the disease gets worse and worse, the skin becomes hard, thickened, tense and inelastic, yielding uneasily to the motions of the limbs, and appearing to undergo a kind of hypertrophy; the primary patches of the disease are no longer distinguishable, but the integument is covered with hard, dry, and thick white scales; numerous chaps of various depths soon follow, furrowing the surface in all directions, but especially in those of the natural folds of the skin (*psoriasis inveterata* Willan, *agria* of the ancient writers); and in those rare cases in which the trunk and extremities are involved in one common incrustation, the disease assumes a hideous appearance, and the surface of the body has been compared by some pathologists to the rugged bark of an aged tree. This circumstance has even led M. Alibert to designate this last and inveterate stage of the disease, under the name of *dartre squammeuse lichenoïde*. The squamæ at this stage frequently rise in strong relief from the skin, exceeding by from a quarter to half a line the level of the neighbouring healthy parts. They are also then produced in such abundance, that quantities may always be gathered from the beds, and shaken from the clothes of patients. These squamæ are occasionally a full line in thickness. It is in the vicinity of the articulations, that chaps or cracks occur most commonly; these get deeper and deeper, bleed when motion is attempted, and often pour out a glutinous fluid that dries up into linear incrustations. Further, the parts affected are frequently the seat of a burning pruritus, especially during the night. To conclude, considerable superficial excoriations have been seen to form upon the back, buttocks and lower limbs, when these parts were the seat of this disease, which caused the patients much and extreme suffering.

4th. Under the title of *psoriasis gyrata*, Willan has described a squamous vermiform eruption, characterized by squamous bands, spirally twisted or arranged longitudinally, and traversed by numerous superficial lines, corresponding evidently to the natural folds or wrinkles of the skin. These bands, however disposed, are affected with a very slight furfuraceous desquamation. I have met with but two cases of this variety, in neither of which could I observe any thing like papulæ, or round squamous patches, analogous to those of *psoriasis discreta*. This eruption is seldom attended with pruritus, even when the temperature of the surface is increased by exercise or any other cause.

684. *Psoriasis* may continue from a few months to several years; it is always of long duration when the patches are numerous and it can be traced hereditarily.

685. Independently of the remarkable varieties presented by this disease, which have now been described, it still offers several additional peculiarities according to the regions of the body it attacks.

1st. *Psoriasis* seldom appears primarily upon the *hairy scalp*. It there usually occurs in the *distinct* form; the squamæ are always yellower and more pulverulent than when they are produced from the trunk. The *confluent* form of the disease is still rarer here. I have, however, seen it covering almost the whole surface of the hairy scalp, and extending to the forehead, in a line parallel with that of the implantation of the hair, under the form of a prominent band, an inch in breadth, whose surface was covered with rough squamæ of a dull white colour, and whose lower edge was red and much raised above the level of the healthy skin. The inflammation of *psoriasis* frequently attacks the bulbs of the hair, which is then detached from the points affected.

2d. *Psoriasis* frequently attacks *the face*, at the same time that it appears on other regions of the body; the eruption, however, may be entirely confined to the countenance. The patches that characterize the disease in this situation are red and furfuraceous, and the squamæ are usually very light and thin. The subcutaneous cellular tissue becomes tumefied when the disease is of long standing and has assumed the characters of the variety designated *inveterata*. On the

ing the general irritation of the skin; frequent ablutions with warm water of the more irritable parts, change to a purer atmosphere, and more efficient nourishment, have been in most cases adequate to the cure, when assisted by internal remedies of this nature."

eyelids it is announced, as indeed it is everywhere else, by the formation of papulæ, which usually appear about the angles of the eyes; the eyelids soon become stiff, tense and chapped; and in children the eruption is occasionally followed by the loss of the cilia and hairs of the eyebrows. Several other scaly affections of the eyelids, as well as the disease which, following Willan, I formerly described under the name of *psoriasis of the lips*, now appear to me to belong to the group of pityriases, among which they will be found discussed.

3d. *Psoriasis* of the *trunk* rarely occurs alone; the disease almost invariably affects the extremities at the same time. When inveterate, its squamæ are commonly thinner and smaller than those observed in *psoriasis* of the extremities, especially when the knees and elbows are the parts affected.

4th. *Psoriasis* of the *scrotum* is a rare disease; when it does occur it generally becomes *inveterate*, and is attended with excessive pruritus, and most painful chaps. I have met with a case of *psoriasis discreta*, in which the patches were disposed in a line parallel with the raphe. The circular spots of *psoriasis discreta* occurring on the scrotum and verge of the anus in children, have been known to be mistaken for syphilitic tubercles, from which they differ in their mode of formation, which is that of squamous papulæ, in the more decidedly scaly look of their surface, and generally by the almost uniform existence at the same time of scaly patches upon the belly and thighs.

5th. *Psoriasis* of the *prepuce* is also of very rare occurrence, almost always becomes inveterate, and is attended with thickening of the skin, and painful and bleeding chaps, which are occasionally accompanied by some degree of swelling in the lymphatic glands of the groin. This form of *psoriasis*, usually very obstinate among adults, has occasionally required the operation for phymosis for its removal. It is of great consequence not to confound the squamous patches by which *psoriasis* of the prepuce begins with a syphilitic eruption occurring on the same part.

686. I have, lastly, to make particular mention of three varieties of *psoriasis* of the hands:

1st. *Psoriasis palmaris* may be distinct or confluent; in either case the disease begins with broader elevations than those of the other varieties: they are reddish in colour and the seat of a considerable degree of heat and itchiness; pressed upon strongly, or pinched, they become painful; and if rather numerous, the patient is compelled to give up every kind of manual labour. In the confluent species, the palm of the hand swells generally, and becomes of a uniform violet-red colour. The feeling of heat which was complained of at first, becomes gradually less distressing, and ceases at length, in a great measure, whilst the painful pruritus that accompanied it, becomes much less troublesome; during this time the cuticle that surrounds the elevations grows considerably thicker, acquires a yellowish colour like the skin of the heel, dries up and becomes friable, and at last of a dead white on the summits of the patches. At this period, the altered and cracked epidermis covering the elevations is detached, either spontaneously or by the nails of the patient, and leaves a new epidermis through which the corion shines. The epidermis in the vicinity of the diseased parts also undergoes modifications: it becomes considerably thicker than usual, and of a dirty yellow hue; it dries and looks mealy on the surface, and finally exfoliates irregularly, at first in the neighbourhood of the older patches, and then in that of the joints and natural folds of the skin of the hand. The desquamation in this case is always *irregular*, and is very different in appearance from that which happens in the variety next to be described—the *psoriasis palmaris centrifuga*: like it, however, and perhaps even more constantly, it is attended with linear fissures, which penetrate to the quick in the course of the lines of the palm, and with a still greater number of clefts that extend less deeply, and do not even reach the corion.

2d. *Psoriasis palmaris centrifuga*. This variety begins in the palm of the hand by a solid elevation whose summit is covered with a small white and dry epidermic scale; this spot is then surrounded by a reddish ring upon which the epidermis dries and is thrown off circularly. Around this first circle a second is before long formed, upon which a similar process of desquamation takes place, and these circles may appear one after the other, becoming more and more eccentric, until the whole palm of the hand is implicated, and squamous patches even appear on the palmar aspects of the fingers. The diseased parts are

affected with a very troublesome pruritus, which is increased whenever the hand is exposed to any elevation of temperature, or even when the fingers are moved for any length of time. When patients yield to the impulse to scratch the parts affected, the skin assumes a violet-hue, and at a later stage presents numerous cracks that pursue the course of the lines habitually observed in the palm. The surfaces between two of these crevices are covered with very hard and thick squamæ, and the whole palm is stiff and dry. This form of psoriasis has been principally observed among washerwomen and others, whose hands are habitually exposed to the contact of alkaline leys, or among coppersmiths, silversmiths and tinsmiths, the palms of whose hands are irritated by repeated pressure, combined with the contact of different metallic substances. Psoriasis palmaris usually grows worse in winter, and often gets well in summer. After recovery, the skin remains for some time smooth and of a dusky-red colour. It seldom happens that the disease does not recur several times after getting well, when those affected do not give up the craft they may be exercising at the time, and which has been recognized as its occasional cause at least.

3d. There is a variety of psoriasis *diffusa* which is developed on the backs of the hands and is known under the name of *grocer's itch*, because frequently seen among persons exercising this trade, although it also attacks bakers, laundresses, and even individuals of the better classes of society. The eruption begins in the shape of two or three squamous elevations, which spread to such a degree as at length to cover the whole dorsum of the hand. The integuments are before long seamed with numbers of dry and painful chaps; these occur especially over the wrist joint and the articulations between the metacarpal bones and first phalanges of the fingers. This variety of psoriasis is distinguished from the confluent and chronic lichen of the backs of the hands by the circumstance of the latter being always preceded by a considerable eruption of small papulæ. It is also important to distinguish this true psoriasis from the squamous inflammations artificially excited, to which individuals exercising certain callings are subject. When one of these varieties, or any other form of psoriasis extends to the whole back of the hand, the matrix of the nails is occasionally attacked with chronic inflammation, in which case the nails themselves become thickened, bent, cracked and at length detached; they are in due time succeeded by others, but these are liable to be affected in the same way. Psoriasis *plantaris* is a rarer disease than psoriasis palmaris, and less uniformly attended with chapping of the skin.

4th. With regard to psoriasis of the *inferior extremities* I have only to remark, that the disease is very apt to become *inveterate*. The legs then appear furnished with a general adventitious squamous envelop, which does, indeed, bear some resemblance to the lichenous covering of trees with which it has been compared.

687. Psoriasis rarely appears complicated with other inflammatory affections of the skin, if we except lepra. It has, however, been seen especially among children, occurring with characters of the greatest inveteracy along with eczema *impetiginodes*. Amidst the thin squamæ that cover the diseased patches, vesicles and particularly purulent points are then perceived. At a later period, these surfaces may become excoriated, and form thin, lamellar, yellowish-coloured scabs like those of the eczema. It occasionally happens, especially when children are attacked with the disease during the period of teething, that, on the first invasion, or during the course of psoriasis, a certain degree of derangement is apparent in the functions of the digestive organs. It was this circumstance, undoubtedly, that led Willan and Bateman to speak of epigastric pains, lassitude, headache and various other symptoms as precursors of psoriasis, which are, in fact, rarely observed in connection with the disease unless when developed under the circumstances indicated.

688. *Causes*.—Next to eczema and lichen, psoriasis is one of the most common of the chronic affections of the skin. Of all the variety of forms assumed by the disease, that which I have designated psoriasis *discreta* is the most common; in a given number of cases this will be found in the proportion of three-fifths to the whole. Psoriasis shows itself principally among adults, between the ages of twenty-five and thirty years; women of a nervous and sanguine temperament are particularly obnoxious to its attacks. Of all the chronic and non-contagious affections of the skin, psoriasis is that the hereditary nature

of which is most satisfactorily ascertained. The seasons have a very marked influence on the production of this disease; it is usually developed in the beginning of the spring or autumn. The influence of different trades or professions appears limited to a few local varieties. To conclude, irritation of every kind, direct or indirect, applied to the skin, may prove the occasional cause of psoriasis; the disease has, in fact, been seen succeeding repeated attacks of lichen, prurigo, different other diseases of the skin, and the application of a common blister.

689. *Diagnosis*.—Psoriasis can only be confounded with three diseases, which like it affect the squamous form, namely lepra, pityriasis and scaly syphilis. There exists, indeed, between lepra and psoriasis a very great similarity. The resemblance of psoriasis *discreta* to lepra is more particularly striking. Both of these affections of the skin commence as solid papular-looking elevations, both soon assume the shape of circular scaly patches, and these in the same patient frequently present the appearances characteristic of psoriasis *discreta* on the trunk, and those distinctive of lepra on the knees and elbows.

Some recent writers have consequently maintained that lepra and psoriasis were nothing more than two varieties of the same disease. There are, however, certain characters which distinguish these two eruptions, or, if it must be so, these two degrees of the same form of inflammation, from each other. The patches of psoriasis *discreta*, for instance, are never so broad as those of lepra, neither are their edges raised, nor their centres depressed like those of the latter; in psoriasis, too, the squamæ adhere more firmly and are less abundantly produced than those of lepra. The differences between lepra and psoriasis *diffusa* are still more marked. The patches of the latter are irregular and not depressed in their centres, those of the former are exactly circular, and even when several leprous spots are blended together, their originally circular shapes continue to be proclaimed by the arcs of circles presented on their circumference.

Psoriasis is distinguished from syphilitic scaly patches (psoriasis *syphilitica*, Willan), by the coppery or livid hue of the latter, which is deeper towards their centre than their circumference; they are also without true squamæ, being covered by a transparent epidermic layer, which is usually detached circularly, exposing a smooth and shining surface of a coppery-yellow, bounded by an epidermic edge. Syphilitic blotches, further, are not accompanied with any pruritus, and are generally complicated with evident venereal affections of the pharynx or conjunctiva, with nodes, nocturnal pains, &c., and get speedily well under the influence of mercurial medicines carefully administered. Lastly, these blotches disappear from the circumference towards their centre, a character which of itself distinguishes them sufficiently from the squamous patches of lepra and some of the varieties of psoriasis.

Psoriasis *discreta* of the hairy-scalp differs from pityriasis of the same part, by appearing under the form of patches which, beneath the squamæ, always present a red central point that rises above the level of the skin generally.

690. The varieties of psoriasis designated by Willan *diffusa* and *inveterata* commonly prove very obstinate diseases, more so even than lepra. Psoriasis *discreta* vel *guttata*, in a general way, is less rebellious than the *confluens* vel *diffusa*, which in its turn is less intractable than the *inveterata*; this last variety, indeed, is often absolutely incurable. When psoriasis *discreta* begins to get well, the amendment is announced by the sinking of the patches, and takes place at first in one or several points of a particular district, from which it spreads to the other regions affected. When the varieties *diffusa* and *inveterata* end in recovery, the chaps of the skin disappear, the inflammation of the corion diminishes gradually, the altered epidermis is replaced by one of less thickness, less dry and inclined to crack, and after many successive desquamations, the dermis in the points affected becomes covered with a cuticle similar to that of the healthy integument.

691. *Treatment*.—The medical treatment and dietetic plan pursued in psoriasis ought to be based on the same principles as those that guide us in lepra; the curative means only require to be modified according to the more or less highly inflamed condition of the integuments. When psoriasis *discreta* is recent, and an adult is its subject, the disease must be attacked by one or two venesections. I am in

possession of a sufficient number of facts to show that this measure is constantly serviceable, and the same conclusion has been come to by many other practitioners. Plain baths, or better still, narcotic and emollient temperate baths, which lessen the irritation of the skin and the pruritus with which it is constantly accompanied, are to be employed at the same time and subsequently. The douche and vapour-bath are also frequently found of service in the cases of adults. By using these alternately with sulphureous-water baths, confluent psoriasis, accompanied with no great degree of inflammation, are frequently got rid of in the course of three or four months. When confluent psoriasis is of old standing, a modification of the skin may often be advantageously attained by anointing it with an ointment of the tartrate of antimony; the same practice has even been found serviceable in some cases of the *inveterate* disease, although in these the alteration of the skin is so deep that the affection is generally incurable, at least among the aged. *Inveterate* psoriasis is always improved by the use of the emollient and narcotic bath, as well as of the vapour-bath and douche. Among the aged, attacked with inveterate psoriasis, whose skin is thickened and indurated in different parts of the body, the treatment must be limited to such palliative measures. The same plan also appears to me better than any other when the subject of the disease is a member of the labouring class of the community, who would certainly have a relapse as soon as he was thrown upon his old occupations and habits. Such patients, labouring under inveterate psoriasis, have been seen, who derived no benefit whatever from taking the vapour-douche and bath more than one hundred and fifty times, or having undergone the most energetic internal treatment, from which, indeed, unpleasant symptoms of different degrees of severity resulted.

In the treatment of psoriasis *diffusa* and *discreta* the exhibition every day for some months, of half an ounce of Epsom salts, or two drachms of subcarbonate of potash, or a few grains of calomel in combination with the resin of jalap, so as to procure several alvine evacuations, has been favourably recommended, patients at the same time making use of the tepid-bath; the purgative medicine, however, is immediately to be suspended should unequivocal symptoms of gastro-intestinal disturbance at any time make their appearance. This plan seems more particularly available in psoriasis of the face and hairy scalp.

The deuto-chloride of mercury, in the dose of one-fourth of a grain, and the sulphurated sulphite of soda in the quantity of a scruple, daily, have also appeared to accomplish some cures of psoriasis. The tincture of cantharides is another medicine which has been tried in the different species of psoriasis, particularly the *inveterata*, with some success; the dose has been carried gradually from five to sixty drops every day, when no appreciable disturbance in the digestive, respiratory or urinary organs supervened. The medicine is often continued for three or four months before any favourable change takes place in the state of the skin. One or other of the common arsenical solutions has also been strongly recommended in this obstinate form of disease. Arsenic of course requires great care in its exhibition; its effects must be closely watched, and it is advisable to give up its use for a few days every now and then. It is undeniable that by means of these active medicines several of the varieties of psoriasis, even the most inveterate, have been cured; but it is no less certain that the majority of the cures thus accomplished have been but temporary, relapses having occurred the following spring or autumn; that such relapses are more especially frequent among the labouring classes of the community, and lastly, that the greater number of cases of psoriasis *inveterata* treated by such means have been in nowise amended, although the medicines were continued for five or six months. I am therefore of opinion that it is in general inexpedient to put patients affected with psoriasis *inveterata* upon an arsenical course, in the faint hope of deriving a mere temporary improvement, with the fear before our eyes of inducing some obstinate derangement of the digestive organs, or of permanently injuring the general constitution. (a)

(a) I shall, in a subsequent page, introduce cases to show the efficacy of the arsenical treatment, but it must be conceded that there are good grounds for the author's cautionary remarks on this point. The

In a word, then, psoriasis *discreta* and *diffusa* can be successfully attacked by measures less dangerous than those just mentioned, by the vapour bath, ointment of white precipitate, &c., &c.; and to me a palliative plan of treatment appears the only one available in cases of inveterate psoriasis, especially when its subjects are individuals belonging to the labouring classes of society.

692. The *local* varieties of psoriasis offer the same curative indications as the general disease. Fomentations, baths, cataplasms, emollient and narcotic unguents are all useful when the skin is red and painful. In psoriasis *palmaris* simple baths and fomentations, the vapour douche, and calomel ointment are habitually employed. When the disease has arisen from, or seems to be kept up by any evident outward cause, the first indication of course is to make this unavailing.

#### Historical Notices and particular Cases.

693. The Greek physicians, under the title of *psora*, evidently indicated two different diseases. That which they designated *ψώρα ἰκνός*, or *ulcerous psora*, appears to correspond with the pustular inflammation described in this work under the name of impetigo; the other, which they entitled simply *psora* or *leprous psora* (*ψώρα λεγκός*) was probably the squamous disease we have just been engaged in describing. Galen<sup>1</sup> makes use of the word *psoriasis* to signify a *squamous state of the eyelids and scrotum*; but his description appears equally applicable to pityriasis, lichen, and other diseases affecting these parts as to the malady now denominated psoriasis. Nevertheless it is on the strength of this passage that Willan has felt himself authorized to collect, under the common title of *psoriasis*, every non-contagious squamous inflammation different from lepra and pityriasis. The word *psora* does not occur in the writings of Celsus; this author, however, has clearly pointed out the characters of the *leprous psora* of the Greeks, or *psoriasis*, in his definition of the second species of impetigo.<sup>2</sup> Willan conceives that the Arabian writers refer to psoriasis under the name of *usagero*, a word which is rendered by the Latin translators *serpedo* or *serpigo* and *impetigo*.<sup>3</sup> Psoriasis was subsequently mentioned rather than described by Mercurialis, Hafenreffer, Plater, and others under the name of *psora* and *scabies sicca*, titles also given to lichen. The disease was spoken of by Manardus, Fernelius, Sennertus, Willis, &c., under the title of *impetigo*. The following passage of Sennertus appears peculiarly applicable to psoriasis *diffusa*: "cognoscitur morbus quod cutis dura, sicca, aspera et quasi squamosa redditur; adest pruritus; et malum in dies latius sepiet, et ab initio exiguo sese latè diffundit."<sup>4</sup> Several English writers might be referred to who have described psoriasis under the names of *scaly tetter* and *dry scall*. Willan was the first who gave a full and accu-

following case, related by Mr. Erichsen, (*Med. Gaz.*, 1843), conveys wholesome admonition.

"In illustration of the bad effects that may result from the injudicious use of the preparations of arsenic, I may mention that I have at present under my observation a young lady, of a highly nervous temperament, but otherwise perfectly healthy, and without any hereditary disposition to disease, who, whilst suffering from an attack of psoriasis of the legs some years ago, was advised to take Fowler's solution, which she did in the hope of speedily getting rid of, to a delicate female, a disgusting affection, to such an extent, without the knowledge, however, of the medical attendants, that she brought on extensive derangement of the stomach, which was followed by a violent neuralgic attack, together with, at a subsequent period, a distressing train of hysterical symptoms, which have terminated in a state of dementia, that, having now existed for nearly four years, may almost be looked upon as incurable."

<sup>1</sup> Galeni Opera. De oculo, cap. 7, def. med.

<sup>2</sup> "Alterum genus peius est, simile papulæ fore, sed asperius rubicundiusque figuras varias habens; squamulæ ex summâ cute decidunt," &c.—(Celsus, de medicinâ, lib. v. sect. xxviii.)

<sup>3</sup> Serpedo est asperitas quæ in superficie accidit cutis et ad nigredinem declinat, aliquando ad ruborem. Peliginis autem chronicæ et diuturnæ in quâ non exoriatur cutis, signa sunt, quod in profunda est membri, et squamulæ ab eâ tolluntur rotundæ quales piscium videmus squamas.—(Haly Abbas. Theor. lib. viii. cap. 16.)

<sup>4</sup> Sennert. Med. Pract., t. i. 3o de impetigine.

rate account of the disease under the title adopted in this place. Bateman and Gomez have followed him without modification in their several works. The still more recent observations of Mr. Plumbe tend to show the identity of psoriasis and lepra, and those of Dr. Duffin go more particularly to prove the inflammatory nature of these two diseases. Some French pathologists have referred to psoriasis vaguely under the name of *dartre sèche*. Alibert has described the disease in its severest form (the psoriasis *inveterata*) under the title of *dartre squameuse lichenoides*, and has given several cases of the varieties *discreta* and *diffusa* under the common name of *dartre furfuracée*.

Some observers, in opposition to the opinion generally entertained, believe that psoriasis may sometimes be transmitted by contagion,<sup>1</sup> but the facts quoted in support of this opinion are any thing but conclusive.

Cases of the different varieties of this disease, and remarks on their treatment, occur in many of our periodicals.<sup>2</sup>

CASE CXII.—*Psoriasis discreta of the axillæ; the gelatino-sulphureous douche*. Madame D \* \* \* was attacked in the beginning of March, 1826, with psoriasis *guttata* of the axillæ, a disease from which she had already suffered much two years previously, and which had only yielded to the long-continued use of sulphureous baths and purgatives. When I was consulted, there existed under the right axillæ three oval patches of considerable size, and two or three small elevations as large as millet-seeds. The patches were red, not scaly; their edges were not raised, nor their centre depressed like those of lepra; they had nothing of a coppery nor livid tint like syphilitic blotches. They were further very itchy, and the patient scratched them when asleep or only half awake, by which the pruritus was subsequently greatly increased, and the patches next day made to look more highly inflamed. The pressure of the corsets also irritated them during the day; they had never discharged. In the left axillæ there were five patches of a similar description, two others situated on the olecranon were covered with white squamæ of considerable thickness. I recommended the sulphureous bath and douche from a watering pot at the temperature of 28° Reaum. Twenty baths for a quarter of an hour, and fifteen douches continued for ten minutes each time, restored this lady to perfect health.

CASE CXIII.—*Psoriasis discreta of the scalp; blood-letting and purgatives*. Alphonse \* \* \* was affected two years ago with a dry scall of the eyebrows, which got well by being anointed with grease and washed frequently with Eau de Cologne. Within the last year a similar disease had made its appearance on the scalp, and during the last three months had spread rapidly. March 20th, 1826.—The right frontal region, the ears and the scalp are exclusively affected with psoriasis *discreta*, four patches of which, covered with squamæ, not prominent, and of the form and size of a shilling, exist on the right side of the forehead. The squamæ are pulverulent, and have a slight yellowish tint; the skin under them is red, and the margins of the patches blend with the healthy integuments. There are also a few patches on the concha of the ear, and a great many more of a small size, circular shape, and covered with minute furfuraceous and yellowish-coloured squamæ, are discovered on the surface of the hairy scalp, more particularly on the right side near the angle of junction between the frontal and temporal bones. Many of these patches are confluent, and not very regularly circular. They are only affected with pruritus when the head is accidentally heated, and have not caused the loss of the hair. The rest of the body is unaffected with any similar patches, but a few solid elevations, already squamous on the summits, are visible on the arms. The whole of the principal functions are performed with regularity. (*V. S. ad 3xii; an ounce of Epsom salts, with intervals of two days, repeated sixteen times; lotions with water nearly cold, night and morning.*) The cure was complete towards the end of May, 1826.

CASE CXIV.—*Psoriasis discreta of the limbs; diffusa of the trunk*.

<sup>1</sup> Gazette Médic., 1832, p. 110.—Bull. des sc. méd. de Ferussac, t. xvii. p. 44.  
<sup>2</sup> Journ. Hebd., première série, p. 258 (psor. inveterata cured by the solut. of Fowler).—Journ. Hebd., t. iv. pp. 74-77; t. vii. p. 432; t. viii. p. 108.—Revue médic. Juin, 1830, p. 341 (employment of the chloruret of sulphur).—Lond. Med. Gazette (employment of nitrate of silver).—Lancette Française, t. v. p. 42.—Journ. des hôpitaux, p. 349.—Journ. complém. des sc. méd., t. xxxix. p. 45; t. xliii. p. 71.—Lond. Med. Gaz., v. xi. p. 278.

J. D. le T \* \* \*, seven years of age, was attacked with psoriasis in the month of June, 1826. A number of small elevations appeared on the arms and hands, but soon vanished again. Towards the end of August, of the same year, several of the papular elevations of psoriasis appeared on different regions of the body. (*Baths, anti-scorbutic syrup.*) This child was brought to me on the 4th of September, 1826. Two very broad squamous patches exist on the back of the trunk; one superiorly, between the shoulders, is entirely covered with squamæ; the second, inferiorly, and stretching almost completely across the lumbar region, is less thickly beset with squamæ, and presents indications, here and there, of healthy skin. On the shoulders and back of the neck, a few smaller patches also occurred; these were from three lines to half an inch in diameter, prominent, and covered in the centre with partially detached epidermic lamellæ. Under these squamæ the skin was dry, and presented a red colour which disappeared with pressure. Near the large lumbar patch several smaller ones were observed. The anterior part of the chest was almost entirely occupied with large squamous patches, between which appeared numbers of small islets of healthy skin. These patches, like the rest, were covered with dry, epidermic laminæ, rough to the touch; the corion beneath which was also of a red colour, which disappeared on pressure. A considerable number of patches of psoriasis *discreta* existed on the surface of the abdomen, divided by a broad but irregular squamous band which extended from the ensiform cartilage to the pubes. On the limbs various patches, of different sizes, and sundry papular-looking solid elevations, one or two lines in diameter, and slightly prominent, were distinguished. The patches were circular, red at their base, and covered on their summits with minute squamæ, which were not long of being detached. After their fall, the epidermis occasionally formed a little circle of a dull white colour around the place they had occupied, in the centre of which a red and prominent point was perceived. Various other compound patches, of very irregular shapes, were formed by the union of two or more of the papulæ or squamous rounds. Lastly, a few small patches, not more than from five to six lines in diameter, of a circular shape, and covered over with minute squamæ, of a white colour, and adherent or easily detached, were observed. Upon the face, and especially the forehead and parts about the outer ends of the eyebrows, there were a number of the papular elevations and squamæ of psoriasis *discreta*. (*Eight leeches to the band of healthy skin, between the two dorsal patches, emollient and narcotic temperate baths; the diluted sulphuric acid.*) On the 14th of September the good effects of the treatment prescribed were apparent in the cessation of an adventitious sero-purulent secretion which was going on from several of the patches, and by a slight degree of sinking in several of them. (*Leeches and baths as before.*) On the 21st the acid was renewed, and four leeches were applied under the ears, and seven to the region of the navel; the cutaneous inflammation was yielding gradually. 20th.—The skin is now in a great measure free from squamæ, and appears stained here and there of a reddish brown; no new squamous elevations were formed. (*Temperate narcotic bath; three drachms of Epsom salts in the morning; fasting every other day.*) October 8th.—There are now no visible traces of the squamous inflammation; the skin, however, still presents some reddish stains, on the surface of which the epithelium is smooth and shining.

CASE CXX.—*Psoriasis discreta. Lepra*. A young washerwoman, aged eighteen, was attacked without assignable cause with psoriasis *discreta*, in the beginning of the year 1826. The disease first appeared on the elbow and anterior aspect of the right forearm, next upon the opposite arm, and lastly on both of the inferior extremities and trunk. May 10th, 1826.—At this time there were observed upon the skin, 1st. A number of solid elevations, the size of millet seeds, red at their base, and covered on their summit with a minute scale of a dull white colour: 2d. Several papulæ which have been torn with the nails, and are covered with little brown-coloured scabs, the size of pins' heads, and exactly similar to those of prurigo: 3d. Various patches from three to four lines in diameter, flattened and red, and dry on the surface, which is covered with minute squamæ. When the squamæ are detached, the patches present a red-coloured central point similar to that they exhibited at their origin; the tint of this point in some of them is so deep that it approaches a violet. Other

patches are of much larger dimensions than these, and are of an irregular round or oval form; their edges, raised above the level of the surrounding integuments, are of a very deep red; the tint gradually diminishes in intensity from the circumference of the different patches, towards the centre, which looks slightly depressed, and of a rose colour, so that these patches resemble in every respect those of lepra. Several patches of a still larger size are extremely irregular in their outline, and evidently formed by the fusion of two or more into one. On the surface of these compound patches, a great many superficial furrows, similar to, but more conspicuous than, those naturally presented by the epidermis, are observed. The squamæ are very small, and very thin. The integument in the intervals between the patches is of singular whiteness and delicacy. The inflamed parts are affected with a pruritus, and sense of heat, of considerable intensity, which are always increased after meals, and during the night. The whole of the internal organs, particularly those of the digestive functions, appear to be perfectly healthy; the catamenia are regular, (*V. S. B. ad 3xii. Two drachms of sulph. soda in real broth; plain bath every other day at 27° R.*) May 18th.—The patches are less inflamed; the aperient does not distress the patient, and is ordered to be continued. 26th.—The papular elevations are much fallen; several of the squamous patches have vanished entirely, and others present two very remarkable appearances, being here reduced to complete rings, within which the skin looks healthy though somewhat sallow, there, to mere arcs of circles. The same plan of treatment was continued, and the cure was accomplished within six weeks.

CASE CXVI.—*Psoriasis palmaris; blisters.* A. B., aged forty-two, labouring under palmar psoriasis confined to the right hand. Various measures which had been recommended, failed to do much good, probably, from not having been regularly employed. Two flying blisters applied to the palm of the hand were followed by the detachment of the altered epidermis, and the formation of one that was smooth and permanent.

CASE CXVII.—*Psoriasis discreta of the limbs, diffusa of the elbows: calomel ointment.*—Fr. Chastel had been affected with psoriasis of the elbows, since the end of July, 1832. On the 14th of January, 1833, the disease had extended considerably along the dorsal aspect of the arms and forearms, these regions being occupied by two large patches, irregular in their outline, raised above the general level, furrowed by a great many linear chaps, and covered with squamæ of a dull-white colour, which could be readily rubbed off with the finger, when the red and prominent corion beneath was exposed. Patches of a similar description occurred on the lumbar region. On the outer surface of the thigh and knee, and on both of the forearms, the disease presented itself in a simple form, the patches being small, isolated, circular, and covered with dry white squamæ. The patient made no complaint of pruritus, or smarting, and the principal functions were regular. He was put upon the decoction of dulcamara, ordered to rub in the calomel ointment, and to take the plain bath. By the 20th of January, the good effects of this treatment were already very apparent; the squamæ were, indeed, still reproduced, but they were not so copious, not so white, and the corion under them, which at first was very red and prominent, now presented a pale rose tint. Half a pound of ointment containing one ounce of calomel had been rubbed in, and no symptom of pyalism was manifested. The same treatment was continued to the 1st of February, when the oily appearances of disease remaining were a few papular-looking eminences as large as pins' heads. The ointment was now discontinued in order that the effects of the dulcamara might be the better studied. The decoction was prepared with two ounces of the herb to each pint of water. After the lapse of a week this medicine seemed to have done no good; on the contrary, squamæ began to be reproduced in several places. A recurrence to the calomel ointment speedily brought about a notable improvement, which by the end of the month was still more evident. The dulcamara was given up and a gum-lemonade substituted for it; the plain water-bath was continued the whole time. The patient went on favourably; the skin, with the exception of a very small patch on the elbow, being quite free from disease. The vapour-bath was ordered in lieu of the simple water-baths hitherto used; and on the 10th of March the places mentioned were touched with the nitrate of silver. The eschars produced were

detached on the 19th, leaving the skin they had covered smooth and of a vivid red; this tint soon disappeared, and on the 1st of April the integument had recovered its natural colour. The patient was dismissed on the 8th of the month, well, having been forty-four days under treatment, during which time there had been expended in the way of inunction nearly five pounds of lard, containing ten ounces and six drachms of calomel, neither the salivary glands, the mucous membrane of the mouth, nor the gums having shown any symptom of irritation.

CASE CXVIII.—*General Psoriasis. Desquamation from the parts covered with hair.*<sup>1</sup>—James Shooter, twenty-nine years of age, entered St. Bartholomew's Hospital on the 14th of July, 1828, affected with rheumatism of the joints and a cutaneous disease. The patient had been affected eighteen years previously with a red or scaly eruption upon the thorax, which after two years was either cured or disappeared of itself. Seven years afterwards, another eruption of the same kind, but perhaps of less severity, made its appearance, and has continued since then to the present time. The scalp is entirely covered with minute whitish squamæ, which are readily detached by rubbing the hair or scratching the integument. This part is not red, but is very hard and immovable under the finger, and feels stiff and unyielding to the patient. The forehead is occupied by several patches of a reddish-brown colour, which project slightly above the general level. Several other patches occur which are covered with squamæ; these are readily detached and the subjacent skin is red; on looking narrowly into this region, it is seen to be covered with quantities of fine white squamæ. The face presents the same morbid appearances as the forehead; the skin is hard, thickened and stiff; the difficulty experienced by the patient in speaking, from this state of the integuments, is very perceptible. The ears and surfaces behind them are even more affected than the rest of the head; the squamæ are larger and more confluent, if the expression may be used, and the skin is redder here than elsewhere. The neck and breast, however, of all the regions are those that are most deeply affected; the skin, besides being covered with many squamæ, is extremely red, rough, chapped and very stiff. In moving these parts the patient complains of a very unpleasant sensation produced by the dryness and stiffness of the integuments. The other parts of the body present the same morbid alteration in various, generally inferior, degrees of intensity. On the backs of the fingers a number of small isolated and perfectly circular squamous asperities, traversed in the centre by a hair, are perceived. The skin thus beset is extremely rough to the touch, and feels like a file. The asperities only occur in situations furnished with hair, that is to say, in the middle of the dorsal aspect of the first and second phalanges. By detaching them from the skin by means of a pin, the projections are found to be owing to an agglomeration of squamæ, looking like minute grains, within the epidermic prolongation that surrounds each hair. The patient had often plucked out the hairs thus surrounded, but the asperities always grew again with the hair. The roots of the hairs of the arms presented the same appearance, but in a very superior degree. A blister was applied to the surfaces thus affected, but failed to excite vesication. The patient was bled several times, and to a large amount; he only appeared to derive signal relief from the first venesection. (a)

(a) *Psoriasis inveterata. Arsenical treatment successful.*—"Sarah Partons, ætat. twenty, of lymphatico-sanguine temperament, being stout, rather pale, with gray eyes and light brown hair, came under my care on the 12th January, for psoriasis of the legs, arms, knees, and elbows, of thirteen years' standing. Her father and brother (who are now under my care) labour under the same disease. There are a number of patches of psoriasis, varying from the size of a sixpence to that of a crown piece, about both legs and arms, and a few on the back. Immediately below the left knee there is one as large as the palm of the hand, and the points of both elbows, but more particularly the left one, are covered by thick scaly incrustations, extending some way down the posterior aspect of the forearm. The diseased patches were in a very indolent condition, there being no inflamed areola about them, and being unattended by any tingling

<sup>1</sup> Communicated by Mr. Tarral.

or itching. The general health was good, and there were no dyspeptic symptoms of any kind. As the disease was of such long standing it had been subjected to a great variety of treatment, and she had been a patient at two of the metropolitan hospitals, at one for a period of eight months, without receiving any benefit. I therefore, as she was very anxious for a cure, determined to try at once the effect of arsenic, and accordingly ordered her two and a half minims of the solution of the arsenite of potassa twice a day; the biniodide of mercury ointment diluted with three pints of ung. cetacei, to be rubbed into the diseased patches night and morning. The quantity of the solution of the arsenite of potassa was gradually increased until the 27th, when she was taking seven and a half minims three times a day. By this time the diseased patches on the arms, and some of those on the legs, had been cleared of their scales; the affected skin was, however, redder than natural, and rapidly covered itself with scales of epidermis if the use of the ointment was interrupted. On the 28th some constitutional derangement, as headache, lassitude, pain in the eyes, and thirst, came on: the solution was accordingly discontinued. On the 4th February it was resumed in doses of five minims three times a day, which quantity was continued without any disturbance, either local or constitutional, until the 10th March, when, as the disease appeared to be entirely cured, with the exception of a red stain as it were, of the skin in the site of the affected patches, the dose of the solution was diminished to three minims, which quantity was continued, in order to prevent a relapse, until the end of the month. The ointment of the biniodide of mercury had been persevered in during the whole of this time, its strength having been increased to equal parts of the ointment of the pharmacopœia and of spermaceti cerate." Mr. Erichsen—(*Med. Gaz.*, 1843.)

*Psoriasis of the neck and back: chronic rheumatism. Cure of both diseases by liquor of hydriodate of mercury and arsenic.*—"Lawrence Keane, ætat. forty-six, an old sailor, of a sallow complexion, with dark hair and eyes, placed himself under my care on the 17th January last, for psoriasis of the posterior part of the neck and back, under which he had been labouring for the last four years. He states that, having been shipwrecked about twenty-four years ago, he was attacked with acute rheumatism, since which time he has never been free from pains in his limbs. I ordered him twenty minims of the solution of the hydriodate of arsenic and mercury three times a day, and a lotion of the bichloride of mercury to wash the affected parts with. On the 28th he had the dose of the solution increased to thirty minims, and on the 15th of February he was perfectly cured of the disease of the skin, the rheumatic pains, from which he said he had not been free for twenty-four years, having ceased entirely for some time past. Since this date I have several times seen him, and he continues perfectly well in every respect."—*Ibid.*

*Psoriasis inveterata with eczema impetiginodes cured by the sulphur vapour bath.*—"The subject was a gentleman about forty years of age, who from his boyhood has been afflicted with a most inveterate cutaneous disease, but from which he is sometimes quite free. His parents were not known to have had any skin disease, and he has no clue to enable him to account for its origin. When this gentleman was first subjected to the employment of the bath, he was unable to walk; his legs, from the toes to the middle of the thighs, were incased in a thick scab, with long deep fissures, from which issued an abundant ichorous discharge. The thighs above this were studded with impetiginous pustules, the sacrum, gluteus muscles, and part of the lumbar region, were likewise covered with scab containing deep cracks. The arms and axilla on one side were covered with large patches of scab, all discharging the same kind of fluid. He was obliged to move with great caution, lest he should extend these cracks, or occasion fresh ones, which were always attended with much pain and inflammation. He had been in the habit of taking and persevering in the use of medicine, but was not aware that he derived much benefit from it.

"He was directed to take three emollient vapour baths, and afterwards to persevere daily in the use of the sulphureous fumigating bath, and to take occasionally opening medicine. After the third fumigation, the amendment was evident, and he expressed himself much more comfortable in his feelings; he continued them for a fortnight with regular progressive improvement. At the expiration of a

## PITYRIASIS.

Vocab. *Dandriff, Pityriasis, Porriigo.*

694. Pityriasis is a chronic and non-contagious inflammatory affection of the skin, characterized by the evolution of red *points* and more frequently of red *spots* or *patches* from which a *mealy* or *foliaceous* desquamation soon commences and continues till the disease is either cured or gets well spontaneously.

This affection may make its appearance within a short space of time upon almost every part of the body in succession, (*general pityriasis*), or remain confined to any one region in particular (*local pityriasis*).

695. *Symptoms.*—General pityriasis is one of the least frequent and most obstinate of the diseases of the skin; it almost always invades without precursory symptoms; patients complain, in those regions that are about to become affected, and most commonly in the extremities, of a violent feeling of itchiness, or rather of a painful and tantalizing prickling sensation, which seems to have its seat under the skin, between it and the flesh. If the part thus affected be examined, and it chance to be without hair, a number of very superficial *erythematous blotches* are perceived. The heat of the surrounding integument is almost uniformly increased, the subcutaneous cellular tissue is swollen, sometimes painful when pressed upon, and the soft parts generally seem to suffer from distension. It may be difficult to demonstrate this primary redness when the scalp is the part affected; but the phenomenon is always abundantly evident on other regions of the body when looked for early enough. Within a few days the blush diminishes in intensity and soon disappears entirely; the epidermis then cracks, becomes less adherent, and a process of desquamation commences which varies in its characters according to the nature of the surface affected. On the outer surfaces of the legs and arms the cuticle is thrown off in foliaceous lamellæ, which continue to adhere for some time, in one case by their centre, in another by either of their extremities, so as to appear floating, as it were, on the surface of the skin. These lamellæ, formed by the cuticle nowise

month, the arms and axilla were well, and the scab on the legs was now only in patches, the left leg being much the best. There now came on a fresh accession of disease, showing itself in pustules with yellow heads a little above each inner ankle; higher up there were numerous small vesicles containing clear lymph; some other parts of the legs still, however, went on improving, and the fumigations were continued; this accession was not of long continuance, but scabbed over, healing underneath. He now complained of heat and itching in the face, particularly about the chin; he had slight feverish symptoms, for which he was directed a dose of the submur. hyd. and some saline medicine: he became relieved: *achores* made their appearance and gradually spread over the lower jaw, containing yellowish matter, forming scabs, with surrounding inflammation. To this part he pretty constantly applied flannels wrung out of hot water, and covered it with a bread and water poultice at night: there was no cracking of these parts, but much watery discharge.

"He had used the fumigations daily six weeks; he now complained of stiffness, itching, and redness in the left groin. On examination, the inguinal glands were enlarged, hard, and painful to the touch; as the swelling of the glands subsided, the redness increased, and he had intertrigo, which became very troublesome to him. A space the size of a large dollar next made its appearance on the right clavicle, near the humerus, of a bright threatening aspect, and a smaller spot of the same appearance showed itself on the left clavicle, both itching very much, and with moist exudation; these spots in forty-eight hours became joined by an inflamed line about an inch broad, hanging, as it were, like a necklace: round the larger spots there came many small-sized pustules with yellowish matter in them; these did not extend; the large spot gradually became whiter in the middle, extending to the edges, disappearing slowly, leaving a shining, smooth red surface, which, with the connecting line, gradually went away: of the intertrigo he was not quite well when business called him into the country. The legs, back, and arms were quite well: the gentleman used the bath seven weeks."—*Ibid.*

thickened, vary from about three to eight lines in diameter. Those parts of the skin from which they have been recently detached or from which they have been removed by the action of the nails, the rubbing of the clothes, &c., are usually of a rose colour; further, when patients have yielded to the impulse to scratch, occasioned by the violent pruritus which accompanies the disease, the parts of the skin which have recently shed their cuticle pour out a serous, yellowish-coloured fluid, similar to that observed in the moist eczemas, and occasionally so abundant as completely to soak the linen or other clothing with which the parts affected happen to be covered. When this adventitious circumstance occurs to such an extent, it is apt to render the diagnosis of pityriasis obscure.

Pityriasis is generally less severe on the insides of the limbs, and the desquamation then always consists of smaller laminae of the cuticle; it is often, indeed, pulverulent. Behind the ears, about the clavicular fossae, the axillae, bends of the arms, wrists, navel, prepuce, groins and insteps, the inflamed skin has something of the look of intertrigo, that is to say, it is rough, moist, and slightly chapped in the direction of the natural folds of the skin which are powdery on their edges. On the anterior part of the breast and belly the desquamation always occurs in much smaller lamellae than on the posterior surfaces of the trunk. On the regions of the olecrana and patellae, and especially on the palms of the hands and soles of the feet, where the cuticle is naturally thicker, the exfoliation takes place in broader and thicker laminae than elsewhere; on the face and hairy scalp, on the contrary, it is almost uniformly powdery in its appearance.

Pityriasis is accompanied with violent pruritus, especially of those parts where the eruption is recent, and of those where it is accidentally exasperated; the symptom then gains such a degree of intensity that the sleep is disturbed, and is only changed into a sensation of the most distressing kind by the efforts of the patient to allay it by scratching; the satisfaction, however, the enjoyment experienced by yielding to the impulse, is described by patients as surpassing every other they have known. After the state of excitement or exaltation thus induced, has passed away, patients experience smarting sensations of considerable violence, and fall into a kind of dozing state which is frequently followed by sleep.

As to the principal functions, they are not in general very remarkably disturbed; yet it does occasionally happen that patients, labouring under extensive pityriasis, present functional disorders of the digestive organs. I have seen all the symptoms of chronic inflammation of the mucous membrane of the stomach and bowels under such circumstances, and remember one case in which the severe suffering occasioned by acute pityriasis extended to the whole surface of the body, and the repeated serous evacuations that took place from the bowels even proved fatal. Amenorrhœa is occasionally observed to precede or to follow an attack of pityriasis. I have never observed any thing like a true febrile paroxysm except in those cases in which the eruption broke out over almost the whole surface of the body at once, or at those times when the disease seemed to increase in severity, or otherwise, when an inflammatory affection of the intestines was superadded to the pre-existing malady.

The continuance of the symptoms of *general* pityriasis, and their mode of succession and increment, are subject to numerous shades of individual variety. The disease is frequently seen arising in situations where it never before appeared, at the same time that it is vanishing upon others where it had appeared fixed for a great length of time. The very appearance of the disease, indeed, is modified by these same circumstances: powdery or scaly, as in slight ichthyosis, upon those points where the inflammation is declining but still lingers in a trifling degree, of a vivid red and moist upon those where the inflammation has been accidentally increased, whilst in those places where desquamation is no longer going on, the skin has a white and slightly yellowish tint.

The cellular membrane is more or less tumefied in those places where the inflammation possesses some acuteness, and in the lower extremities, even when there is little apparent redness under the squamæ. When the disease extends to the greater portion of the surface, patients can generally gather a considerable quantity of squamæ from their beds every day. Lastly, when parts provided with hair are attacked, the disease causes its partial fall.

696. I have already mentioned the principal varieties of appearance presented by pityriasis occurring on different regions of the body. The better to expose the characters of the local varieties of this disease, however, I here add a few particulars connected with each:—

1st. *Pityriasis capitis* is, of all these varieties, the most frequent and that which has been longest known; it has, however, been often confounded with the desquamations consequent on psoriasis, lichen, and eczema, and with those which take place without inflammation from the scalp in some individuals.

Individuals attacked with *pityriasis capitis* suffer habitually from a considerable itching of the scalp, especially on the first attack of the disease, and at the period of subsequent exacerbations; they are then led to scratch or rub the head with different degrees of force, when a whitish powder is detached, consisting of minute epidermic squamæ. The secretion of these goes on continually, and a quantity may at all times be detached by rubbing with the hand, or the action of a brush. By separating the hair in different places, numbers of small, red, irregular, and very superficial patches may be discovered under the squamæ, disseminated over the surface of the scalp. The skin on these points is shining, dry, and rough to the touch. The red patches, it is to be observed, are only very distinct in those places where desquamation has but recently been established; after having been long affected, instead of being red, the scalp becomes, on the contrary, of a rather dull white in the places affected.

It rarely happens that the inflammation reaches a very high degree of intensity in this variety of pityriasis. I have, however, met with some patients who complained of a feeling of stiffness and tension, of burning heat and insupportable pruritus in the hairy scalp. When this is the case, besides the ordinary attendant epidermic desquamation, there is almost always an exudation of a thin but glutinous fluid, similar to that secreted by surfaces affected with eczema. This matter agglutinates the hair and squamæ into masses, and when the disease continues in this state for a month or two, the head looks as if it were covered with a gray or whitish cap, composed of the hair and an abundance of squamæ matted together, the superficial layers of which, drier and more friable than those that are deeper, have the greatest resemblance in point of colour to the mineral named asbestos (*teigne amiantacée*, Alibert). When an attempt is made to isolate the particular hairs, they are found buried as it were and lost amid scaly masses; and if, by means of pretty strong pulling, a few locks be separated from the mass, they are so strongly agglutinated, and so much mixed up with squamæ, that they still form stiff bundles only to be divided into others of smaller dimensions: the individual hairs can only be separated from each other with extreme difficulty. When the hair is clipped off pretty close to the scalp, after having been softened by means of poultices and fomentations, the skin is found of a rather vivid red on numerous points. The hair is only found detached from a spot here and there: baldness forms no feature in this disease, in which *pediculi* are also much more rarely encountered than in favus.

Whether *pityriasis capitis* consists of a mere furfuraceous desquamation, or of the abestous cap that has been described, it may in either case extend to the eyelids, and occasion the fall of the eyelashes. In young children the disease is most commonly seen on the upper part of the forehead and temples; in the aged it frequently extends to the eyebrows, and when severe, almost uniformly spreads to the face and different other regions of the body. *Pityriasis capitis* is a disease that always lasts long; it may exist for months and even for years. It is known to be approaching amendment when the secretion of furfuræ becomes less copious, and when the serous exudation, when it has taken place, no longer goes on. A new, smooth and shining epidermis is formed when the recovery is complete.

697. *Pityriasis palpebrarum* may also exist alone, and independently of any anterior manifestation of the disease on another region. The only peculiarity presented by this variety is the frequency with which it causes the fall of some of the eyelashes, and the propagation of the inflammation upon the conjunctiva, it differs, and may be distinguished from psoriasis developed on the same parts, by the erythematous look of its patches and flimsiness of its squamæ, which contrast strongly with the papular elevations that announce the development, and the thick squamæ that afterwards characterize psoriasis.

698. *Pityriasis labrum*, is a variety that has hitherto been confounded with psoriasis, a disease, however, from which it differs in being evolved on the lips and surrounding skin, not as papular elevations, followed by thick squamæ, but under the semblance of minute red stains, to which succeed a general redness and a continual desquamation of the epithelium of the lips, and occasionally of the cuticle of the neighbouring skin. The desquamation goes on in the shape of little thin and transparent laminae, very similar to portions of the healthy epidermis dried, or of the epidermis whose inner surface has imbibed a little serum previous to its desiccation. The lips, in this state, are affected with heat and tension: the epithelium gets yellow and thickened, it then cracks, and falls off in laminae of considerable size. It frequently happens that these continue to adhere for some time by their centre, when their edges are loose and already dry, so that a new epidermis is formed under the one about to be detached before it falls; this new cuticle then grows yellow, cracks, peels off, and falls in its turn, to be succeeded by another which undergoes the same changes and shares the same fate. This is always a long continuing and obstinate affection; every now and then it gets worse than usual, when the lips look swollen and of the brightest red. It is very different from that transient inflammation to which the lips are subject, attended with chapping and the detachment of the epithelium, which is induced by exposure to cold, or happens as a consequence of different acute diseases; this slight affection soon passes, whilst true pityriasis is always a lengthy and troublesome disease. The causes of *pityriasis labrum* are frequently obscure; I have observed it in two individuals, great talkers, who had a trick of always biting their lips.

699. *Pityriasis palmaris* and *plantaris* are varieties which have hitherto been confounded with psoriasis affecting the palms and soles. The two diseases, however, may be distinguished by the following circumstances: Psoriasis begins in the shape of papular-looking elevations, the summits of which are soon afterwards covered with dry squamæ of a dull white colour; pityriasis, on the contrary, commences as small red spots or stains, irregular in their outline, which spread, and before long acquire a yellowish hue, probably in consequence of a slight exudation from the corion, which thickens the epidermis, by penetrating its inner surface. The epidermis then dries, cracks, and is constantly peeling off in foliaceous lamellæ; this exfoliation may extend to the fingers, and even take place under the nails, which are then occasionally detached. The skin almost always appears bathed in perspiration around the diseased points, which, on the contrary, are uniformly dry. I once attended a patient in whom this squamous affection appeared in the soles of the feet, a year after having attacked the palms of the hands. The heel and anterior part of the sole of the foot were painful when the erect posture was assumed, and during the act of walking.

700. I have observed the *inside of the mouth* affected with chronic inflammation and habitual desquamation of the epithelium, especially about the base of the tongue, without any antecedent or concomitant affection of the pharynx, stomach or lungs,—*pityriasis oris*. This state continued during five or six years with but brief intermissions, the principal functions being all the while performed with great regularity. At the time a desquamation of this kind was going on, one patient complained of heat, and often of painful sensations, difficult to define, in the interior of the mouth. In a woman who was similarly situated, almost the whole of the mucous membrane of the mouth was habitually of a grayish-white colour, and when the epithelium was thrown off from the tongue, its surface presented several patches of a bright red colour, which continued until the investing membrane was either formed anew, or again rendered thick and opaque.

701. The *prepuce* in the male and *labia majora* in the female are also occasionally the seat of superficial chronic inflammations which cause exfoliations of the epithelium, and an increase in the secretion of the follicular fluids; several of these affections in their course, their principal phenomena, and their rebellious character bear a singular affinity to pityriasis.

702. *Causes*.—*General* pityriasis is happily a disease of rare occurrence; I have observed it more frequently among women than men; patients are commonly altogether at a loss for any cause to which they can assign their disease. The causes of *local* pityriasis are also,

for the most part, very obscure. It appears occasionally to be excited among men by the action of the razor on the chin. The repeated action of a rough comb or hard brush may possibly conduce to its development on the hairy scalp.

703. *Diagnosis*.—The natural exfoliation which frequently takes place from the skin of the infant, a few days after its birth, is of too short a duration, and appears under circumstances too particular to be confounded with pityriasis. The *scurf* of the scalp, often observed at the period of birth, is formed by a hard, yellow, and friable matter deposited on the anterior and upper part of the head, and bears a much stronger resemblance to an incrustation than to an exfoliation of the epidermis. This scurf, indeed, continues without any appearance of desquamation for many months, unless it be got rid of by the aid of fomentations or other applications that soften and permit it to be removed; it no more consists, in fact, of the epidermis, altered and dried, than the scurf which is sometimes observed on the scalp of elderly individuals negligent of personal cleanliness.

The skin of the scalp and of the extremities in some adults, and especially in some aged persons, is occasionally affected with an *habitual exfoliation* of the epidermis, which differs essentially from pityriasis by being attended with neither redness, heat, nor any other morbid sensation. Certain desquamations of the epidermis, also, which follow acute diseases, differ essentially from pityriasis in their origin and transient nature. The desquamation, or rather the exfoliation of the cuticle that happens in pityriasis, differs in its character from that formation of squamæ which takes place in all the varieties of psoriasis, inasmuch as the cuticle, in the latter disease, is thickened, dry, rough and of a dull white colour. But the feature that distinguishes these two diseases from each other, more than any other, is the circumstance of the red patches of psoriasis always rising above the level of the general integument, whilst those of pityriasis are not at all prominent. Further, when the inflammation runs very high in pityriasis, the skin, especially when scratched, is very apt to pour out an abundant serous secretion, whilst in psoriasis it always continues dry. Lastly, in *acute* pityriasis the subcutaneous cellular tissue is often swollen and painful over a large extent of surface, a circumstance which never happens in psoriasis *discreta*, and which, in psoriasis *inveterata*, is only observed to occur in limited spaces. The heat and pruritus that accompany pityriasis are, moreover, much more troublesome than the same phenomena in psoriasis; and pityriasis, when general, is much more frequently complicated with symptoms of constitutional disturbance and derangement of the digestive functions than psoriasis.

When pityriasis is compared with lepra the same points of difference are detected, with two distinguishing features in addition; the circular form of the patches of lepra, and their mode of recovery from the centre towards the circumference. The detachment of the cuticle in ichthyosis is not preceded by redness or morbid sensations of the skin. The desquamation that follows chronic lichen and eczema is preceded by the evolution of papulæ and vesicles. I shall by and by have occasion to contrast pityriasis with acrodynia and with pellagra, but I must here pause to expose the characters that distinguish it from chloasma (*pityriasis versicolor*, Willan), and from melasma (*pityriasis nigra*, Willan), diseases which I have felt called upon to transfer to another order, that, namely, of the adventitious *pigmentary discolorations*. In the first place, the most striking feature in the two diseases, last mentioned, is undoubtedly the change of colour presented by the skin; further, if some degree of desquamation does take place at one period in the progress of these diseases, an habitual and abundant exfoliation of the cuticle forms no point in their history. Neither is there any of that serous exudation which I have mentioned when speaking of acute pityriasis; lastly, the ease with which chloasma is cured, and the deplorable resistance of pityriasis, in almost every instance, to remedial measures of every kind, show an essential difference in the nature of these two diseases. As to melasma (*pityriasis nigra*, Willan), when desquamation has once taken place, it seldom happens that this phenomenon and the other symptoms of the disease return with any intensity, or prove of any duration (*Vide* Chloasma, Melasma).

704. *Prognosis*.—*General* pityriasis is one of the most obstinate diseases of the skin. When the inflammation extends to the lining

membrane of the internal passages, it always proves, like that affecting the outer integument, very rebellious; in one case I have even seen it end fatally. The whole of the *local* varieties of pityriasis, particularly that of the lips, are constantly very difficult of cure, and are subject to frequent returns.

705. *Treatment*.—When, in *general* pityriasis, the exfoliation from the epidermis is great, and when the skin looks vividly red and pours out an abundant serous secretion from various places, when the subjacent cellular membrane is swollen and the heat of the surface is increased, blood-letting, combined with the temperate mucilaginous bath, the antiphlogistic regimen and diluents, seldom fails to give considerable relief, at least for a season, a circumstance, however, which should not induce the neglect of this, the most important of these measures, when the patient appears able to stand it. The inflammatory affections of the bronchi, bowels and genital organs which occasionally make their appearance in the course of pityriasis, and especially at the periods of its paroxysms, are also relieved by the detraction of blood; but they do not yield with the same readiness to this practice as the inflammation which is induced in these parts by external and appreciable causes. It would therefore be wrong to attempt to cut short these inflammations by the severest antiphlogistic means and repeated blood-letting. After a first or a second bleeding, which may have been very decidedly beneficial, a third generally appears to have no influence in modifying the disease: it is even seen occasionally to return with all its original violence a few days after a freest use of the lancet. Another circumstance which ought to be noted is that the blood is often buffy in this disease, and continues so, unmodified by repeated venesections, during its whole course.

In *acute general* pityriasis, *opium* is often employed with advantage to procure sleep and lull the pruritus and heat of skin so much complained of; this is also one of the best medicines we possess for combating the obstinate diarrhœa that occasionally comes on in the course of the disease. Purgatives and the preparations of *arsenic* cannot be prescribed with the same propriety in this as in the generality of the squamous inflammations, pityriasis being much more frequently associated with gastro-intestinal disturbance than any one of them, and this is a state which these medicines are apt to induce, and one which they would certainly aggravate did it already exist. Simple baths, emollient topical applications, and the vapour-bath prove more generally useful than the sulphureous or alkaline bath, both of which are contra-indicated when the skin is of a vivid red and the subjacent cellular substance is painful and swollen. When the skin, however, scarcely looks coloured under the epidermic lamellæ, the vapour-bath and douche may be administered with advantage. But it is with *general* pityriasis as with almost the whole of the chronic diseases of the skin that are independent of appreciable causes,—a solid and enduring cure is only to be obtained by a general change of the constitution, brought about by dietetic means long and regularly pursued, effected naturally by the progress of years and the modifications undergone by the organization, or accidentally induced by some intervening disease, such as measles, scarlatina, &c.

The *local* varieties of pityriasis frequently prove very rebellious also; yet that of the hairy scalp of infants at the breast occasionally gets well spontaneously or by mere attention to cleanliness, after several months continuance. The variety of pityriasis *capitis* which attacks adults and the aged, and is characterized by a simple powdery exfoliation of the epidermis and pruritus, without serous discharge and matting of the hair, only requires attention to cleanliness, and the application from time to time of some soothing unguent. The severer variety, however, which occasionally occurs along with general pityriasis, but which may also exist alone, and is denominated *teigne amiantacée* by French writers, requires more active treatment. After having softened the mass of dried exudation, hair and squamæ, by means of poultices, vapour-baths, &c., the hair must be clipped off as near to the skin as possible with scissors curved on the flat. The vapour-douche must then be continued, and may be alternated with alkaline lotions; purgative medicines should next be cautiously tried; and whenever symptoms of excitement appear, when the scalp becomes of a bright rose colour in several places, and appears moistened with a serous exudation, leeches should be applied behind the

ears. In a case of pityriasis of the lips, I have detailed the routine of treatment usually pursued. The white precipitate ointment and vapour-douche are the means which have generally appeared to me most efficient in curing pityriasis of the palms and soles. Pityriasis of the mouth, nipple and genital organs have as yet been too little studied to admit of any thing like a satisfactory view being given of the value of therapeutic means in regard to them. (a)

#### *Historical Notices and particular Cases.*

706. The Greek physicians have rather hinted at than described *pityriasis*. Galen<sup>1</sup> entitles those persons *πυρράδες*, *furfurosi*, *quibus asidue furfures in capite gignuntur*. Alexander Trallianus, and Paulus Ægineta<sup>2</sup> tell us that *pityriasis* consists of slight or furfuraceous exfoliations of the epidermis. Several of the translators of the Greek writers have Latinized the word *pityriasis*; others have rendered it by *porrigo*, and have thus committed an error which they might have avoided by translating *pityriasis* by *furfures*, *capitis farrea nubes* as Quintus Serenus Sammonicus had already done. Celsus, in truth, having under the title of *porrigo* comprehended several diseases frequently evolved on the hairy scalp, which were described at a later period under the common name of *tinea*, the word *porrigo* from this time forward occurs with two different meanings attached to it; by some, such as Lorry and Jos. Frank, it is used to indicate the pityriasis of the Greeks: “Desquamatio epidermis nullo prævio aut præsententi cutis vitio originem debens, relicta abnormi pellis subjacentis conditio *Porrigio* dicitur” (J. Frank); a definition in which various epidermic exfoliations, independent of an inflammatory cause, are evidently included; whilst others, Willan, Bateman, &c., have used the word *porrigo*, in the acceptance of Celsus, to designate the diseases very commonly entitled *tinea*, and which are but varieties of *impetigo*, *favus*, &c., induced by peculiarity of situation. The *alvarati* of Avicenna appears to correspond to the pityriasis of the Greeks:—“Est, modus excorticacionis levis accidentis capiti propter corruptionem accidentem in complexionem proprie cum impressione in superficie cutis.” Alibert has given a representation of pityriasis under the title of *dartre furfuracée volante*. Willan, as I have already had occasion to mention, has described under the names of *pityriasis versicolor*, and *pityriasis nigra*, two alterations of the pigmentary body which I have detached from this group. Jos. Frank, in his description of *porrigo*, has included the *pityriasis palmaris*, *scrotalis*, and *diffusa* of Willan. Other writers have described, under the name of *pityriasis* or *porrigo*, the furfuraceous desquamation consequent on lichen of the face, &c. These various meanings attached to the word *pityriasis* have caused no small amount of confusion in the writings of authors otherwise commendable.

There is a case detailed by Marcellus Donatus,<sup>4</sup> and quoted by Schenckius, which appears to be one of general pityriasis. The case published by Hoepfner<sup>5</sup> also appears to me to correspond to this disease; and yet the changes undergone by the skin on different parts of the body in this case bore a different appearance from those commonly observed in *pityriasis*; thick and yellow-coloured incrustations, for example, are stated to have occurred in some places, and in others red and excoriated patches, sprinkled over with reddish points, appearances very similar, therefore, to what are seen in *impetiginous* eczema. Forestus<sup>6</sup> and Mercurialis<sup>7</sup> have treated at considerable length on *pityriasis* or *porrigo*. Roederer<sup>8</sup> has published a dissertation upon

(a) In the chronic stages of *pityriasis*, the treatment will differ but little from that recommended in *psoriasis*; and the various remedies recommended in the latter, may be had recourse to in the present disease. My favourite wash of the fluid chloride of soda, will be found one of the best topical applications.

this subject which I have had no opportunity of consulting. Several observations on pityriasis are to be found in different periodical publications.<sup>1</sup>

CASE CXIX.—*General pityriasis; complications.* Martha Mullet entered the Hôpital St. Antoine, January 19th, 1828, on account of rheumatism confined to the joints of the right foot, and while there was attacked with a squamous inflammation of the skin. The catamenia had disappeared in the 48th year of the patient's age, without any unpleasant symptom. In the course of the month of February the skin of the face was observed to be the seat of a number of small red spots or stains, which speedily became covered with minute squamæ, and the affection spread so rapidly that within a few days it had involved a very large portion of the trunk. The disease began in the points corresponding to the follicular eminences, as very small solid red elevations, the bases of which were surrounded by a narrow rosy circle; the skin of the parts affected acquired, in this way, a general rosy tint. These elevations were soon covered on their summits with a very small, thin, and whitish scale, which was readily detached. Some redness remained even in those parts where the eruption was of oldest standing, and there the heat of the surface was sensibly increased; generally, however, it was almost entirely concealed by furfuræ of a dull white hue, which in several places even formed a layer of some thickness, the external surface of which was detached in the form of powder. The arms at the same time, became affected in a similar way, especially on their outer aspects, where the squamæ were from four to five lines in diameter, much larger than those of the back, and of a more regularly rounded figure. The scalp, also, and those parts of the face which had escaped in the first instance, were affected, by and by, with an eruption of red spots which were succeeded by squamæ. The backs of the hands, and those parts upon which the body rested, when laid horizontally on the back, the usual posture of the patient, became covered with squamæ of great comparative thickness, under which the skin was of a more vivid red than on any other point. On the knees the appearance of the eruption was nearly similar, only the squamæ were even thicker; they also projected slightly, and the portions of the integuments they covered were of a still more fiery tint than elsewhere. Several months afterwards the desquamation extended to the points of the fingers, the exfoliation taking place there in large flaps, the whole cuticular covering of the pulps being thrown off in a single piece; under the nails there remained for a very long time a substance of a yellowish-white colour, which by scraping was detached in the form of furfuræ. The different appearances that have now been detailed continued without remarkable change till the month of December, when the cold, rather than the medical treatment, seemed to produce some slight improvement. The squamæ and hair, however, became matted together by means of a glutinous exudation, and acquired a glistening appearance like *asbestos*. The hair, when parted in different places, showed the surface of the scalp of a vivid red colour, and beset with a multitude of minute orifices whence the serous agglutinating fluid was discharged. The patient, since the commencement of the disease, has had repeated attacks of profuse leucorrhœa, of colic and bronchitis.

Mild diluents and blood-letting caused some diminution in the redness of the skin and pruritus, with which it was affected; but these phenomena re-appeared within a few days in their original intensity. The salt-water-bath, repeated six times only, seemed but to cause a greater degree of irritation, a more vivid tint, and increased heat of the surface. The tincture of cantharides, in doses of no more than three drops, continued for three or four days successively, occasioned so profuse a diarrhœa, attended with tormina to such a degree, without appearing at all to influence the disease of the skin, that antiphlogistics were immediately resorted to anew, and these seemed to do some good. Gelatinous baths were now prescribed, but without effect; one of the regions was touched with the nitrate of silver, but this application did no good. Arsenic was tried, as a last resource, and the solution of arseniate of soda was prescribed in doses of ten drops, gradually increased to half a drachm; but after the third dose of the latter amount the patient complained so violently of pains in the bowels, and showed so many symptoms of gastro-enteritis that this medicine was abandoned also. The cold of the month of De-

cember was the only thing that seemed to do any good; the disease has since remained unmitigated, and will probably continue so indefinitely.

CASE CXX.—*General pityriasis. Chronic enteritis.* Madame D\*\*\*, aged sixty-one, of good constitution, born of healthy parents, and herself the mother of six lively children, was always very regular until the age of forty-eight, when the catamenia disappeared entirely. Two years afterwards the patient had first a violent pain in the left knee, and within two days perceived a vivid redness, attended with extreme itchiness in her left groin, from the skin of which the cuticle soon began to crack and be thrown off. This disease of the integuments spread rapidly, and ended by implicating the whole body except the palms of the hands and soles of the feet. In this state the disease continued for six years; it then improved, and ultimately got well under the use of the warm-bath and diluents. Within a year, however, the patient had a relapse. Bathing and leeching did no good now, and Madame D\*\*\* entered La Charité, March 3d, 1834, labouring under general pityriasis, which had already continued for upwards of three years. At this time the lower extremities were hard and swollen, pitting under the pressure of the finger. They were covered, principally on their outer aspects, with largish squamæ, which were readily removed by simple friction. The parts of the skin that had been freed in this way, looked red, and a plentiful serous exudation, similar to that of eczema, began to be poured out. On the arms, the same state obtained, the squamæ being very large on the outer aspects of the limbs. On the abdomen, desquamation in a less degree was going on, the squamæ being furfuraceous; on the loins, however, they were as large as on the extremities. The forehead was the part of the face most severely affected; the ears were also covered with squamæ, and quite moist from the abundant serous secretion. The patient suffered greatly from a feeling of heat in the whole surface of the skin, and of a pruritus that occasionally became excessive; she then scratched herself severely, deriving the utmost enjoyment from the operation, after which the skin became extremely red, and poured forth an abundance of the serous fluid.

This patient had, in addition, long suffered from diarrhœa; her colour was pale and sallow; in other respects she was well. Simple bathing, the vapour and sulphur bath, the nitric acid, decoction of dulcamara, blisters, and blood-letting, both general and local, modified the state of the skin in some slight degree: the desquamation became less abundant; but when the patient was discharged on the 8th of May, she was still suffering from diarrhœa, which neither regimen nor opiates had been able to check, and on the whole the disease of the skin remained much in the same state as it was when she entered.

CASE CXXI.—*General pityriasis; diarrhœa; subcutaneous abscesses: death.* Marie Paul, aged twenty-two, had long been subject to a *tetter*, which every now and then assumed the acute type, and principally affected the parts behind the ears and the bends of the arms. Some time in the month of July 1831, the patient had to contend with serious moral afflictions, and shortly afterwards she observed that the whole surface of her body had become red, and was affected with a desquamation incessantly renewed. The digestive functions were disordered at the same time, and the patient felt generally unwell. On entering the Hôpital de la Charité on the 27th September, 1831, almost every part of the surface was found affected with pityriasis; the face is entirely covered with the eruption; but around the ears and eyelids, which have lost their ciliæ, and are inflamed on their edges, the skin is red and moist, and the disease there presents the characters of acute eczema, without a trace of desquamation; from the cheeks, on the contrary, the epidermis is detached in flaps of extreme thinness, and of different sizes, exposing a smooth and slightly moist surface. The skin of the neck only looks cracked transversely in different places. On the arms, breast, belly, thighs and legs, a nearly similar state of affairs obtains: the epidermis is incessantly falling off in irregular shreds, which are transparent and rather soft, from being moistened with the serous exudation that is everywhere poured forth from the red diseased surfaces underneath. When the body of the patient is handled for some little time the fingers become moist and clammy.

<sup>1</sup> Journ. Hebdom., t. vii. p. 459.—Revue Médicale, Juin, 1830, p. 317.

To these cutaneous affections are superadded pain of the epigastrium; quick and compressible pulse; tongue red at the point, loaded in the centre; diarrhœa; insomnia, or disturbed sleep; want of real appetite; loaded and scanty urine. (*Rice-water with gum for drink; gummy potion, with half an ounce of syrup of poppies; beef-tea and milk; six leeches to each side of the neck; emollient cataplasms; bath at 28 R.*) The patient was so weak that she could not continue in the bath for any length of time. The skin generally is red and moist; the desquamation goes on; the febrile symptoms increase in severity; the epigastrium is more painful. (*Eight leeches to the epigastrium; mucilaginous drink; demi-lavement.*) 28th.—Matters going on still more unfavourably; the patient was ordered to lose four ounces of blood from the arm; but little, however, could be obtained. 30th.—A second attempt to bleed the patient was not more successful than the first, on account of the small size of the veins. Oct. 1st.—A number of small superficial abscesses were discovered, several of which were seated in the substance of the skin, whilst others, of somewhat larger size, extended into the subcutaneous cellular tissue, and presented an evident fluctuation. Some of them were opened, others, by reason of the opposition of the patient, were left to themselves. The patient exhales a fetid odour, which becomes more powerful every day, so that the nurses now approach her with great reluctance. Her state gets more deplorable every hour; the diarrhœa continues; she is greatly emaciated; the beat of the heart is rapid and feeble; the respiration quick and short, &c. She died on the night of the 5th. On opening the body ulcers, and other alterations characteristic of chronic inflammation of the intestines, were discovered.

707. I here subjoin two cases from the Philosophical Transactions, in which the general and habitual desquamation to which the skin became subject, was preceded by fever, and other serious symptoms, after which appeared a general eruption of red spots. These cases differ from those I have just detailed in the circumstance of the general desquamation being renewed after a fresh febrile attack, without any new eruption. In ordinary pityriasis, as we have seen, the desquamation goes on incessantly, and is not got rid of but with great difficulty. These cases of desquamation, however, differ from those that take place consecutively to exanthematous fevers, in having been habitual and frequently repeated. There is another case, similar to these two in its circumstances, detailed in the Ephemerides Naturæ Curiosorum,<sup>1</sup> and a fourth has been related by Mr. Newell,<sup>2</sup> which got well under the use of the Cheltenham waters continued for several seasons. I am anxious to direct attention to these cases, which present such remarkable discrepancies from those of common pityriasis. They appear to form a kind of transition link between this disease and the eruptive fevers. Cases of this kind are not yet sufficiently numerous to allow of their being thrown together into a particular group; but I have given several a place here with a view to their perhaps being made the basis of an arrangement that will one day become more precise.

CASE CXXII.—*Case of general desquamation of the cuticle, particularly of that of the hands.*<sup>3</sup> Mr. W. Wright, about fifty years of age, was first seized about ten years ago with a singular kind of fever which has returned many times since, even twice in the course of the same year, attended with the same symptoms and circumstances, appearing generally to be brought on by obstructed perspiration, in consequence of catching cold. Besides the common febrile symptoms upon the invasion of the disease, his skin itches universally, more especially at the joints, and the itching is followed by many little red spots with a small degree of swelling; soon after his fingers become very stiff, hard, and painful at the ends, and at the roots of his nails. In 24 hours, or thereabouts, the cuticle begins to separate from the cutis, and in 10 or 12 days this separation is general, from head to foot, when he has many times turned the cuticle off from the wrists to the fingers' ends, completely like gloves; and in the same manner also to the ends of his toes; after which his nails shoot gradually from their roots, at first attended with exquisite pain, which abates as the separation of the cuticle advances, and the nails are

generally thrown off by new ones in about six months. The cuticle rises in the palms and soles like blisters, but has no fluid under it; and when it comes off, it leaves the subjacent skin very visible for a few days. Sometimes, upon catching cold, before he has been quite free from febrile symptoms, he has had a second separation of the cuticle from the cutis; but then it is so thin as to appear only like scurf, which demonstrates the quick renewal of this part.

CASE CXXIII.—*Repeated attacks of general desquamation of the cuticle.*<sup>4</sup> Mr. A. B., aged thirty-five, enjoyed good health till about his thirty-fifth year; his business, as a miller, and maker of French barley, exposes him to a great heat and clouds of dust. On the first cold caught, after entering on this employment, a fever attacked him, and this has returned once, and sometimes twice, a year, chiefly in the autumn, attended with a loosening and detachment of the cuticle. The disorder begins with violent fever, attended with pains in the head, back, and limbs, retching, and vomiting, the skin being dry, the tongue furred, the thirst urgent, bowels constipated, and urine high-coloured. The whole surface of the body then, usually, but not invariably, became yellow; it afterwards became florid, having the appearance of a rash; on which he felt a great uneasiness for several days, with a numbness and tingling all over him, when the urine began to deposit a thick sediment. About the beginning of the third week from the first attack, the cuticle appeared elevated in many places, and in eight or nine days afterwards it became so loose as to admit of being easily removed in large flakes. The cuticle of the hands, from the wrists to the fingers' ends, came off whole like a glove. The patient was never disposed to sweat, and when this was attempted to be forced he grew worse; nor was he much at ease till his urine deposited a sediment, after which he felt but little inconvenience but from the rigidity of his skin. The nails were not detached, as in the preceding case.

CASE CXXIV.—*Pityriasis of the lips.* M. D \* \* \*, aged thirty-six, has suffered for the last fifteen years with a pityriasis of the lips; the disease is confined to the coloured parts, and has never spread either to the skin without, or to the lining membrane of the mouth within. The epithelium becomes hard and dry, cracks, and is detached in small shreds, so that in the course of four or five days it is completely renewed over the surfaces affected. Whilst the desquamation is going on, the lips are stiff, and the patient keeps moistening them with his tongue. The affection is most troublesome in winter, when it is more constantly attended with chaps than at other seasons. M. D \* \* \* is in the habit of talking much, and with his voice pitched high; he, himself, attributes his malady to a practice he has long indulged in of biting his lips; he also suffers from a kind of tic before each renewal of the desquamation. He has, from the beginning, tried a host of remedies against his distemper—common cerate, cucumber ointment, the *pommade de Regent*,<sup>5</sup> and even that of *Frere Côme*,<sup>6</sup> the latter only inflamed the lips and made them very painful. Some time afterwards, the lunar caustic was tried; and the parts affected were subsequently touched with a muriatic acid liniment, which irritated them anew, in a very distressing manner. M. D \* \* \* also tried lotions of the natural sulphureous waters of Barèges, but all proved futile, and the patient returned to the use of simple cerate, his lips remaining subject to an habitual desquamation. A great variety of internal medicines were also tried, without any one of them appearing to exert the slightest influence on the progress of the disease. These details M. D \* \* \* gave me when he consulted me in the winter of 1823. I recommended him to keep his lips anointed for a fortnight with an ointment of the acetate of lead; this application, which seemed at first to make the desquamation less frequent, and less extensive, failed at length, like every thing else, in giving relief. I then desired the patient to apply three or four leeches, repeatedly at intervals, to the inner surface of the lips; but he showed a repugnance to this measure, and I did not recommend any other. M. D \* \* \* has never suffered from an attack either of psoriasis, or of any chronic inflammation of the skin of a different nature, on any of the other regions of the body.

## SQUAMOUS INFLAMMATIONS ARTIFICIALLY EXCITED.

708. Squamous inflammations, arising under the influence of accidental excitement, differ from those we have just been engaged in considering, in their natural tendency towards recovery when not kept up by the constant action of the cause which has produced them.

709. The irritation caused by an indifferent razor occasionally produces a degree of redness in the skin, followed by desquamation, which has been classed with the pityriases. This trifling complaint disappears entirely when the skin is no longer subjected to irritation.

710. A squamous inflammation is frequently observed on the backs of the hands of grocers, and those persons who handle alkalies, spices and other stimulating substances; the skin looks red, slightly puffed, and squamous, and is commonly traversed by dry and painful chaps, more especially across the joints between the metatarsal bones and phalanges, and between the carpus and bones of the forearm. This affection is speedily cured by a change of occupation, or by keeping the hands for a time from the action of irritants. Eruptions of the same kind are occasionally observed among bricklayers, masons, engravers, &c.

711. Washerwomen are also frequently attacked with a squamous inflammation of the hands, and lower parts of the arms, excited by the prolonged immersion of these parts in water, and especially in alkaline leys. The parts become habitually red, and covered with a hard, dry and brittle epidermis, which falls off and is renewed incessantly. Those individuals whose hands are still more constantly kept plunged among irritating fluids, above all dyes, are subject to redness and swelling of the hands, with numerous deep fissures of the epidermis, which is always coming off in shreds. These chaps are frequently seen impregnated with colouring matter which cannot be got rid of by washing; they also frequently penetrate to the quick, and the pain and swelling they occasion, attended with stiffening and impediment to the motions of the hand, are often extremely troublesome. These latter varieties of squamous inflammation disappear like the others by a simple removal of the cause to which they are due; they get well much more slowly, however; the skin being swollen, and as it were hypertrophied in its entire thickness, so that it has lost its natural pliancy. The state of chronic inflammation of the integument seems also to be kept up in part by the irritation of the numerous chaps with which it is affected.

712. The nature of the whole of these accidental inflammations of the skin is to be distinguished by their causes, which patients almost always mention. They also differ from diseases of the same class induced by a morbid internal cause, in their mode of appearance; they are, in fact, simple diffuse chronic inflammatory affections of the skin, whilst lepra and psoriasis begin as papular elevations, and pityriasis as small red spots or stains upon the surface of the healthy skin. Further, lepra and psoriasis are evolved by the growth and multiplication of *circumscribed patches*, whilst the accidental squamous inflammations extend generally and irregularly. Lastly, these affections differ from pityriasis in this:—that they commonly cause more stiffness and chapping of the skin, and are occasionally attended with accidental vesicles and pustules.

lupus, cutaneous scrofula, cancer, Greek elephantiasis, tubercular syphilis, and accidental and artificially excited tubercles. Some pathologists are of opinion that lupus and cutaneous cancer do not always begin as tubercles; they have not, however, given any exact account of the forms under which they suppose that these two diseases may begin. I think it almost unnecessary to observe that this group of diseases is very different from that which Willan and Bate-man have designated under the name of *tubercles*, which includes alterations of the most dissimilar description, such as carbuncle, warts, rosacea, elephantiasis, furuncle and lupus.

715. Tubercles, whatever their nature, are occasionally solitary, but much more frequently numerous. They begin in the shape of flattened elevations, larger and harder than papulæ, and frequently of the same colour as the healthy skin that surrounds them; or they first appear as spots of a reddish colour. Tubercular affections are almost always chronic in their character; they may continue stationary for many months, and even for several years; but when accidentally irritated, tubercles are apt to increase in size, and to undergo different alterations. At a later period they soften or are destroyed by an *ulcerative* process, becoming covered with scabs when the sore is exposed to the air. These changes have distinct characters peculiar to each of the tubercular diseases. In relation to their origin, nature, appearance, progress and termination, the tubercles of lupus, scrofula, cancer, Greek elephantiasis and syphilis, have, in reality, nothing in common save their form; and although much more restricted than that of Willan, this group is only to be regarded as an artificial means of facilitating the diagnosis of these diseases.

716. The tubercular diseases at their acme, are in general easily distinguished from all other affections of the skin. Tubercles alone constitute small *solid* organized tumours, having a tendency to ulceration. The smaller dimensions of papulæ, and their essentially pruriginous character prevent them from being confounded with tubercles. As to *tumours*, properly so called, they are distinguished from tubercles in having no disposition to softening or ulceration, and in neither being preceded nor accompanied by any other symptoms of inflammation. When tubercles are partially or wholly destroyed, the *sores* and *scabs* which succeed present particular characters which are sufficient not only to separate these diseases from others of a different class, but even to distinguish each of them individually. In each particular case, after having discovered the existence of tubercles, we ought to ascertain whether they are *primitive*, or are *consecutive* to some other elementary form of disease, as also, whether they are *natural* or have been *artificially* excited. Tubercular diseases are always very serious in their tendency, and extremely difficult of cure.

717. In the body of this work I have intentionally omitted any account of several exotic diseases which show themselves in a tubercular form; in the attached vocabulary, however, some notice will be found taken of them. (Vide *Frambæsia*, *Radesyge*.)

## LUPUS.

Vocab. *Lupus*, *Noli me tangere*.

718. Lupus is a chronic cutaneous inflammation which usually appears in the shape of external tubercles of different sizes, singly or in clusters, of a livid colour and indolent character, followed either by ichorous and phagedænic ulcers, which become covered with brownish, and usually very adherent, scabs—*lupus exedens*; or by extensive changes in the structure of the skin, but without preliminary or consecutive ulceration—*lupus non exedens*. This disease may be confined to the face, and even to one of its parts, or may attack at once, or in succession, several regions of the body. The two varieties, which have been indicated, are very distinct in their external appearance, and to a certain extent in their mode of treatment. (a)

(a) The following paragraphs indicate the view which M. Bielt takes of lupus. "This disease has been described under the name of *dartre rongeante*, by Alibert, who has divided it into three varieties, based on the causes which produce them: 1st. *Dartre rongeante idiopathique*; 2d. *Dartre rongeante scrophuleuse*; 3d. *Dartre rongeante*

## IX.—TUBERCULA. TUBERCULAR INFLAMMATIONS.

Vocab. *Tubercula*.

713. The tubercular inflammations are characterized at their height by the occurrence of *tubercles*, or small solid, circumscribed, indurated, and enduring tumours, which, after continuing for some months, often for several years, almost uniformly end by becoming changed in their nature, and falling into a state of ulceration.

714. The number of tubercular inflammations reckoned is six:

719. *Lupus exedens* or *noli me tangere*, is commonly developed on the alæ or tip of the nose. It makes its appearance as a small external tubercle of a dusky-red colour, and hard consistency, whose progress is usually tardy. It sometimes commences as a chronic inflammation of the mucous membrane of the nasal fossæ, with redness and swelling of the nose in general; a thin scab or crust then forms at the opening of the nostrils; this is removed, and a second and thicker one succeeds it—an ulcer has in fact been formed, and soon extends to the alæ of the nose. Under other circumstances a livid or purple tint, and some swelling of the end of the nose, are the first symptoms of the disease observed. The redness increases, a superficial sore is formed, which becomes covered with a scab, and the ulcer extends in depth. It often happens, too, that one of the alæ of the nose swells, grows painful and of a purplish hue; a slight ulcer then forms and becomes covered with a little scab; this the patient commonly picks off, when it is replaced with a thicker one, under which the ulcerative process continues to go on, the scab being found to increase in thickness every time it is renewed; the patient scarcely makes any complaint; the skin, and occasionally the cartilage, are silently destroyed, and an ulcer of a bad character, from which a fetid sero-purulent discharge is poured out, is at length discovered, as if by accident, established under the scab.

The nose is occasionally red on the superficies only, and this in a very equal and regular manner; sometimes instead of being of its ordinary size and shape, the nose becomes pointed, sharp, and tapering, the nostrils tending continually to close. The cartilage at the angle which unites its two lateral halves superiorly, seems then to project, and presents a red tint that is even perceptible through the soft parts.

The ravages committed by this disease vary extremely; almost the whole of the nose disappears in one instance, and the point only suffers a little in another, in which case it often looks as if a piece had been removed with a cutting instrument. When such ulcers have been arrested and healed up, new tubercles occasionally form on or near the cicatrices, and the parts which had been spared originally may be entirely destroyed by a renewal of the ulcerative process; even the whole nose and septum may vanish before its destructive influence. The ulceration may prove rapid or slow in its progress: sometimes after existing for several years, a small portion only of the nose is lost; in other instances, happily of rarer occurrence, the whole of the member is destroyed in from fifteen to twenty days (*lupus vorax*). Sometimes, if the disease is interfered with, it seems to acquire new energy: the point of the nose assumes a livid red colour, which, though it may seem to disappear, returns within two or three days; incrustations, which are attended with acute pain, and grow very thick in the course of a few days, form in the interior of the nasal fossæ, whence a puriform fluid distils, and the point of the nose is then rapidly destroyed. The disease seems every now and then to be advancing towards recovery, when the part that was almost

*venérienne*; this last evidently belongs to the syphilitic complaints, and the author himself describes it under that head.

"*Lupus* is a disease which sometimes commences with spots of a violet red colour, but most generally with livid, indolent tubercles, and is above all characterized by its tendency to destroy the surrounding parts and subjacent tissues, under the form of ill-conditioned, ichorous ulcers, which become covered with very adherent brownish scales, which, on falling off, discover that the disease has continued its ravages.

"*Lupus* presents many differences, not only in its seat, the rapidity of its progress, and the extent of the destruction it produces, but also in the mode in which these ravages are committed, and in the form of the ulceration. Thus, sometimes it confines its attacks to the surface, sometimes it successfully invades the subjacent parts; at others, again, it is accompanied with a real hypertrophy of the skin; hence M. Bielt has divided it into three varieties: 1st. That which destroys the surface; 2d. That which destroys the subjacent parts; 3d. When it is accompanied with hypertrophy. This division is wholly practical, and much facilitates the study and description of the disease."—Cazenave and Schedel, *Practical Synopsis of Cutaneous Diseases*—Philadelphia Translation.

cicatrized, turns to a vivid red, is attacked anew with painful ulceration, and is covered with a thick scab under which the destructive inflammation makes rapid progress.

In *lupus exedens* of the skin of the nose, the mucous membrane of the nasal fossæ is almost always affected with chronic inflammation. In some rare cases, altogether independent of a syphilitic cause, the septum is even destroyed before the outer surface of the nose is implicated. When the destruction commences in the skin, again, it extends to the pituitary membrane, spreads along the nasal fossæ, and is even occasionally reflected over the mucous membrane of the arch of the palate to the gums, which are then deeply furrowed. Besides the destruction, which is discovered when the scabs that have long concealed the mischief wrought by this disease are removed, it is very common to find the openings of the nostrils contracted in a greater or less degree by the thickening of the affected parts, or by the indurations consequent on the formation of cicatrices.

2d. The tubercles of *lupus exedens* are occasionally evolved near the *commissures of the lips*. Thick incrustations cover the ulcers, and the patient cannot open his mouth without pain. After having destroyed a considerable extent of parts about the commissures, the ulcers often extend to the movable substance of the lips, in which case, by the shrinking of the cicatrices when the disease gets well, the opening of the mouth is apt to be considerably diminished.

3d. The *lower eyelid* is occasionally attacked with *lupus exedens*, and the ulceration generally spreads to the skin of the cheeks and to the conjunctiva palpebralis. The eyeball in this case imperfectly protected, inflames, the conjunctiva thickens, the cornea loses its transparency, and by and by becomes so dim that total blindness follows. If the eyelids are not entirely destroyed, the sores in healing cause their eversion; the eyes then appear of twice their usual size, a circumstance which, added to the vivid red of the conjunctiva, produces hideous deformity.

4th. It sometimes happens that one or more tubercles are evolved on the face, which, after continuing long stationary, increase suddenly in number as well as in size. The skin in the spaces between them swells and becomes œdematous in appearance, the tubercles then unite by their bases, and the whole mass falls into a state of *irregular ulceration* of bad character. The sore is covered with a blackish-looking and very adherent scab, and spreads by degree to the neighbouring parts. *Lupus exedens*, in this way, frequently attacks almost the whole of the face. When the ulcerative process stops, cicatrization takes place in the form of irregular white bands, which stretch from the parts where the mischief began to those in the vicinity, and are very similar in their appearance to the cicatrices that result from extensive burns.

5th. *Lupus exedens* occurs with symptoms of still greater severity. Whilst it is advancing among parts still untouched, it returns and attacks the cicatrices, whether of old or recent date, which have resulted from its previous existence. These disappear very rapidly, and fresh tubercles, developed like a hard, rough, and swollen band around them and the ulcers that exist, become open before long and add to the havoc going on. In the course of a few months the disease may thus ravage not only the greater part of the face but a large extent of the surface of the neck. The nose is frequently implicated in the destruction, and when the scabs are detached, the alæ or a portion of its end is found gone. When, by means properly directed, the progress of the disease is arrested, the skin, beset with numbers of small, red, and scallow tubercles, becomes covered with minute squamæ, and white and firmer cicatrices ere long succeed upon the ulcerated points. When the ravages of *lupus* have been thus extensive, the face is seamed with irregular cicatrices, often of a dull white, but occasionally of a rosy red colour, tense, shining, pretty thick in some places, but so thin in others that they appear transparent and on the point of giving way. This latter character they present especially on those parts that have been oftener than once attacked. These cicatrices seem frequently to hold by their extremities to two different tubercles, between which they stretch like lines of communication. They often appear covered on various points of their circumference with blackish incrustations, which, however, are commonly soon detached.

6th. *Lupus exedens* rarely attacks the integuments of the chest, or

of the extremities; these regions are more frequently the seat of the *lupus non exedens serpiginosus*.

7th. Lastly, in one variety of *lupus exedens* the ulcers are beset with small, soft, red and spongy-looking and very prominent *tumours*, which occasion much deformity. This variety is one of the most formidable, but it occurs rarely.

8th. *Lupus exedens* often continues for years, committing the most frightful ravages, without the general health appearing to suffer in any degree. Yet, when not only the skin but the cartilage of the nose is rapidly destroyed, some patients show unequivocal symptoms of chronic inflammation of the lining membrane of the stomach, intestines or bronchi, and several even sink under a species of slow fever accompanied with colliquative diarrhœa; such a termination of *lupus*, however, so rarely happens, that when it does occur, it ought probably to be ascribed to an accidental complication, rather than to the influence of the disease itself.

720. *Lupus non exedens*. This variety occasionally presents itself as a single tubercle, of a yellowish-red colour, developed in the substance of the skin,—*lupus non exedens simplex*. I have observed a solitary tubercle, possessing these characters, continue on one of the cheeks in several children for a number of years, and leave; at a subsequent period, a small cicatrice in the spot it had occupied. The disease, however, more commonly begins in the face, as an irregular cluster of little tubercles of a dingy red colour, and a flattened or lenticular form, scarcely rising above the level of the skin. In some cases, they implicate a great portion of one or of both cheeks, of the forehead, and even of the *face in general*. These tubercles do not ulcerate on their summits; and the sores that are occasionally encountered in the circumference of the clusters, are so rare that they must be held entirely accidental. The disease spreads by the formation of fresh tubercles, which spring up near those that already exist, and thus by degrees increase the area of the diseased surface—*lupus non exedens serpiginosus*. The skin and subjacent cellular substance often become affected with an indolent infiltration, and the diseased surfaces look puffy and enlarged. The yellowish-red colour of the tubercles disappears under the pressure of the finger. The patient does not experience any pain; but touching the parts causes uneasiness; and the diseased surfaces frequently become sensible after violent exercise, and indulgence in spirituous liquors. The tubercles begin to shrink in the centre of the group; the skin there grows red, shining, slightly furfuraceous, and subsequently assumes the look of such a cicatrice as is formed after a superficial burn; it is, however, beset with points of a yellow coppery colour, due to the tubercles which, from shrinking themselves, or from the tumefaction of the neighbouring subjacent parts, are brought to the level of the skin. The clusters appear mingled with white points and bands, which are evidently cicatrices, owing to the disappearance of tubercles of another date, and which in vanishing have caused this singular alteration of the integuments. The tubercles of *lupus non exedens* are habitually affected with an epidermic desquamation, which is usually most remarkable around the circumference of the clusters where they are best defined.

The features occasionally become very much enlarged in this disease; the cheeks, soft and flabby, or pasty, preserve to a certain degree the print of the finger, and look as if they were affected with the Arabian elephantiasis. The forehead and eyelids are puffed, and the eyes, covered with hypertrophied masses, seem sunk and hidden in the bottoms of the orbits; the lips, too, are considerably swollen, and often form two enormous, flabby masses, which expose the mucous membrane of their inner surface turned outwards; the ears, in fine, occasionally participate in this general tumefaction of the face. The tubercles of *lupus non exedens* are rarely affected with ulceration; such as does occur is accidental, very superficial, and covered with thin, laminated and but slightly adherent incrustations. This disease continues for an indefinite period; whether left to itself or modified by the action of various therapeutic agents, the affected parts never regain their natural state completely; the tumefaction of the skin and subcutaneous cellular tissue diminishes, the tubercles shrink and disappear, but the skin continues thin, shining, smooth to the touch, and seems to have lost something of its proper thickness.

2d. *Lupus non exedens* occasionally appears on the *extremities* in one or more clusters of small flattened lenticular tubercles, of a

yellow-red tint, changing subsequently into patches of an irregular circular shape, the areas of which are red, furfuraceous, often traversed by prominent bands, whose salient edges are evidently tuberculated, and covered with firmer and thicker squamæ. When this eruption is left to itself, fresh tubercles appear successively in the circumference of the primary clusters, and encroach more and more upon the healthy integument; in this way I have seen the disease extend over the whole of a limb, the arm, for instance, from the shoulder to the wrist. The extremity thus affected, became much larger than the one on the opposite side, and even acquired the dimensions which the same part presents in Arabian elephantiasis. The motions of the elbow-joint were executed with pain and difficulty; the extent of the disease was sharply defined towards the shoulder superiorly, and near the wrist inferiorly, by a tuberculated line covered with squamæ. The skin of the arm and forearm, changed into a kind of indurated tissue of a paler colour than the healthy integument, was puckered or ridged with numbers of bands similar to those that follow burns, and sprinkled over with lenticular spots of a brown and dirty yellow, owing to tubercles that had shrunk or were buried in the substance of this tumid skin. The subcutaneous cellular membrane was infiltrated, and in several places, pitted under pressure. At intervals, variously remote from each other, sometimes under the influence of the deuto-ioduret of mercury exhibited internally, sometimes to all appearance spontaneously, the skin and cellular substance under it were attacked with a low kind of inflammation, attended with some swelling, heat and pain, but without any distinct external redness. A serous exudation then took place from a number of fine pores, or openings which were visible on the surface of almost the whole of the tubercles, and into which the point of a large pin might have been insinuated. This *intervening* inflammation was always followed by a diminution in the size of the extremity, and the dispersion of a certain number of tubercles. I have, however, seen this variety of *lupus non exedens*, disappearing about the shoulder, at the same time that the disease was making rapid advances around the elbow and forearm.

3d. *Lupus non exedens* is occasionally evolved *below the ear*, and on the *nucha*, whence it extends in one instance towards the throat and shoulders, in another towards the occipital region, which it despoils completely of hair.

721. Both of these varieties of *lupus* appear at first sight to be diseases entirely of a local nature. Those who are attacked with them are commonly in the enjoyment of pretty good health at the time; females, indeed, occasionally complain of something like derangement in the periodical discharge, especially when the constitution appears to have a scrofulous taint, and when the disease is of some extent; yet I have known several women who suffered from old and inveterate *lupus* in whom the catamenia had always been regular and pretty copious.

Of all *intercurrent* diseases erysipelas is the one which is most frequently observed along with *lupus*. The occurrence of this inflammation is occasionally to be accounted a lucky accident, especially in the *lupus non exedens serpiginosus*, inasmuch as under its influence a certain number of tubercles are always dispersed, and the whole disease may even be brought to a fortunate conclusion. But it also happens now and then that an attack of erysipelas, even in effecting a desirable modification in the state of the diseased integuments, may be attended with nervous symptoms of such severity as to make its occurrence subject of deep regret. As to the diseases of the skin and other affections which existed previously to the development of *lupus*, the whole, with the exception of scrofula, perhaps, appear to be strangers to its cause.

722. *Causes*.—*Lupus* is happily a disease rather of rare occurrence. It is most generally developed between the sixteenth and twenty-fifth year, and seldom shows itself after the age of forty. Scrofulous children are of all individuals those who are most obnoxious to its attacks; yet it undoubtedly occurs among the robust who have lived in the habitual enjoyment of excellent health. The disease is frequently uninfluenced by the arrival of puberty, and may recur in those who have suffered from it in their youth. It seems to be more common in the country than in towns; and, perhaps, also to attack women more frequently than men. The poor inhabitants of Haute-Auvergne who

live on acrid food, such as old cheese, tainted meats, &c., and house with their cattle, are often attacked with it. The disease is not contagious, and is seldom seen among the better classes of society. Blows, falls, &c., under the influence of which it has seemed occasionally to be developed, can only be regarded as determining and occasional causes of the disease.

723. *Diagnosis*.—Lupus is easily distinguished from rosacea, Greek elephantiasis, syphilitic affections, and the other forms of cutaneous disease that present tubercles, or ulcers covered with incrustations of varying thickness. Scrofula is peculiar to individuals of a strumous constitution; the tubercles, sores, and affections of the bones and lymphatic glands that accompany it have peculiar characters. Further, scrofulous ulcers extend by the detachment of their edges from the subjacent tissues, and the formation of sinuses, in consequence of the softening and suppuration of lymphatic glands, of caries of the bones, &c.; whilst the ulcers of lupus are the effect of a process that consumes the skin and neighbouring parts from without, inwards—from the surface towards the deeper structures. The red colour, the erythematous areola that surrounds the circumscribed indurations which succeed the pustules of rosacea, and these pustules themselves, which are generally met with in the neighbourhood of such indurations, are so many characters distinguishing this affection from the discoloured and indolent tubercles of lupus. In Greek elephantiasis the general tawny colour of the skin, the form and arrangement of the tubercles, which are nearly of the same tint, and present themselves as small knotty and unequal tumours, as well as the partial augmentations in size, succeeded by swellings that deform the face, are so many symptoms foreign to lupus *non exedens*. Further, the tubercles of this variety of lupus are commonly arranged in circular groups, the limits of which are strongly marked and covered with squamæ, which is not the case with Greek elephantiasis. With the slightest attention it seems impossible to confound the circular clusters of lupus *non exedens* though covered with squamæ, with the patches of lepra, the areas of which never show any thing like the cicatrice of a burn, nor the lenticular stains of a tawny yellow hue, produced by such tubercles as have shrunk, or such as are arising in their circumference (§ 674). The ulcers of Greek elephantiasis are always more superficial than those of lupus *exedens*, and show no tendency like them to attack the neighbouring healthy parts. Lastly, the tubercles of Greek elephantiasis are commonly disseminated over several points of the surface of the body, and are accompanied with many other symptoms that never occur in lupus.

The crusts of impetigo, yellow, prominent, rugous, and often very slightly connected, especially on the face, are very different from the thick, brown and firmly adhering scabs of lupus *exedens*, which, moreover, terminates in ulceration and cicatrization, consequences never seen in impetigo. It is also of importance to distinguish lupus *exedens* from some cancerous and syphilitic affections of the skin. Cancerous tubercles, very hard and often painful, are evolved among subjects more or less advanced in life, on the nose, cheeks and lips, especially, and generally exist for some considerable time before they ulcerate; lupus *exedens*, on the contrary, almost never appears in persons past the prime of life, and its tubercles are unaccompanied with pain from the first. Phagedænic cancer frequently commences in a solitary tubercle; in lupus *exedens* there are usually several, and in lupus *non exedens* there are almost uniformly a considerable number. Further, cancerous ulceration is often attended with considerable swelling of the soft parts, and the neighbouring vessels are dilated and varicose; these sores are also made worse by the application of escharotics; when the nose is the part affected, the bones also suffer and exhibit alterations characteristic of the disease. Lastly, cancerous sores discharge plentifully and are painful; they are not covered with thick dry scabs like lupus.

Syphilitic tubercles un-ulcerated, are more rounded, larger, and prominent in a greater degree, they are also of a more coppery red colour, without epidermic exfoliation, and have less tendency to ulcerate than those of lupus *exedens*, whose tubercles, flattened in their forms, and accompanied with a slight puffiness of the skin, are almost always covered with a small epidermic lamella; they are arranged in clusters, the circumference of which is strongly defined, while the centre is erythematous, furfuraceous, and traversed by lines or bands of a dull

white colour. To conclude, syphilitic tubercles, as consecutive symptoms of a venereal affection, are favourably modified by mercurial preparations, and commonly appear in individuals of a certain age, whilst lupus resists mercury in every form, and makes its attacks most generally among children and persons before the age of puberty. The ulcers that follow syphilitic tubercles are deep, and their edges are tumefied, of a coppery red tint and sharply cut; whilst those of lupus *exedens* differ in their causes and in their mode of destroying parts. In lupus *exedens* of the nose, the skin is commonly first ulcerated, the cartilages and bones being only attacked consecutively, and often after a very long interval has elapsed from the beginning of the disease; in syphilis, on the contrary, the bones are the structures that usually suffer first; and it is only after portions of them are affected with necrosis that the skin is perforated with ulcers. Lastly, tubercles and ulcers of syphilitic origin are almost always accompanied with symptoms that distinctly tell of their nature, such as nocturnal pains in the bones, exostoses, iritis, and often with tubercles or sores of the mouth, pharynx, velum palati, &c. The solitary tubercles of lupus *exedens* of the cheeks have frequently been mistaken, during their stationary period, for small sanguineous tumours or nævi; they differ from these, however, both in their structure and mode of formation, as well as in their tendency and termination. (Vide *Tumour vascular*, in Vocab.)

724. *Prognosis*.—Lupus is always a very obstinate disease. Months and even years commonly elapse before it yields to any form of treatment. Lupus *exedens* is not generally subdued until a considerable extent of parts has been destroyed, and always leaves indelible and deformed cicatrices behind it. The disease proves so much the less troublesome, and its effects less deplorable, as we are called upon to treat it at an earlier period of its existence, and as its progress has been slow. So long as the cicatrices remain soft, bluish, and convey to the finger something like a feeling of fluctuation, and so long as they are surrounded with tubercles of different sizes, there are grounds to apprehend a renewed attack of erosive inflammation, in which case the tubercles ulcerate, and the cicatrices already formed are not long of again becoming open. Puberty, and the establishment of the menstrual flux, which among women produce favourable changes in the greater number of chronic skin complaints, appear to have little influence in modifying or mitigating the destructive character of lupus.

725. *Treatment*.—The first indication in commencing the treatment of lupus is to endeavour to modify the general constitution by appropriate remedies. The disease itself is at the same time to be combated by such external and internal medicines as appear to exert a salutary influence on the development and progress of tubercles and the ulcerative process. When individuals of a flabby or evidently scrofulous habit are attacked with lupus, they may every morning take with advantage a tablespoonful of a solution of the hydrochlorate of lime, made by dissolving a drachm of the salt in a pound of water; every eight days the dose may be increased by a spoonful, and the medicine may at last be carried to the length of ten or even twelve spoonfuls in the course of the day with propriety. This is a preferable medicine to the hydrochlorate of baryta, the activity of which sometimes gives grounds for apprehension. Chalybeate mineral waters and the artificial preparations of iron may also be tried. I myself make frequent use of a powder composed of carbonate of iron, cinchona and cinnamon. Others have recommended the carburet and sulphuret of iron. Sulphureous baths taken every day, for one or two months, the patient continuing immersed for several hours each time, are also powerful means of modifying flabby and scrofulous constitutions. Bitter medicines, such as the infusion of gentian, &c., and above all, the preparations of iodine, are employed with the same views. Food of good quality, the moderate use of some generous wine, a residence in a dry and bracing air, are also powerful modifiers of constitutions of the above description.

Each variety of lupus presents particular indications:

1st. It is seldom that we are called in time to attempt the resolution of the primary tubercles of lupus *exedens*; patients generally present themselves with ulcers more or less extensive. When any tubercles exist, they appear disseminated in the neighbourhood of some ulcer, which it is then of the last consequence to check in its destructive progress. This is generally effected by means of caustic applications;—the animal oil of Dippel, the nitrate of silver, potassa fusa,

butter of antimony, super-nitrate of mercury, arsenical powders and pastes, and the actual cautery, have each had, and still have, their supporters. When the disease is very extensive, the cauterization ought to be at first confined to a single part, and extended successively to the whole of the affected surfaces. When the ulcers are covered with scabs, these must previously be got rid of by means of softening poultices. In *lupus exedens nasi*, when this part is affected with an indolent enlargement, and its surface is of a purplish hue, and covered with an epidermic exfoliation, it is often advisable to carry a hair pencil, dipped in the animal oil of Dippel, gently but repeatedly over the whole extent of the diseased skin. The nitrate of silver employed in solution, in a similar manner, has, however, generally appeared to me a preferable application. In the more serious cases, the nitrate of silver is very advantageously employed after the parts affected have been once or twice touched with the acid nitrate of mercury or the arsenical paste of Frère Côme; it is the most useful escharotic, indeed, whenever the object proposed is to cauterize superficially and with little pain. The acid nitrate of mercury may be applied not only to the ulcers of *lupus exedens*, but to the tubercles themselves, and to such of the cicatrices as remain bluish and soft, and threaten again to break open. When the end proposed is to produce an eschar of considerable depth, which is often necessary, the acid nitrate of mercury has indisputable advantages over the other active caustics that are often employed in the same intention, such as the potassa fusa and butter of antimony. A small dossil of lint is dipped in the solution, and applied to a portion of the diseased surface twelve or fifteen lines in diameter; a little soft dry lint is then to be laid over the space cauterized; this trifling operation is not performed without the infliction of severe pain. The surfaces destroyed in this way are at first of a greenish-white colour; a yellowish and slightly adhering slough or scab is gradually formed afterwards, and the eschar is finally thrown off at the end of a week or a fortnight. Arsenical pastes can only be employed with safety as escharotics, by enforcing precautionary measures of the greatest strictness against their entrance into the nasal fossæ. The use of the acid nitrate of mercury as an escharotic, has the same disadvantage as the arsenical paste, in occasionally causing a considerable degree of erysipelatos inflammation; this consequence, however, is in general much less severe, and far more transient with the mercurial than with the arsenical preparation.

In *lupus* of considerable extent affecting children, women, and subjects of irritable constitution, the ulcerated surfaces, freed from incrustations, may be dusted over with a thin layer of a powder composed of ninety-nine parts of calomel, and one of arsenious acid. This application is much employed by M. Dupuytren, according to whom it acts rather as a specific than as an escharotic. Should the affected parts be covered with an imperfect cicatrice, it is even advisable to destroy this, and to apply the powder four-and-twenty hours afterwards. Should there be any difficulty in getting the powder to adhere in sufficient quantity, it may be mixed with a little gum-water or simple ointment and applied; in this case, however, the dose of arsenious acid employed must be increased by one or two hundred parts. In every case we are to wait till the powder or unguent falls off of itself, which usually happens after the lapse of eight or ten days, and then renew the application until a complete cure takes place, which is occasionally accomplished within eight or ten weeks, that is to say after five or six applications of the remedy. When the ulcerated surface is of considerable extent, it is advisable to apply this compound powder to a space of about two inches square at a time, and only to cover the whole extent of parts affected by degrees. Lastly, when the ulcers of *lupus* are of very old standing, and extremely indolent, great benefit is occasionally derived from covering them with a blister, before beginning the application of the powder or salve above mentioned. The advantages possessed by this powder over the arsenical paste in common use, (*pâte arsenicale de frère Côme*), are those of not exciting erysipelas in the tissues around the diseased structures to which it is applied and in cauterizing much less deeply, so that it may be used again and again without danger to the patient. The relative proportions of its component ingredients may be changed by the cautious practitioner, according to the extent and circumstances of the case he has in hand; but it seems important

that neither be omitted, inasmuch as both appear necessary to its action, without our being able to determine precisely the part which each of them plays in the general effect.

726. The arsenical powder of frère Côme<sup>1</sup> is a more energetic external remedy, which seems more particularly available in cases of old and obstinate ulcerated *lupus*, the ravages of which have been found uncontrollable by other less active applications. It is well to have recourse to this preparation at the very outset in *lupus exedens* of the cheeks. To prepare it for use a small quantity must be made sufficiently thin upon a piece of broken earthenware plate, and by means of a spatula spread upon a surface that ought not to exceed eight or ten lines in diameter. This application is almost always followed by some degree of erysipelas, which, when slight, may be left to itself; but when it proves severe, when the face becomes very much swollen, and the patient complains of violent headache, whilst the pulse is full and frequent, blood-letting must be practised, leeches attached behind the ears, emollient or laxative lavements thrown up, stimulating pediluvia employed, &c.; the inflammation soon abates, and the only consequence of the application of the arsenical caustic that remains is a blackish and thick eschar which continues very long adherent. These are all much more effectual modes of producing eschars and arresting the current of diseased action in *lupus* than the use of the actual cautery, a remedy which in this complaint is nearly abandoned at the present day. In *lupus exedens* of the nose, indeed, it frequently aggravates the disease, causing the cartilages to swell and be absorbed; it would appear to be rather more applicable in *lupus* of the cheeks. Whatever the form of cautery or caustic employed, when the eschars are detached, they seldom fail to expose an ulcerated surface of the best appearance beneath them; a single application of the caustic, however, is generally insufficient to accomplish a cure; ten, fifteen, twenty, thirty or more, may be necessary in the course of several years, when the diseased surfaces are very extensive and of ancient date; a cure, indeed, is seldom or never consummated but by perseverance and undeviating attention. Whilst this is going on, when the nose is the seat of the disease, it is necessary to guard against the contraction of the nostrils, which then frequently show a great tendency to close up. They must be enlarged, when they have shrunk in any considerable degree, with the knife or caustic, and kept from again shrinking during many months by means of tents of prepared sponge.

727. During the treatment, patients should avoid exposure to excessive heat or to rigorous cold. By want of attention to this simple precaution, cicatrices that appeared sound have frequently been seen to open out afresh. When the disease is accompanied with any evident functional disturbance, this must be remedied by appropriate means. When amenorrhœa complicates it, the return of the catamenia must be solicited, and the appearance of this discharge kept up by every means at our disposal; when it cannot be brought back, a few leeches should be vicariously applied to the external parts, when symptoms of general uneasiness, or pains in the head, &c., seem to indicate the periods of its natural flow.

728. *Lupus non exedens* is a more obstinate disease, if possible, than the one we have just been engaged in describing; in the hope of effecting the resolution of the tubercles which characterize it, the most powerful medicines of every description have been pushed to the uttermost. The tisan of Feltz,<sup>2</sup> Pearson's solution of arseniate of soda, in doses, increased from a scruple to a drachm daily; Fowler's solution of the arseniate of potash even in hazardous doses; arsenic, in a word, in every form, has appeared to exert but a very slight influence on the evolution and progress of the tubercles of this variety of *lupus*. The animal oil of Dippel has been tried, but with results too diversified to enable us to have any reliance on its powers.

The deuto-iodide of mercury, in doses gradually increased from one-fourteenth or one-tenth to one-fifth of a grain daily, is the only one of all the internal medicines that I have tried, which has appeared to me to exert an indubitable influence upon the progress of the tubercles of *lupus non exedens*. After continuing this medicine for a month or two, the parts covered with tubercles frequently become painful, and after a kind of local or intestine inflammation, attended

<sup>1</sup> White oxide of arsenic, cinnabar, and animal charcoal.—Tr.

<sup>2</sup> A decoction of crude antimony, sarsaparilla, and fish glue.—Tr.

with vague and irregular symptoms of general febrile disturbance, the tubercles begin to shrink, and many of them disappear entirely. After continuing the use of the deuto-iodide of mercury for two or three months, patients should leave it off for some short time, and thus try its influence repeatedly. Besides the undoubted action exerted by this preparation on such tubercles as already exist, its influence on the general constitution in preventing completely the formation of fresh tubercles, is not less remarkable. Nevertheless, despite my utmost care in the exhibition of the medicine, and all the watching I could give its action, I have occasionally had to contend with symptoms of inflammation in the large intestines which compelled me immediately to suspend its use, if, indeed, I was not obliged to abandon it altogether. (a)

External applications have been administered with some success in this form of lupus. In the foremost rank of remedies of this class must be placed the inunction, over the districts occupied by tubercles, of the ioduret of sulphur ointment (℞. Iodid. sulphur. gr. xviii; Adipis sul. ʒi), of an ointment of the proto-ioduret of mercury (℞. Proto-iodid. hydrarg. gr. xxx; Adipis ʒi), and of the deuto-iodid. of mercury (℞. Deuto-iodid. hydrarg. gr. xviii; Adipis ʒi). Under the influence of one or other of these unguents, rubbed on the affected parts, the skin becomes hot and red, and the tubercles frequently shrink and disappear entirely. Yet cases do occur in which these applications produce little or no amendment, if they do not perchance excite unpleasant erysipelas of the face.

729. The occurrence of this inflammation as a consequence of the internal use, or external application of these preparations, however, frequently appears to have a beneficial ulterior effect, not only on the part in which it is developed, if this chance to be beset with tubercles, but, further, on the clusters at some distance from the seat of this new affection. This circumstance was presented to my notice in a very recent instance in the Hôpital de la Charité: A young woman labouring under lupus non exedens of the cheeks, forehead, and left arm, was attacked with erysipelas of the face, and during the continuance of this kind of exanthematous fever, the skin of the arm underwent as evident an improvement as that of the cheeks.

730. In the hope of preventing the extension of the tubercular clusters of lupus, I have isolated them by an incision, as well as by a deep application of caustic; but in vain; fresh tubercles appeared beyond the artificial boundary I had traced. The destruction of the clusters by caustic, or their extirpation with the knife, would be attended with no good effects in the greater number of cases: to cure this variety of lupus completely it were necessary to eradicate the unknown cause under the influence of which its tubercles are evolved; and it is probable that the only means by which this can be in any way accomplished consists in the exhibition of those medicines which pervade the whole system, and alter it deeply.

#### Historical Notices and particular Cases.

731. Hippocrates mentions *eating* or *gnawing* herpes, 'ΕΡΙΠΕΤΕΣ ἑσθιόμενοι' and eating ulcers θηγία.<sup>2</sup> Celsus has amalgamated the account of these two forms of disease, in his description of *therioma*,<sup>3</sup> in which the striking and essential features of lupus may be recognised. From this time the denominations, herpes *esthiomenes*,<sup>4</sup> herpes *exedens*,<sup>5</sup> herpes *ulcerosus*,<sup>6</sup> and darte *rongeante*,<sup>7</sup> eating tetter, and

(a) The benefits promised in the text from the use of the iodide of mercury, may, with still stronger probability, be procured by the iodide of mercury and arsenic, (Donovan's solution)—Dr. Dunglison (*New Remedies*, 4th ed.), among others, speaks favourably of this preparation, employed both internally and externally.

<sup>7</sup> Alibert. Précis théorique et pratique sur les maladies de la peau.

*phagedænic* ulcer have been in very general use among medical authorities. The translators of the Arabian writers introduced the titles *formica corrosiva*,<sup>8</sup> and *formica ambulativa*; by which they rendered the Arabic word, that appears to correspond to the esthiomenous or eating herpes of the Greeks. The term *lupus*, introduced into our modern nomenclature, by Willan and Bateman, had already been applied by several writers of the middle ages to designate an *eating ulcer*,<sup>9</sup> in the same sense, therefore, as the term herpes *exedens* was employed of old. The disease which we have described under the name of Lupus, has further been confusedly spoken of under that of *papula fera*,<sup>10</sup> although the disease mentioned by Celsus under this title is evidently lichen *agrius*. Lupus has also been described under the head of *noli me tangere*,<sup>11</sup> a designation which has likewise been applied to cancer; and Delpech,<sup>12</sup> under the name of lupus of the fingers, has given the details of an ulcerous disease attended with extreme pain, to relieve which he was even compelled to divide the ulnar nerve. Alibert first described lupus under the title of *darte rongeante*, but has more recently designated the disease under the denomination of *esthiomene*. Messrs. Cazenave and Schedel, who have taken great pains to expose the characters of this disease, have, like myself, adopted Willan's name, *lupus*, which has the advantage at least of not designating as *phagedænic* or *eating* the whole of the varieties of this disease, one of which does not even cause ulceration of the skin. M. Bachelet de Lindry<sup>13</sup> was certainly to blame when he united, under the title of *darte rongeante*, the details of cancerous sores, and of ulcerated syphilitic tubercles of the skin. M. Arnal has mentioned a lupus *exedens* of the septum nasi, and arch of the palate.<sup>14</sup> The remarks of M. Bielt,<sup>15</sup> and of M. Paillard,<sup>16</sup> on the use of the ointment of the deuto-ioduret of mercury, may be consulted with advantage. The observations of M. Lugol<sup>17</sup> on the employment of iodine in cutaneous *phagedænic* scrofula; and those of M. Lemasson<sup>18</sup> on the exhibition of opium and iodine in combination, will also be read with profit. To conclude on the subject of escharotics, the dissertations of M. Guillerminéau on the nitrate of silver, 4to., Paris, 1824, of Mr. Godart on the acid nitrate of mercury, 4to., Paris, 1826, and the essay of M. Patric on the art of applying the arsenical paste, 8vo., Paris, 1817; as well as an account of several cases of lupus treated by caustic applications, in the Journal Hebdomadaire,<sup>19</sup> will be found to give a large amount of information. The case related by M. Brillouet,<sup>20</sup> under the title of *darte rongeante*, is evidently one of impetiginous eczema.

CASE CXXV.—*Lupus non exedens* serpiginosus; *deuto-ioduret of mercury*; *erysipelas*; *bitters*; *improvement*. Hélène H \* \* \*, aged nineteen, of fair complexion, was received into the Hôpital de la Charité, in December, 1832, labouring under lupus, which had appeared, when she was but three years old, upon the upper part of the left arm, and extended from thence, in spite of various applications, as far as the wrist. To this extent of surface the disease continued limited during twelve years. At the age of fifteen, however, when the catamenia first made their appearance, the disease, besides increasing in severity on the arm, began to attack other regions,—the cheeks, chin, upper part of the right buttock, and neighbourhood of the left knee. All the remedial measures again enforced, proved as unavailing as ever against the progress of the disease.

On the entrance of the patient into the hospital, the whole of the left arm, from about three finger-breadths below the thick of the shoulder to the wrist, was one mass of disease; it was bounded above and below by a distinct rank of tubercles, several lines in breadth,

and presenting a sharp and well-defined edge towards the healthy skin, and was higher here than on the inside, towards the diseased surface, where it was flattened, and covered with whitish or yellowish squamæ. Seen from a certain distance the disease had very much the appearance of a large cicatrice produced by a burn; but more narrowly inspected, the whole surface was found beset with hard, flattened, and, in general, but slightly prominent tubercles, of a dusky red colour, and varying in size from that of a large pin's head to that of a pea. The greater number of these tubercles, which were more prominent than the generality, were without squamæ; the remainder were scaly on their surface, and disseminated over the limb, more especially in the line of extension. The squamæ were thin, easily detached, and broader in the circumference than in the centre of the tubercles, around which they formed an irregular indented circle. Besides these squamæ, quantities of flimsy lamellæ, bran-like in appearance, were seen at the bottoms of the furrows which intersected the whole of the diseased surface. The skin in the spaces between the tubercles was of a pale rose, or slightly violet hue. An irregular whitish cicatrice extended between the arm and forearm, impeding the ready extension of the elbow-joint. The bursa that lies over the olecranon was distended with fluid.

Both cheeks were almost completely covered with a pretty regularly circular patch of lupus, the circumference being formed by a well-defined raised ring of flattened, yellowish tubercles, and its middle, of a rose colour generally, but mottled with white, naked in some places, in others covered with flimsy epidermic scales. Under the chin and on the forehead there were two small clusters of not more than three or four tubercles each, covered with thin squamæ.

The patient was at first put upon a course of bitters, combined with the exhibition of one-twenty-fourth of a grain of the deuto-iodide of mercury daily, whilst the clusters on the cheeks were regularly rubbed with an ointment of the ioduret of sulphur. The dose of the deuto-ioduret was gradually increased till the tenth of a grain was taken at a time. The iodide of sulphur was continued in frictions externally; the patient took a few simple and then several sulphureous baths (March, 1833). Towards the end of April the squamæ which covered several of the tubercles of the arm were detached, and not reproduced. The tubercles looked shrunk, but those that bounded the disease inferiorly and that were the largest, did not appear to have undergone any modification. About this time, however, a kind of excitement seemed to take possession of the forearm, which became swollen, painful and generally shining on the surface. The tubercles which on the entrance of the patient were of a dull red or pale rose colour, enlarged, got more sensitive, and anon were affected with a serous exudation to such an amount that the patient was obliged to change the linen dressing that was now applied several times a day. A minute orifice could be perceived by close inspection on the summit of several of them, and when those that were swollen and of an oval shape were pricked with a needle, a globule of transparent, yellowish serum could be expressed from them. At a later period these tubercles declined in size, became less sensitive, shrunk to the level of the surrounding skin, faded generally in depth of colour, and ended by disappearing completely. The skin of this part, however, did not recover its natural pliancy. The patches of the face underwent no remarkable change. During the month of May the internal medicine was continued; the external application was suspended, and gelatinous were substituted for sulphureous baths. The state of the disease was everywhere stationary. During the course of June, the deuto-iodide of mercury was carried to the length of one-eighth of a grain daily, and for five or six days consecutively the sulphur ointment was rubbed upon the affected parts. On the 15th general uneasiness was complained of, and the patient was attacked with vomiting of bilious stuff. There was no fever. These symptoms I ascribed to the deuto-iodide, and ordered it to be suspended for five days; the common effervescing draught checked the sickness. The medicine was not resumed before the 12th of July, when it was again prescribed in the dose of one-twelfth of a grain. Vomiting supervened for the second time, and was now accompanied with fever. Leeches were applied to the epigastrium, and the patient was confined to low diet. The unpleasant symptoms soon ceased.

August.—The deuto-iodide was resumed and continued to the

15th, when it was suspended, and decoction of bark and gentian, with carbonate of iron, prescribed in its stead. The same medicines were continued during the whole month of September. The disease seemed nearly stationary. October 5th.—Uneasiness, retching. 6th.—An erysipelatous point appeared on the face (*mercurial inunction*). 7th.—It extended to the forehead (*V. S. B. ad 3xii*); fever in the evening rather severe; some delirium during the night; the diseased arm became hot, and slightly swelled; the erysipelas spread to the scalp. 9th.—Incessant delirium; decubitus on the back; pupils dilated; no answer to questions; diminished sensibility of skin; prostration; difficult deglutition; breathing deep; skin hot; pulse 110 per minute. (*Venesection in the morning; forty leeches in the evening to the mastoid processes; ol. ricini.*) 12th.—Continuance of the cerebral symptoms; coma; the erysipelas fading. (*Ol. Croton, gttss. 2. Whey with cream of tartar; blisters to the clusters of the cheeks.*)

13th.—The comatose state continues; pulse weak and frequent. (*Ice constantly to the head.*) 14th.—The ice continued; a purgative glyster brought away a copious and foetid evacuation from the bowels; the comatose state ceased; the face was desquamating rapidly. The remarkable point in the history of this erysipelatous fever is this: that many of the tubercles of the forearm and arm shrunk away. The bold lines, too, that bounded the disease above and below, disappeared almost completely. This favourable change, however, was purchased with a severe illness, and a subsequent attack of melancholic delirium, in which the patient fancied her life, and that of her relations, were threatened, &c., and which was not dissipated for many months after her return to her family. She left the hospital on the 1st of November, 1833.

CASE CXXXVI.—Lupus exedens of the left ala nasi. P. F. C., aged thirty-one, entered the Hôpital de la Charité the 3d of April, 1833. Except an habitual cough depending on a chronic bronchial affection, this man had always enjoyed good health until he became locally affected with lupus around the nostrils, about eighteen months ago. At this time, without known or suspected cause, a spot (*bouton*) of considerable magnitude, and of a deep red colour, probably a tubercle, appeared on the furrow corresponding with the upper edge of the cartilage which forms the left ala of the nose, with no other symptoms than a slight feeling of tension and itchiness, that led the patient to scratch the part; this caused it to ulcerate; it became covered with a yellowish scab, by picking which, the progress of the disease seemed to be accelerated. Other tubercles made their appearance in the neighbourhood of the spot first formed; but these did not ulcerate. The skin upon which they were evolved was of a deep-red colour, and covered with squamæ. C \* \* \* had entered himself a patient of the Hôpital St. Louis in March, 1832, six months after the appearance of the disease. There the sore was cauterized; vapour-baths were administered; the parts affected were anointed with an ointment of the deuto-ioduret of mercury; an infusion of hops and chalybeate medicines were prescribed. Various other medicines were subsequently tried, among them the syrup of Cuisinier.<sup>1</sup> Having got considerably better he left the hospital.

When C \* \* \* entered La Charité, the anterior and outer part of the left ala nasi, near its junction with the cartilage of the septum, was destroyed; the part in this situation presenting a semicircular notch, irregular in its outline, of a sallow-red colour, and partially covered with laminated yellowish-gray scabs, which adhered pretty firmly, and clung more especially to the inner surface of the remaining portion of the ala nasi. Externally the skin was of a deep-red, and covered also with small, half-raised squamæ. The right ala nasi was in the same condition, especially in three different places, corresponding to so many small tubercular elevations. The patient only complained of a little smarting in the affected parts from time to time. There was no unpleasant odour, and no discharge. The patient was at this time labouring under one of his habitual attacks of bronchitis, which was acute in its character, but was successfully treated by rest, mild diluents and purgatives.

After washing the nose with decoction of althea, the diseased structures were touched with the nitrate of silver in substance, on the 20th of May. On the 23d, after bathing anew with decoction of althea,

<sup>1</sup> A comp. syrup of sarsaparilla, senna, &c.—7r.

and applying an emollient cataplasm to remove the incrustations which had been but imperfectly got rid of before, the parts affected were touched in the morning with the acid nitrate of mercury. This caused severe pain, which lasted till mid-day. The eschar was not detached till the 27th, after a vapour-bath. The sore appeared covered with small nipple-like projections, and was of a bright-red colour. Fresh laminated scabs soon covered the ulcerated surface; they were thinner than at first, and the vapour-bath, which the patient took every day, caused them speedily to fall. June 5th.—Sulphureous baths and an infusion of hops were prescribed; the latter was replaced by the decoction of sarsaparilla. On the 10th the deuto-ioduret of mercury was ordered in the dose of one-tenth of a grain. Under the influence of these various measures the squamæ and scabs were reproduced with less rapidity, and the small tubercles of the right ala nasi faded.

20th.—The diseased surfaces were again touched with the acid nitrate of mercury, but without any improvement following: the disease was stationary. The deuto-ioduret on the 25th was carried the length of one-eighth of a grain, and continued at this dose to the 14th of July, when the patient requested his discharge, and left the house imperfectly relieved.

CASE CXXVII.—*Lupus exedens of the nose.* M. C. Boulard, a sempstress, aged twenty-three, became my patient in the Hôpital de la Charité, the 17th of September, 1833. This girl is in the habitual enjoyment of good health; she lives in an airy situation, and has abundance of wholesome food. It is now about three years since a scab formed in the inside of the right nostril, without remarkable local phenomena, and when she felt herself in perfect general health. This scab always returned when the patient picked it off with her nail. The part then became *chapped*, pouring out a kind of sanies which concreted into scabs; the chap extended slowly but evidently, and a lenticular tubercle made its appearance on the anterior part of the lobe of the nose. The patient now took various tisans without advantage. The application of a plaster, finally, which was kept open for several weeks, caused much pain, and swelling of the nose and face; a fortnight afterwards the end of the nose sloughed off.

When Boulard entered the Hôpital de la Charité, the one-half of the right ala nasi was completely destroyed, so that the septum could be readily seen; and a second sore, developed in the median line on the point of the nose, had rendered it bifid. The soft parts that ought to have formed the point of the nose were gone, and the lower part of the cartilage of the septum was eroded. In the angles of the sore small scabs of a yellowish-brown colour, were observed resting on moist surfaces of a pale rose tint, and mammillated on their surface. The skin of the nose to the distance of five or six lines from the ulcer was of a deep red, swelled, and covered with squamæ, for the most part of a light gray colour, thin and dry. The transition from the diseased to the sound integument was rapid, and marked by a distinct line, above which, however, a few epidermic furfuræ were still conspicuous. The principal functions were regular; the appetite good; only the catamenia, which had appeared four days too soon, were less copious than wont.

The patient was at first directed to take an infusion of hops, a tonic powder, (℞. Ferri subcarb. ʒ; pulv. cinchon. gr. xxx; pulv. cort. cinnamon. gr. xii.) and to use the sulphureous bath every day. Emollient poultices were further applied to the nose to facilitate the removal of the scabs and squamæ.

Sept. 20th.—Application of the acidulous proto-nitrate of mercury, especially to the angles of the sore. The pain excited by this was severe, and some degree of swelling followed. In three days the eschar had fallen, and the parts were again cauterized; the pain on this occasion was less than at first; no great improvement was perceptible. Yet the redness of the nose had declined, and the squamæ were formed less rapidly than heretofore. The medicines were continued. The catamenia which should have appeared between the 20th and 21st of October failed, and the patient complained of lassitude, general uneasiness and headache.

November 2d.—An erysipelatous blush showed itself upon the nose, and by next day had spread to the cheeks; the inflammation did not

appear very active; headache, tongue foul, thirst (*dilutents; mustard foot-bath, venesection, low diet*). 4th.—The erysipelas has extended to the whole of the face; general symptoms as before; the blood abstracted is not buffy. The scabs in the right nostril are so thick that they obstruct the passage considerably. 6th.—The erysipelas ceased to spread, the febrile symptoms became moderate. 7th and following days, the erysipelas was resolved, and desquamation took place from the whole of the parts which had been inflamed. The lupus was now found to have undergone a remarkable change. The redness about the ulcer had disappeared; the skin of the nose was smooth and white, the eroded parts were dry and covered with scabs of extreme tenuity. (*Sulphureous bath.*)

Towards the end of November the catamenia again failed to make their appearance, and the lupus which had hitherto worn a favourable aspect began to ulcerate afresh. (*Renewed application of the caustic solution; lotions with a wash of sulphuret of potash.*) The lupus again looked better; but the patient became indisposed with febrile symptoms, which lasted to the 15th of November, when the application of fifteen leeches to the external organs put a period to the accidents, during the continuance of which a perforation had been made through the septum narium. The sulphureous baths were again tried, and repeated applications made of the nitrate of silver. The patient quitted the hospital some time afterwards, not sensibly better than when she entered.

CASE CXXVIII.—*Lupus exedens of the chin, cheeks and lips, in a person of scrofulous habit.* A young shepherd, eighteen years of age, was received into the Hôpital St. Antoine, in 1828, labouring under a tubercular affection of the chin. In his youth he had suffered from crusta lactea (*eczema impetiginodes*) of the scalp. At the age of nine the lymphatic glands of the neck enlarged considerably, and several of them formed abscesses and burst, leaving indelible cicatrices under the angles of the jaw.

The tubercles of the chin were of a violet-red colour, considerable size, slightly conical shape and ulcerated on the summit. The ulcerative process soon spread over the whole of the chin, without penetrating deeply among the subjacent tissues. The sore was concealed beneath enormous scabs, nearly an inch in thickness, rising above the level of the skin, and surrounded with a red, and, as it were, erysipelatous blush. The lips, cheeks and nose became rapidly the seat of new tubercles and ulcers; the upper lip was particularly red and swollen. The eyes were inflamed and slightly sensible to the light; there was a large pterygium on the right eye; the conjunctiva of the left was red and inflamed; the lower eyelids of both sides were somewhat everted; the nostrils poured out a plentiful discharge of thick mucus, which dried up under the form of crusts. On the right cheek there were three tubercles in a state of suppuration on their summits; the left cheek and malar region were possessed by a broad but not very deep ulcer.

This patient continued under treatment for nearly a year; bitter medicines internally, and sulphureous baths externally, were employed; the powder of calomel and arsenious acid were applied repeatedly; but despite of all that could be done, new tubercles continued to be developed and to fall into a state of ulceration.

CASE CXXIX.—*Lupus of the nose in a scrofulous subject.* Diogue, aged thirty-six, had menstruated at eighteen, and continued to do so irregularly ever since. At the age of fourteen a *spot* (*bouton*), probably a tubercle, made its appearance on the lobe of the nose, and continued in the same state for about a year, when it ulcerated and was followed by several others. This woman then went into an hospital where she took various medicines—infusion of hops, baths, and the elixir of Peyrilhe, and the ulcer cicatrized, but only after the destruction of the right ala of the nose, and with the contraction of the opening into the nostril of the same side. Two years afterwards the disease recurred, and Diogue became a patient in the same hospital. Under similar treatment, continued for two months, she recovered a second time; but, probably, in consequence of her indolence or her negligence, the right nostril was wholly obliterated, and all that remained of the left one was a hole, scarcely perceptible, and only capable of admitting a thread.

## SCROFULA.

Vocab. *Scrofula, Struma.*

732. The title scrofula, as is well known, is given to a general and constitutional affection, usually proclaimed by glandular or articular enlargements, which are frequently followed by ulcers and fistulous sores. Occasionally, however, this disease appears on the surface of the body, when it is characterized by lesions peculiar to itself; tubercles of a livid red, which remain very long indolent and stationary, make their appearance on different regions of the skin; these end at length by becoming softened and perforated, when they discharge a serous or puriform fluid, which, exposed to the air, dries up under the form of crusts or scabs.

733. The tubercular formations characteristic of cutaneous scrofula are the lesions which it is my object to treat of in this work; not only because the skin is the element in which they appear, and because they have peculiar and distinguishing characters; but, further, because it is often of the highest importance, in a therapeutical point of view, especially, to distinguish these from other tubercular diseases. It is therefore mainly with a view to prevent errors in diagnosis that I have determined to describe cutaneous and subcutaneous scrofula, and scrofulous ulcers in these situations.

734. It would seem that cutaneous scrofulous tubercles may be developed on every region of the body; but they are most frequently seen on the face, neck and upper extremities. They often appear in the vicinity of the scrofulous ulcers consecutive to glandular or indolent subcutaneous abscesses. I have also observed them succeed the bites of leeches in persons of scrofulous habit. They are seldom numerous, and more frequently isolated than in clusters. The *isolated* tubercles commence as small spots or stains of a livid red colour, and unaccompanied with heat, pain or itching. The finger applied to these spots detects something hard, like a grain of barley or small kernel imbedded in the substance of the skin. One or two months after its first appearance, the small spot, which has become gradually more and more prominent, acquires the tubercular character very decidedly. These tubercles are usually no larger than a pea, in some cases they equal a small olive in size. If they increase in size, at a subsequent period, it is only when they begin to soften. This softening, which is one of their principal characters, is accomplished with extreme slowness. It is already perceptible to the touch, before the surface and the circumference of the tubercles show any symptoms of excitement, and very long before they become open. The softening usually begins in several points, when the tubercles are of any size; and each of these softened points occasionally bursts outwardly and very generally at different times. The form of the tubercles is then irregular, they are uneven on the surface, full of depressions and elevations, and often present a small and recent perforation covered with a scab. Under other circumstances, whether in consequence of the softening, after having begun in the centres of the tubercles, extending from thence to their entire masses, whether, after having begun in several places, from ending in the formation of no more than a single abscess, the whole of their superficies becomes soft and fluctuating to the touch. Arrived at this stage, scrofulous tubercles may still remain stationary for a very long time: the skin, red and livid, is neither materially softened, nor perforated, and if the tubercle be now punctured, a few drops of a serous rather than of a purulent fluid escape. The opening continues for a very long while fistulous, and when it does cicatrize, be it naturally or after repeated applications of caustic, a small hard and irregular nucleus or kernel always, or almost always remains in the part affected. Matters are much the same when the tubercle is left to itself, and it bursts after an interval of one or more years; the violet colour of the skin grows less intense, but the induration does not give way in the same proportion. It very rarely happens that true ulcers succeed these little tumours.

735. Cutaneous scrofulous tubercles may occur in clusters of larger or smaller extent. Under this form they occasionally appear on the outer aspect of the arm, forearm, back of the hand and fingers, coinciding for the most part with other evident strumous affections of the bones and conglobate glands. The form and dimensions of these

clusters are rather variable: generally they are not less than an inch, nor more than from two to three inches in diameter. The tubercles thus agglomerated stand out in relief from the skin; they form mammillated or knubbly clusters, the violet-coloured surface of which, is pretty firm in some points where the tubercles are not dissolved, soft and fluctuating in others where this has taken place, moist in those parts where the contents of the tubercles have made their way to the surface, and covered with lamellar scabs in those where the discharge has become hard and dry. When the constitution has suffered profoundly under the influence of scanty and unwholesome fare, and of the privations of every kind that attend upon extreme poverty, the tubercular patches sometimes put on a very peculiar appearance; their surface to a very considerable extent, becomes soft, fungous, of a grayish white or ruddy violet colour, without any morbid increase of temperature and almost without pain, at the same time that it is habitually defiled by a yellowish, and sometimes sanguinolent, serous exudation. This variety of cutaneous scrofula is still slower in its progress and more rebellious to all remedial treatment than the preceding.

736. Subcutaneous scrofulous tubercles are small circumscribed tumours, situated in the cellular substance, under common integument, and developed not only in the vicinity of glandular enlargements but in districts that are free from all other disease, and particularly on the upper extremities. These tubercles are flatter and less movable than enlarged lymphatic glands, and are distinguished at the outset by a small circumscribed lenticular hardness, situated under the skin, which is movable over them, and unaltered in its colour. They usually continue for a long time stationary in this their first stage; insensibly, however, and by very slow degrees, they increase in size, and at length attain the volume of a walnut or small egg.

It is only at a considerably advanced period of their growth that the skin, which had hitherto preserved its natural mobility, becomes adherent to the centre of these subcutaneous scrofulous tubercles; it is also in this point that at a still later period the skin acquires the peculiar livid red colour characteristic, among other things, of the affection which subsequently spreads to the base of the tumours.

The tumours, firm at first under the finger, become soft at length, and if opened at this stage, a small quantity of greenish-coloured, serous fluid, thickened with whitish flocculi or curdy-looking matter, is evacuated. If left to themselves the skin over their centre commonly gets thinner and thinner, and an opening, which is always of greater size than in *cutaneous* scrofulous tubercles, is finally established. The skin is then almost always loosened to the base of the tumour, and is at last destroyed to such an extent that it is no longer a fistulous opening which is presented to us, but an open ulcerated surface. When these tubercles burst spontaneously, their fistulous openings yield nothing but a little serum, and a few curdy fragments, a quantity of which always continue in the tumour and may be expelled by a sufficient degree of pressure exerted on its base. When these tubercles arise near the edges of scrofulous sores, they are evolved and soften less tardily than under other circumstances. Their contents are also occasionally evacuated under the loosened edges of these ulcers.

737. Scrofulous ulcers are consecutive to cutaneous and subcutaneous tubercles; to excoriated chilblains, and indolent abscesses; to caries and white swelling, &c., occurring in strumous constitutions. They are more particularly frequent on the neck, and next on the extremities. They are in general of small extent; yet they are occasionally observed to multiply astonishingly in some particular region of the body, and to destroy, for instance, the skin of the neck, and a considerable portion of that of the chest and shoulders.

The isolated cutaneous tubercle seldom proves the primary cause of true ulceration; it frequently shrinks, and cicatrizes, after becoming softened. This kind of tubercle of a large size, however, does occasionally end in an ulcer, the dark red or livid, hard and indolent edges of which penetrate deeply into the skin.

The edges of the ulcers consequent on *cutaneous* scrofulous tubercles collected into clusters, are of a brightish red, considerably swollen, not very painful, and apt to bleed on the slightest touch. Those of the ulcers that follow *subcutaneous* scrofulous affections,—tubercles, enlarged glands, indolent abscesses, caries, &c., present several pecu-

liarities: they frequently form loose flaps, detached from the subjacent tissues, doughy, and very commonly of a livid red colour, which indicates very accurately on the exterior, the distance to which the loosening extends internally. The *bottoms* of scrofulous ulcers of the skin, consequent on agglomerated and confluent tubercles, are often pale and without granulations, but puffed and flabby. The discharge from these ulcers is sanious rather than purulent, and, in drying, forms greenish and brownish incrustations, which are by and by detached from the surfaces to which they adhered by a fresh secretion of the sanious fluid. The bottoms of these sores in other cases remain constantly bedewed with this peculiar secretion, and are very uneven, and of a yellowish-gray in different places. The lymphatic glands in the vicinity of such ulcers are frequently enlarged; in the neck especially, they seem now and then to form a kind of case for the sore; at other times, again, they appear as lumps lying at their bottom or clustered like a chain around their circumference. The open mouths of fistulous passages, which run towards softening tubercles or indolent abscesses in the vicinity, are frequently to be observed on the surface, or under the loose edges of these ulcers. When this is the case, and the fistulæ are long and tortuous, the discharge is apt to remain, and occasion burrowing under the skin and the surrounding structures. It happens occasionally, also, though very rarely, that gangrenous eschars of a brownish-gray colour, are formed at the bottom of scrofulous ulcers. To conclude, in those cases in which the periosteum is exposed by the progress of scrofulous ulcers, this membrane swells and becomes covered with soft grayish-coloured fungous excrescences.

The progress of scrofulous ulcers is, in general, extremely slow; they frequently continue for years together without any material alteration in point of extent or otherwise. The ravages they commit, and deformities they occasion in some cases, although very extensive, are the work of so tardy a process, that their progressive amount is not perceived; it is only discovered in the end. Scrofulous ulcers differ visibly in this particular from those characteristic of lupus *exedens*, and of the serpiginous or *phagedenic* syphilis. Some cases, however, are on record, designated as *scrofula* (whether this disease were confounded with a lupus, or a syphilitic affection, or there existed an actual complication of one or other of these affections with true scrofula, or whether they were scrofulous ulcers that had been accidentally irritated, it is difficult to say), in which the progress of the disease is reported as having been much more acute.

738. Whether the cure of a scrofulous ulcer is accomplished spontaneously or under the ministration of art, it always takes place with extreme slowness. The surface of the sore looks less pale, its edges not so hard, not so livid, and are less disposed to bleed; it is then covered with granulations of a clearer rose colour, and the discharge becomes whiter and more consistent. The cicatrice that results long continues red, shining, easily torn, puffed and uneven. To this red colour of the scar, a bluish tint succeeds by slow degrees; its surface sinks, and its margins still puffed, often present irregular lumps in their course, a species of consecutive tubercles which are very long of disappearing. The skin frequently exhibits irregular bands which bear a great resemblance to the cicatrices of burns, and here and there numbers of whitish, rounded, and soft inequalities, produced by an excess of integument, and a lax state of the portions that have escaped alteration; these having been long distended and lost their elasticity, recover it very slowly, and are puckered up by the newly-formed cicatrices as they shrink and gain solidity. It is not till after the lapse of several years that the cicatrices of scrofulous sores become white, and that these puckerings of the skin disappear. As to the newly-formed bands, like those that follow extensive burns, they are never absorbed entirely.

739. Scrofulous ulcers are occasionally formed under, or in the neighbourhood of the nails (*scrofula unguealis*). Whether the phalanges of the fingers have been primarily swelled, softened, and ulcerated, or not, these scrofulous sores are generally observed to commence in a swelling which attacks the skin in the neighbourhood, of the nails, especially towards their roots. This swelling increases slowly and forms a puffy rim of a livid red colour, which ulcerates and grows fungous at a subsequent period. The bone of the last phalange frequently enlarges; the whole finger swells, and its extremity acquires

the shape of a little club. The nail then becomes misshapen, looks black, grows soft, and is partially detached. In this state the extreme round of the pulp of the finger enlarges and forms a kind of fungous ring, in the centre of which the diseased and partially loosened nail is perceived. The nail is at length thrown off, and an irregular reddish, naked surface is left, from which misshapen horny productions are thrown out. These often take a faulty direction, and by their irritation tend to keep up inflammation in the surrounding parts.

740. Individuals affected with scrofulous tubercles or ulcers, further, almost invariably exhibit other morbid phenomena characteristic of the *strumous constitution*. The most common of these are enlargements of the lymphatic glands, chronic inflammation of the edges of the eyelids, chilblains, sores, indolent abscesses, and white swellings of the structures about the joints, caries and tubercular affections of the bones, pulmonary and mesenteric tubercles, &c. Attention to these different symptoms may frequently be of service in doubtful cases, inasmuch as they lead us to the true nature of certain cutaneous and subcutaneous tubercles, and of the ulcers which succeed them.

741. Individuals who are the subjects of scrofulous affections are usually of fair complexion, with light or clear brown hair, large blue eyes, the pupils dilated, and the sclerotic coat of a bluish tinge; the point, and especially the alæ of the nose, and the upper lip are often thick and swollen; the nose secretes habitually in excess; the lips chap and become painful in winter; the teeth are disposed to get incrustated with tartar; the jaws are large; the cranium is often shaped like a calabash; the chest is narrow, the thorax generally contracted, the belly large, and the articulations bulky. One or several of these characters are very commonly observable; it is seldom that they all occur together. It is also to be observed that individuals with black hair and dark eyes, and who do not appear at all deficient in vigour of constitution, are occasionally seen the victims of scrofula, which appears then to be developed under the influence of the law of hereditary descent, or in consequence of insalubrious regimen.

742. *Diagnosis*.—The diseases with which the tubercles and ulcers of scrofula may be most readily confounded are the tubercles and ulcers of lupus, syphilis, and cancer. But independently of the fact that cutaneous scrofula is almost always accompanied by other alterations proper to the general affection, and by unequivocal indications of the strumous constitution, the tardy progress of scrofulous tubercles, which become inflamed internally, and then cause perforations of the skin, the pale and fungous appearance of the ulcers, and their violet and frequently loosened edges, admit of no mistake in the diagnosis.

743. *Prognosis*.—The development of a scrofulous tubercle or ulcer, however trifling its extent, is always a serious affair, for it is one of the manifestations of a constitutional disease, the cure of which is always effected with difficulty, which the progress of years may modify, but will rarely destroy completely, and which is frequently transmitted hereditarily, even when the principal characters of the affection have disappeared. In a particular case, the number, extent, and gravity of the concomitant lesions, when any exist, their character, and their development before or after the age of puberty, are so many circumstances, the due appreciation of which is of the highest importance in predicating with regard to the effects and final issue of the disease.

744. *Treatment*.—The basis of the treatment of scrofula may be thus laid down:—The first and main object must be to accomplish some modification of the constitution by means of appropriate regimen, habits, and exercises. Practitioners are generally agreed in recommending a warm climate and dry atmosphere, living in a healthy situation, exercise in the open air when the season and the weather permit, the use of the temperate or cold bath, dry frictions of the skin, &c. The diet requires particular attention. Good animal food:—beef or mutton, roasted or broiled; bitter, or, as they are termed, anti-scorbutic vegetables,—endive, water-cress, &c.; fresh eggs; roast poultry or game; fresh fish; good beer, or generous wine, mixed with some sparkling slightly chalybeate water, appear to compose the aliment and drink most appropriate to the scrofulous diathesis.

The action of certain therapeutic means have been found, when combined with these most indispensable and primary measures, to aid

their action and to hasten the cure of scrofulous affections. In the first rank of these additional remedies must be placed sulphureous sea-water, and iodated baths. Sulphureous water baths may be readily prepared and administered at all seasons, and their action regulated with the greatest nicety. Besides the general curative effects of these baths, they are found to preserve children from colds and chilblains during the winter, whilst in summer they brace the frame against the enervating effects of the heat. The tub in which this bath is administered, requires to be thoroughly cleaned out several times a year at least.

When sea-bathing is adopted as the principal curative means, patients, after having gone through the season, should be afterwards put into an alkaline bath at intervals, to cleanse the skin.

The preparations of iodine, administered by way of bath and internally, are often of singular efficacy in scrofulous complaints. Iodated baths, in which the iodine is held dissolved by means of the ioduret of potassium, act very advantageously locally, by their active principles being brought into immediate contact with the tubercles and sores, as well as generally, by the absorption of these into the system. I occasionally direct the iodated and sulphureous water-bath to be taken alternately. Whilst the iodine is employed externally in baths, this medicine is commonly exhibited at the same time internally, being begun in doses of half a grain during the first fortnight; three-quarters of a grain during the second, and a grain during the fourth. In every case the half of the dose is to be taken early in the morning; the other half before dinner.

745. The antiscorbutic syrup<sup>1</sup> in doses of from half an ounce to a whole ounce; the bitter tincture of gentian in doses of from two to three drachms; the infusion of hops and other bitters, are also very commonly prescribed for scrofulous children.

746. Other medicines, such as the hydrochlorate of baryta and of lime, the subcarbonate of soda, chalybeates, and mercurial preparations, have also been all severally and particularly recommended in scrofulous cases. (a)

747. The treatment of scrofulous tubercles and ulcers, by local means, although of less importance than that which is directed with a view to modify the constitution, is still deserving of very particular attention: the resolution and suppuration of the tubercles are accelerated by rubbing them with an ointment either of the deuto-iodide of mercury, or of the iodide of sulphur.

The ulcers are stimulated into better action by washing their surface with wine, a weak alkaline solution, or a sulphureous or iodated water, by dusting them over with citric acid, burnt alum, cream of tartar,

(a) Preferably to simple iodine, in the treatment of scrofula, is its combination with an alkali or metal, as in the iodide of potassium and the iodides of iron and zinc. The dose of the former, for a young subject, will be from a quarter of a grain to a grain gradually increased to three grains in the twenty-four hours, in watery solution. The favourite preparation just now, is the iodide of iron in the form of *liquor ferri iodidi*; as directed by the American Pharmacopœia. Dose, ten to thirty or forty drops, according to the age of the subject, twice a day in a little sugar and water. Biniodide of potassium and biniodide of iron are, also, of late well spoken of in scrofula; the former in a dose varying from half a grain to four, and even ten grains three times a day, according to the age of the patient.

Cod-liver oil is also one of the new remedies—nearly enough to have more virtues than it really possesses. For further details of practice in scrofula, and pathological views of the disease, the reader is referred to *Bell and Stokes's Lectures on the Practice of Physic*, vol. ii.

In subjects not very anæmic, and whose digestive system is not materially irritated, I can suppose that Donovan's solution given in small doses, watching carefully its operation, would be attended with resolutive and other good effects in scrofulous tubercles.

The formulæ of the stimulant, rubefacient and caustic solutions of iodine, recommended by M. Lugol for scrofulous ulcers, and of baths in the early stages of the disease, will be found in the different works on *Materia Medica*.

<sup>1</sup> A compound syrup of cochlearia amonica, bitter orange-peel, &c.—Tr.

calomel, &c., by covering them with poultices of sorrel, hemlock, seaweed, and various other topical applications, charged with sulphur or iodine. Fungous growths and loose edges require to be removed with caustic or the knife, when there seems no prospect of a better action, or an adhesive inflammation; a free passage for pus must be established, and fistulous passages laid open when they are discovered in the vicinity of ulcers; bony sequestræ must be searched for, if suspected, and extracted, if any be discovered, when the bones are affected, &c. To conclude, when by means of regimen, combined with internal and local treatment, the ulcers are brought into the condition of simple suppurating sores; their surface must be touched from time to time with the nitrate of silver, or sulphate of copper; their edges approximated by means of adhesive straps; and every attention paid to securing cicatrices that shall be as little unsightly, and cause as small an amount of deformity as possible.

748. Scrofulous sores about the nails occasionally prove obstinate to all these measures of general and local treatment, especially when the chronic inflammation of the matrix of the nail is kept up by the production and presence of the irregular horny substances that have been mentioned. In the severest cases there are puffing and softening of the unguiferous phalange, and this state is followed by such interminable fistulæ that some surgeons then recommend the amputation of the joint as the best and speediest way of getting rid of the evil; this last remedy, however, may generally be safely deferred indefinitely; the deformed nails that are thrown out being alone removed, and the progress of years confided in for bringing about the recovery of the part.

#### *Historical Notices and particular Cases.*

749. The principal morbid changes produced by scrofula, such as glandular enlargements, swellings about the joints, caries of the bones, indolent abscesses, fistulous passages and ulcers, &c., were long ago described with much care and precision; but it was in vain that treatises, *ex professo*<sup>1</sup> even, were searched in the hope of finding a good account of *cutaneous scrofula* in any of its forms, distinct and isolated, or in clusters, or even of *scrofula unguealis*. M. Alibert was the first who saw the propriety of forming the scrofulous affections of the skin into a distinct group.

M. Lugol has detailed a very interesting case of *tubercular cutaneous scrofula in clusters*, and several instances of scrofulous ulcers successfully treated by the preparations of iodine. Mr. Lemasson has published several facts in favour of the combined action of opium and iodine in the same class of complaints.

In several recent works, *scrofula unguealis* is vaguely hinted at, or noticed, mixed up with other varieties of onychia. M. Delpech,<sup>2</sup> however, perceived, and has stated his opinion broadly, that spontaneous onychia might be owing to a scrofulous affection of the matrix of the nails.

When any affection of the skin, other than the one I have described under the name of scrofula (acne, eczema, impetigo, &c.) occurs in an individual of strumous constitution, this condition of the system occasionally modifies the symptoms, and always influences the treatment of the eruption: these facts, however, do not authorize us in considering the accidental disease as a manifestation of scrofula. It is in this point of view that M. De Vering<sup>3</sup> appears to have pushed too far a consideration otherwise of the highest practical value.

CASE CXXX.—*Ulcerated scrofula. Stationary tubercles of the cheeks, and backs of the hands.* A girl, fourteen years of age, of a scrofulous habit, was brought to me for advice, May 10th, 1825. From the mother I learned that this girl had suffered, during the time of teething and subsequently, from sore eyes, which were long of getting well, and kernels under the chin. After her tenth year, several tubercles had also been evolved upon the face. When presented to me, the right ala of the nose, which was red and swollen, was covered with a yellowish-white scab, and the cheek of the same

<sup>4</sup> Vering. *Manière de guérir la maladie scrofuleuse*, 8vo. Vienna, 1832.—§ Des maladies cutanées scrofuleuses.

side was occupied by three tubercles unulcerated, and a fourth whose centre was concealed by a thin brownish incrustation. A tubercle of the same description is seated on the left cheek. The skin of the cheeks in the vicinity of the *alæ nasi* is of a violet-red colour; the lips, especially the upper one, are swelled; the right eye is injected, and the edges of the eyelids are slightly glutinous; the submaxillary glands are enlarged. A large indolent, flat, violet-coloured unulcerated tubercle exists on the back of the right hand. The organs of the chief functions appear to be quite healthy. (*Weak infusion of gentian, and ʒi of the compound syrup of cochlearia daily.*) These medicines were taken pretty regularly for eight months. Towards the end of the treatment two applications of the powder of calomel and arsenious acid (*poudre de M. Dupuytren—vide § 725*) brought about the cicatrization of the ulcer of the nose. The tubercles of the cheek and back of the hand had disappeared, but the skin still continued somewhat swollen, and of a violet colour, in the situations which they had occupied.

CASE CXXXI.—*Scrofulous tubercles of the left forearm.*—Justine Geoffroy, aged twenty-six, of scrofulous constitution, never having had any serious illness. When thirteen years old she had had a small abscess on the left forearm. Six years later, a pimple (*bouton*), which she likened to a large pea, appeared in the same place, but got well in the course of six months. Last winter the patient suffered from chilblains, and the disease reappeared in the old place. At one time the catamenia ceased, and the sore on the forearm by bleeding seemed to supply this discharge. There have always been, and there still remain, several enlarged glands under the lower jaw on the left side.

April 5th, 1830.—On the dorsal aspect of the forearm, two inches above the wrist, numerous mammillary tubercles, isolated or disposed in clusters, and projecting above the level of the integuments, are perceived. Each cluster seems to rest upon a common basis, being separated from its neighbour by depressions or clefts, which are ulcerated in the points where they are narrowest. The surface of the tubercles is moistened with a purulent secretion, and in some places covered with a kind of bluish-coloured false membrane. The size of the mammillary eminences varies between that of the head of a pin and that of a large pea. Another cluster of tubercles, somewhat more numerous, occupying a larger space, and covered with indolent sores, is seen near the one above the wrist; and several isolated tubercles are scattered over spaces which are separated from each other by cicatrices of a general red or livid colour, but presenting whitish points here and there. Several more tubercles, covered with a small scab, also occur disseminated in the neighbourhood of the principal alterations, but still separated from these by bands of healthy integument. A few enlarged lymphatic glands are seen on the left side of the neck. The patient is in pretty good general health; the catamenia are regular. (*Tonic regimen; compression of the tubercular masses.*) April 12th.—The mammillated tubercles have shrunk under the effects of the compression, and here and there small scabs have been formed; a little yellowish pus is deposited between the masses. Next day the patient complained of having suffered great pain in the forearm, and a number of small irregular ulcers, a line or more in depth, were found checkering the mammillary eminences, and giving them the appearance of excrescences.

24th.—The compression appears to have increased the extent of several of the sores; the parts were touched with the acid nitrate of mercury. May 5th.—Compression was renewed on the first of this month, and the tubercles, more and more shrunk, were now almost level with the skin. The sores were getting well. June 18th.—Up to this date the whole of the sores had been gradually healing up, and were now all skimmed over; but on this day the patient complained of pain; the arm became hot; and the upper part of the cicatrice, which had continued of a purple colour, appeared beset with a number of pale yellow points, evidently consisting of purulent matter. These, next day, broke into small round ulcers, between each of which the skin looked pasty and infiltrated; many of them met by their edges on the day following, giving rise to broad irregular ulcers, with yellowish bottoms. Emollient cataplasms, and subsequently sulphur-baths were prescribed. The sores were all whole by the 18th of July, but small purulent points of the same

description, and ending in the same way, still made their appearance from time to time. The patient was discharged on the 12th of November, at her own request, not completely cured.

CASE CXXXII.—*Cutaneous scrofula. Tubercles agglomerated.*<sup>1</sup> César Mortreux, aged seventeen and a half, sprung of healthy parents, but born labouring under small-pox, which was in the family at the time of his birth, so feeble that till he was two years old, it was not supposed he could live. At this age the disease under which he now laboured made its appearance, and his general health seemed to improve. Scrofulous abscesses formed in the neck, buttock, thigh, leg and back of the left hand; the sore that resulted in the last-named situation was much longer of healing than any of the others, and when this was nearly well, scrofula, in another guise, took possession of the backs of the fingers, from whence it spread successively to the wrist, forearm and arm. Within the last fifteen months the disease has made very rapid progress, particularly since the insertion of an issue into the arm in the spring.

July 30th, 1828.—The skin on the dorsal aspect of the wrist was hard, hypertrophied, of a violet-red colour, and diminished in its sensibility; that of the back of the thumbs and remaining fingers presented growths from a line and a half to two lines in length, separated by chaps in the skin, and bathed in a grayish-coloured pus. These growths were covered on their tops with yellowish incrustations, which became soft when bathed, and were then readily detached, leaving the summits of the productions they covered of a delicate rose tint, and sensible to the action of the air. The matrices of the nails were deeply affected; the nails were long and all turned away from the thumb side of the hand; their dorsal surfaces were rough, and generally of a deep gray colour; those of the ring and little finger were entirely black. Patches of growths, of a similar description, two inches in diameter, existed on the dorsal aspect of the wrist joint; two on the inner surface of the forearm were of the dimensions respectively of a crown-piece, and three or four more of rather less size appeared on the posterior surface of the same part. Around the elbow there was an assemblage of at least nine principal patches, of a round shape, and varying from one to two inches in diameter, in general confluent, but in some places leaving narrow intervals in which the skin appeared to be in the normal state, though presenting here and there a few red pustules, which appeared to be the rudimentary forms of the disease; and, in fact, the whole of the patches did finally become blended together by the development of these pustules; so that the elbow was at last surrounded by a diseased surface, five inches in length, by about four in breadth, very similar in its appearance to the patches which have been already described, although the growths in this situation were neither acuminate nor isolated by chaps of the corion.

In addition to these diseased patches, a great number of small pustules were scattered over the forearm and arm. These pustules were generally of the size of pins' heads, though some of them were considerably larger; the latter, under the magnifying glass, appeared to be made up of two or three elementary pustules united. The patient informed us that the whole of the patches on the arm and forearm had been originally formed by the agglomeration and subsequent development of pustules still smaller and redder than those we were now examining. The patches of the fingers were the only ones whose mode of formation he could not recollect.

The skin of the limb generally was hypertrophied, indurated, dry, and presented more or less of a violet hue, especially on the back of the wrist, where it was also less impressionable than in other parts. The whole of the diseased patches that have been mentioned were primary; no one had ever healed, nor changed its place. Those on the fingers only had got well at one end whilst they were advancing on the other; so that the parts on the dorsal aspects of the fingers which were now healthy had once been diseased like those that still continued so. The disease had only once appeared to receive a check; it had even appeared tending to recovery: about the age of eleven, in the month of August, the growths shrunk, the suppuration became greatly lessened, and even ceased entirely for a time during the winter; but on the return of the fine weather the disease also

<sup>1</sup> Iconographie pathologique, in-fol. Paris, 1829, pl. 4. Obs. de M. Lugol.

returned, and has since continued to advance uninterruptedly. The patient has never suffered from local pain, neither has his sleep been once disturbed in the last fifteen months during which this *cutaneous scrofula with morbid growths (scrofula cutanée végétante)* has been spreading with alarming rapidity over the left arm.

Besides the scrofulous cicatrices, of which mention has been made, Mortreux had prominent cheek bones, a thick nose and upper lip; but his skin was bronzed and swarthy, his hair brown and thick, and he showed a generally strong and well-knit frame. The digestive organs were healthy, though the bowels were habitually confined.

The disease was at first treated by iodine and iodide of potassium externally, and iodine internally. The external application was followed by pain and paroxysms of pruritus of the most violent description which were frequently renewed in the course of the day. This treatment, continued for six weeks, did little good, and it was then determined to treat the disease locally in four different ways: 1st, with the iodated iodide of potassium in friction over the elbow; 2d, with the proto-iodide of mercury in friction over the fingers; 3d, with the white oxide of arsenic in friction over the anterior aspect of the arm; and 4th, with the acid nitrate of mercury as an escharotic, over the posterior surface of the limb.

The inunction over the elbow was attended with extreme pain, and the most violent pruritus, and occasioned a very profuse secretion of pus. The growing pustules, however, shrank away. The more circumscribed patches became covered with incrustations, and only secreted a little matter about the centres of the diseased surfaces, which also appeared on the way to recovery. The inunction over the fingers proved less efficacious; nevertheless the diseased patches healed around their circumferences, and the neighbouring skin appeared to differ less from the standard condition. The application of the acid nitrate of mercury succeeded the best of all, especially in regard to a patch situated on the outer surface of the wrist, which had at first been rubbed with the proto-iodate of mercury, a plan of treatment under which it had at first improved rapidly, but soon became stationary. This patch is now (Dec. 29, 1828) nearly healed, after five applications of the escharotic made in the course of nearly two months. The arsenical application seemed to do much good in the first instance, but the amendment did not make any progress. An additional dose of the white oxide of arsenic did not seem to give the medicine any new power over the disease; and as this was a circumstance I had observed in a great number of cases, I ordered this part of the treatment to be given up, and frictions with the iodated iodide of potassium, which had been employed over the elbow with progressive success, to be substituted in its stead.

The watery solution of iodine was administered internally in graduated doses, until a grain of the medicine was taken daily. This quantity has been taken for a month. The other curative means employed were baths for the arm, of a decoction of bark, and a decoction of bran, with the addition of sulphuret of potash; three sulphureous baths were also taken through the week, and three ounces of the compound syrup, or wine of cochlearia, every morning, together with a pint of barley-water, made palatable with syrup of tartar, as drink during the day. Let us just observe, before concluding, that the most efficient of the local measures excited profuse suppuration. I have had occasion to witness this property of the iodine in a very great number of cases. The acid nitrate of mercury also causes a very copious purulent secretion, which makes its way through the eschars, causes them to fall off, and produces incrustations, which, as the diseased surfaces get well, are subsequently less and less frequently renewed.

CASE CXXXIII.—*Scrofula unguæalis*.<sup>1</sup> A villager, aged twenty-four, who had suffered in his youth from indolent abscesses and other symptoms of scrofula, began to complain towards the end of the year 1820, of pain and swelling in the great toe of the left foot, to which succeeded a sore, which at first surrounded the root of the nail, and then extended under it; so that at length the nail became loose, and detached at all points, except its posterior edge. The nail itself was soft, filamentous, readily torn, and was turned back towards the dorsal aspect of the foot; it seemed, like a foreign body in the midst of parts in a state of ulceration, to keep up their irritation: attempts had con-

sequently been often made to destroy it entirely by taking it away; but it was speedily reproduced with the same defective structure as before. This state of affairs continued to January, 1822. The patient was received into the hospital Saint Eloi, at the same time as another patient, labouring under a syphilitic affection of the matrices of the nails. The appearances in these two cases were the same; but the cause, and consequently the essential conditions in each were very different. The scrofulous patient had never run the risk of a venereal affection, &c. He was put upon a diet of animal food and wine, and took bitter and tonic medicines alternately with one of the alkalies: gentian, bark, oxide of iron, and carbonate of soda, were the articles employed; emollient cataplasms and local baths were at the same time prescribed. At a later period, baths, with a solution of the carbonate and even of the pure potash, were tried; the baume vert de Metz,<sup>2</sup> a solution of the muriate of mercury, and then of the nitrate of silver, were one after the other used as transient stimuli. The patient continued under treatment for nearly four months, but the effects of the system pursued were ultimately as favourable as those that followed in the case of syphilitic origin alluded to, under the influence of mercurial preparations. The sore cicatrized, and the nail was reproduced with its pristine consistence, its colour, and nearly its shape.

## CANCER.

Vocab. *Cancer, Noli me Tangere, &c.*

750. Cancer of the skin is proclaimed by one or more tubercles, which, after an interval of time, greater or less in extent, become the seat of acute lancinating pains, and end in ulcers, the surfaces of which sprout in the form of fungi, or, otherwise, which deeply destroy the skin and neighbouring parts. These tubercles consist, in part at least, of scirrhus tissue, or cerebriform matter, the presence of one or other of which constitutes their distinguishing anatomical character.

Cancer of the skin shows itself under five principal forms. 1st, cancer *vulgaris*, or common cancer; 2d, *melanic* cancer (*anthracine*); 3d, *leucoid* cancer; 4th, *mollusciform* cancer; 5th, and lastly, *verrucous* cancer (chimney-sweeper's cancer).

751. Cancer *vulgaris*. The tubercles that characterize this variety may be isolated and solitary, or numerous, and either collected in clusters, or widely disseminated. They are most frequently evolved on the hairy scalp, face, lips, nose, margin of the anus, and about the genital organs. They vary from the size of a grape stone to that of an olive. They are hard and solid, and in their earlier stages do not differ from the surrounding skin in colour. They are occasionally observed to continue indolent for several years; or, from the very date of their appearance, to be the seat of violent pruriginous sensations, or of lancinating pains. Accidentally irritated, these tubercles enlarge, grow livid, and constantly occasion acute suffering, though they may have remained perfectly indolent up to this period; their bases then widen, and extend more deeply; chaps form on the surface, which, at times, pour out some yellowish and sanguinolent serum; under other circumstances, again, the cuticle covering the tubercles is detached from the corion, by the effusion under it of a serous fluid, and the exposed summits of the tubercles then become softened and ulcerated.

752. The ulceration that succeeds, presents itself under three distinct forms: 1st. The ulcer, of varying depth, exhibits a fungous and uneven surface, which, by exposure to the air, becomes hidden under a brownish incrustation; its edges are hard and everted, and the surrounding skin is frequently traversed by small blue veins—the *chancre-like* cancerous ulcer. The pain of a lancinating kind is usually very severe at this period, and is sometimes compared by patients to the passage of red-hot needles through the seat of the disease. Left to itself, the ulcerative process continues to advance among the neighbouring parts. One-half, and more, of the face, has thus been seen destroyed by these *eating* or *phagedænic* cancers, which several pathologists have characterized by the title of *noli me tangere*. 2d. At other

<sup>1</sup> Delpech. Clinique médicale de Montpellier, 4to., t. i. p. 367.

<sup>2</sup> A terebinthinate liniment of the sub-acetate of copper.—Tr.

times the surface of the excoriated tubercle becomes covered with small mammillated elevations, which give it very much the appearance of a mulberry, a state in which the disease may long remain stationary. In this case there are commonly several cutaneous and subcutaneous cancerous tubercles disseminated over the surface of the body. These *mulberry* cancers occasionally attain the size of a walnut; the fluid they secrete dries upon the surface in layers, which, by accumulating, form, at length, prominent scabs, occasionally a little twisted, which have been likened to, and entitled, horns. These scabs are detached by and by, and the tubercles are succeeded by *chancre-like* ulcers. 3d. Under still other circumstances, the growths that spring from the surface of the excoriated tubercles, are much more considerable than in the variety last described, and a tumour results, having a fungoid appearance, and secreting a sanious or sanguinolent fluid from its surface; this constitutes the *fungiform*, or *fungoid* cancer of pathological writers. Where the morbid growth expands superiorly, whilst its neck retains the original dimensions of the ulcerated tubercle, the disease has been entitled *pediculated* cancer. This variety is in general less painful than the phagedænic cancer. It is also almost always solitary. 4th. There is another mode, much more rare, indeed, in which I have seen cancerous tubercles terminate; this is in *gangrene*. The woman in whom this occurred, laboured under a tumour of the right ovary, cancer of the right breast, and cancerous tubercle above the left eyebrow. This tubercle, on a sudden, became very painful, assumed a deep-brownish or dusky-red colour, and losing all sensibility, it came entirely away with the diachylon plaster I had applied to its surface. The tubercle thus detached, exhaled a distinctly gangrenous odour. The resulting sore suppurated kindly, and by and by healed up completely of itself.

753. The tubercles of common cancer are frequently evolved in the *subcutaneous cellular tissue*, where they appear under the form of small movable tumours like grains of wheat, which is painful under pressure. These subcutaneous cancerous tubercles, which must not be confounded with the small tumours occasionally developed in the course of a nervous twig, sometimes continue stationary for an indefinite period; at other times they increase until they equal an egg in size, when they usually become attached to the skin, in which a very remarkable vascular network is then frequently developed. By and by the integument inflames, softens, and gives way, and a fungous growth, after a certain lapse of time, very commonly makes its appearance from the bottom of the ulcer.

754. The tubercles of common cancer have particular anatomical characters. If at their commencement they appear to consist of a mere thickening, with induration of the corion, the indurated parts, at a later period, acquire a considerable resemblance to a mass of lard (*scirrhus*). When they are incised lengthwise, and their interior is examined under the magnifier, they are found principally to consist of a lardaceous tissue, traversed by whitish lines or bands, analogous in point of colour to the fibro-cartilages. After maceration, these tubercles, stripped of their cuticular covering, almost always present a mammillated surface. When they are softened in a slight degree, a whitish matter can be forced out of them by pressure. Besides the peculiar scirrhus tissue which has now been described, cerebriform matter is frequently met with in these small cancerous tumours.

755. Melanic Cancer (*Anthracine* Jurine). Under this title have been described certain small tumours of a melanose appearance, which approximate those of an undoubted cancerous nature in the acute pain which accompanies them, in their tendency to ulceration, and in their disposition to grow again when they have been extirpated. These small blackish and painful tumours would seem to be distinct in their nature from those of pure melanosis, which are most commonly indolent, and occasionally evolved in the corion, as well as in the subcutaneous cellular tissue. Yet if they bear affinity to cancer in their symptoms, and in their tendencies, a lack of exact and often enough repeated anatomical inquiries, leaves us still in doubt whether or not they, like certain cancerous tumours of the liver, contain a mixture of scirrhus tissue or of encephaloid matter, with a portion of melanic substance; perhaps they constitute a mere variety of the melanose tumour. However this may be, these little tumours, according to Jurine, begin as minute black or bluish, and usually itchy spots, which take the form of tubercles slowly, and subsequently

acquire that of true *tumours*, the centres of which are generally more depressed than their circumference.

The tubercles of this variety of cancer sometimes partially lose their original black colour; their base acquires a bistery hue, and their centre something of an olive shade. They scarcely attain the size of a strawberry in some cases, before the integuments give way, with acute and lancinating pains; an ulcer, with fungous and ragged edges, is formed, which pours out a sanguinolent sanies habitually, and at times bleeds profusely. Ulcers of this description are as inveterate as those of common cancer, and M. Alibert is of opinion that the species of tumour which occasions them is even more apt to be reproduced, when extirpated, than those of the other varieties of cancer. Repeatedly, and after cures that were believed to be complete, black points have been observed to appear in the neighbourhood of the cicatrices, which were never long afterwards of spreading and becoming open ulcers.

756. Messrs. Marjolin and Blandin,<sup>1</sup> under the name of *melanic* cancer, have described a subcutaneous tumour, consisting of a hard mass, which occupied almost the whole of the palmar surface of the right hand, and extended over a portion of its dorsal aspect; this tumour was irregularly rounded, lobulated, and traversed by a longitudinal furrow; it was accompanied by pain of a lancinating kind, and its centre, which was ulcerated, uneven and of a livid hue, poured out a fetid ichor. The hand was successfully amputated by M. Blandin. The tissue of which the tumour consisted was hard, of a slate gray, or blackish tint, *creaking under the scalpel*, and under pressure yielding a fluid which stained linen like China-ink; the deep-seated veins of the palm were very much enlarged.<sup>2</sup>

Under the name of *melanic sub-ungual* cancer, M. Dubourg<sup>3</sup> has given the details of a spherical tumour, four inches and a half in circumference, of a blackish colour, mammillated on its surface, the seat of lancinating pains, and presenting here and there erosions, from which slight hemorrhage occasionally took place. The disease had commenced thirty years previously without evident cause: a small black line made its appearance under the nail of the little finger; this continued stationary for twenty-seven years; during the last three years only had it extended, and by degrees spread to the whole surface covered by the nail. At the end of a year the nail was detached, and was succeeded by black fungous excrescences, which increased rapidly in size, assumed a globular form, and exhaled a fetid smell. After amputation, the tumour was found very similar, in its colour and consistency, to a large softened truffle; a larger quantity of fluid than of solid matter, entered into its composition.<sup>4</sup>

M. Lisfranc once removed a melanic cancer, the size of the fist, from the left cheek. The tumour, which was uneven on its surface, had been the seat of pretty severe lancinating pains; it had grown very rapidly, and was accompanied with an enlargement of the sub-maxillary glands. The skin, in its vicinity, was of a violet colour.<sup>5</sup>

757. Before bringing this subject to a close, I think it right to state that if some pathologists, taking the character of the pain with which these melanic tumours are generally affected, their termination, in a very great number of cases, in a fungous ulcer of bad character, and their disposition to be reproduced after having been extirpated into account, have held themselves authorized to consider them as a variety of cancer; others, on anatomical grounds, and insisting especially on the fact of no scirrhus tissue, nor cerebriform matter having been demonstrated in their composition, have assigned them their place along with the melanoses. For my own part, it seems to me evident that certain soft and indolent melanic tumours ought to be separated entirely from cancer; but I think, on the other hand, that those which are attended with lancinating pains, which shoot again

<sup>1</sup> Journ. Hebdom., t. iii. p. 459.

<sup>2</sup> I have noticed this case with a view to show that *melanic* tumours are nearly akin to those of a decidedly cancerous nature, as regards the character of the pain that attends them, the appearance of the ulcers to which they give rise, and the hardness of their tissue.

<sup>3</sup> Journ. Hebdom., t. vii. p. 73.

<sup>4</sup> In its structure and softness, this tumour is assimilated with the melanoses, and in two of its phenomena (*lancinating pains, and fungous growths*), with cancer.

<sup>5</sup> Revue méd., t. ix. p. 189. As in cancer, lancinating pains and glandular swellings are observed in this case.

after their extirpation, and which are of so firm a texture as to creak under the scalpel, have a very great analogy to cancer.

758. *Leucoid cancer*.—I shall, by and by, give a case of this rare variety of cancer which differs from all the others in the milky-white colour of its tubercles. Of these, some are flat, depressed in their centres, and prominent in their edges, which are covered with vascular ramifications; others, again, are rounded, and vascular in the centre, whilst their circumference is of a milky-white colour melting gradually into that of the skin (Case CXXXVII). Under the magnifier, these tubercles appear to be formed by a kind of hypertrophy of the corion, with the infiltration of a milky fluid, and the accidental development of the minute blood-vessels of their centre or circumference. Like the preceding variety, this one appears to proclaim a cancerous diathesis, which is manifested at the same time in other organs.

759. *Globose cancer* is characterized by small globular tumours, of a reddish or violet hue, bearing some resemblance in their external appearance to whortle or juniper berries. M. Alibert<sup>1</sup> has given the case of a woman, in whom a multitude of small tumours of this description made their appearance, some on the scalp, others clustered on the top of the right shoulder, others again scattered over the parietes of the abdomen, over the thighs, legs, and soles of the feet, all presenting the same appearance and possessing the same characters. The patient died under a lingering and painful consumption. The tumours, when cut into, were hard, of a yellowish-white in their interior, and very like lard, both in colour and consistency; some were black on the surface and ulcerated in the centre. To this case, two others, also related by M. Alibert, and one which I shall myself detail by and by, must be assimilated; my case, however, differs from the rest in this, that the small globular tumours consisted of cerebri-form matter, of a pinkish-white, or milky hue (*d'un rose blanc ou laiteux*). This variety of cancer, in which the disease is developed in so singular a manner on the surface of the body, is always a very serious affection; and although a patient labouring under it may now and then be found in the enjoyment of apparently good health, the external disease is certainly significant of a diathesis, which will silently but surely implicate some vital organ at a future time, and make the individual its victim at length.

760. *Mollusciform cancer*. This variety is distinguished by tubercles flattened in their form, or slightly rounded at their centre, indolent in their nature, of the same colour as the skin, and of a size varying from that of a silver twopenny to that of a half-crown or a crown piece. Their surface presents wrinkles or furrows, which are circular and concentric on those of small and middling dimensions, and irregular on those of the largest size. The anatomical character of this variety is a thickening, often very considerable, of the corion, the tissue of which becomes hard and scirrhus in its consistence. I have observed this variety, which, in its external characters, bears great analogy to one species of molluscum, in a woman, whose body, after her death, was found to present several other alterations of a cancerous nature (Case CXXXVI).

761. *Chimney-sweepers' cancer*. *Warty* or *chimney-sweepers' cancer* has been observed to attack the skin of the lower part of the scrotum with especial frequency. It begins in the shape of a warty excrescence, which very commonly continues stationary for several months, and even for several years. After a lapse of time, of various extent, the excrescence pours out an ichorous fluid, which excoriates the surrounding skin, its centre ulcerates, and, although not deep, the sore very soon exhibits all the characters of cancer in the most unequivocal form. Its edges are hard, raised, sharp, as if cut with a pinking iron, and everted; the surface of the sore has an unhealthy appearance; it is covered here and there with fungous growths, and is affected with pain of a greater or less degree of severity. As the disease advances, the neighbouring parts become affected, and the whole scrotum may at last be implicated; or the disease may extend along the perineum; the proper coats of the testis are also occasionally affected; the disease then usually extends to the body of this organ, creeps along the spermatic cord to the inguinal glands, and gains the abdominal viscera. When one of the testes is affected in

this way, it becomes bulky, and very hard, and contracts strong adhesions to the diseased scrotum; the ulcerative process soon gains its substance, and portions of it even slough out. In these cases, the fungous growths, which spring up so rapidly when the disease is confined to the scrotum, are but rarely observed. Both testicles are sometimes simultaneously affected in this way. In proportion as the disease extends its ravages, whether it has been left to itself or have recurred after one or more attempts to excise it, the constitution is insensibly deteriorated; worn out by incessant suffering and want of sleep, the strength of the patient gives way; he loses flesh rapidly; the skin presents a peculiar leaden cast of colour, and is at the same time bedewed with profuse perspiration, which exhales an ammoniacal odour, always to be recognized again after it has once been felt; the fatal termination is very often preceded by an acute affection of one or other of the viscera.

762. This species of cancer is only met with in individuals whose skin is habitually irritated by the contact of *soot*, whence its vulgar name of *soot wort*. It occurs most frequently on the lower part of the scrotum, where the irritation would seem to be most constant, from the confinement of the soot within the wrinkles of the skin. The disease has been observed on the wrist in a gardener who was in the habit of using soot largely every spring for the destruction of snails. It has also been several times seen on the face. *Chimney-sweepers' cancer* is most frequently observed among persons between thirty and forty years of age, but as children are mostly employed in the business of sweeping chimneys, this occupation, as Mr. Earle has very well observed, is not the sole condition necessary to the development of the disease: a peculiar susceptibility or predisposition is required in addition. Although the disease has been almost exclusively seen among chimney-sweepers and those who traffic in soot, it has been said that the smelters of certain metallic ores containing arsenic, are subject to a disease of the scrotum of a similar description.

763. I subjoin a few remarks on cancer studied comparatively in its development and progress on different districts of the skin.

1st. Cancer of the *hairy scalp* has been chiefly observed among the aged; this region seems more subject to the globular form of the disease than any other. When the tubercles which characterize the affection have attained a certain size they are distinguished from steatomatous formations by the sharp lancinating pains with which they are affected, whilst steatomata are always indolent.

Cancer *vulgaris* has also been seen upon the hairy scalp, ending in a phagedænic ulcer, whose ravages extended even to the bones of the cranium.

2d. Cancer of the *skin of the nose* frequently begins in the form of a tubercle (cancer *vulgaris*) developed on the lachrymal sac, or over the lobe, the ala, or root of the member. This tubercle is at first of the same colour as the skin; a number of minute vascular ramifications then appear on its surface; it next becomes red, inflamed, ulcerated, and covered with a brownish and rather adherent incrustation; when its surface escapes all accidental irritation, it sometimes continues stationary for several months and even for several years, the skin that surrounds it neither inflamed nor marked by the ramifications of dilated veins. This cancerous spot is frequently purely local, and independent of any other affection of the same kind, as I had an opportunity of ascertaining in the body of a woman, affected with a cancerous tetter, &c., of the left ala nasi, who died of accidental pneumonia.

Cancer of the nose is often more rapid and destructive in its progress, gnawing the cartilages and consuming the skin. Cancerous masses are also seen evolved underneath the skin, about the root of the nose, which is then observed to be traversed by varicose veins; after producing external deformity in this way, these masses are very apt to extend to the nasal fossæ, where they commit great havoc.

3d. Cancer of the *lips* is proclaimed by a common or melanic tubercle, which is almost always evolved on the lower lip. When this tubercle becomes ulcerated, it pours out a small quantity of sharp ichor, which dries into a grayish or yellowish scab. So long as the ulcer implicates the skin only, it does not extend otherwise than superficially; but when the mucous membrane of the lip is implicated, the sore extends rapidly, penetrates the cellular substance deeply, and destroys the muscles and all the other tissues of the face.

<sup>1</sup> Nosologie Naturelle, 4to., t. i. p. 548.

4th. Cancerous tubercles of the *cheek*, usually flatter, and more indolent than those of the lips, end in ulcers that show a particular disposition to spread superficially. The sore in this case is commonly chapped on the edges, around which creep many varicose veins, and is covered with a yellow or grayish scab; it is only attended with shooting, and not very severe pains at distant intervals. I have also observed cancer of the cheek developed in the form of a fungus.

5th. One or more small tubercles are often found in the *skin of the mamma*, when the gland is itself affected with cancer. These tubercles are commonly flat in their forms, and of a dull white or earthy colour—they resemble, in a word, the leucoid or mollusciform variety of cancer.

6th. The cancerous tubercles of the *extremities* are almost always of a violet colour, and surrounded by varicose venous ramifications. They are particularly apt to occur in those parts of the skin which are morbidly altered; in *navi*, for example. A woman was brought to me for advice, upon the calf of one of whose legs there was a cancerous fungus of the size of an apple. The patient assured me that this growth had been developed upon a blackish pigmentary *navus*, similar to two others, the size of a bean respectively, which existed on the inner part of the thigh of the opposite side. This cancerous tumour was not surrounded by any varicose veins, and the patient, the mother of several children, was actually suckling one of two months' old.

7th. Cancer of the *palm of the hand* and *sole of the foot* generally possesses the character of the melanotic species.

8th. The cancerous tubercle of the skin of the *anus* is commonly single, and situated on some point of the circumference of this passage. It is very frequently accompanied with a chronic inflammation of the rectum. Of course, it is a matter of great importance on no occasion to confound tubercles of this character with hemorrhoidal tumours, or growths of syphilitic origin.

9th. Cancer of the *prepuce* almost always commences as an indolent tubercle; irritated by the sexual act, or the friction of the clothes, it enlarges, becomes painful, and terminates in a fungous ulcer, the surface of which secretes a fœtid and ichorous fluid. Cancerous tubercles of the *vulva* are evolved, and ulcerate in the same manner.

10th. Cancer of the *glans penis* sometimes begins as a warty excrescence, or fungous tubercle. It is frequently accompanied by enlargement of the lymphatic glands of the groin.

764. Cancerous tubercles, and sores of a cancerous nature, are often accompanied with alterations of the same description, developed most commonly in the lymphatic and other glands, in the vicinity of the parts affected; these lesions may be either primary or secondary. We almost always remark, moreover, in individuals labouring under old and inveterate cancer, deep traces of a constitutional affection, of a *cachexia cancerosa*, as it has been named; the skin has an earthy or sallow complexion; the patients are emaciated, &c. It must, nevertheless, be confessed that these constitutional symptoms are in general rather rare among individuals attacked with cutaneous cancer, unless the disease, in consequence of the existence of a truly cancerous diathesis, is simultaneously developed in one or several of the viscera; the implication of these organs necessarily causes considerable disturbance in the principal functions at once, and ultimately inevitable death. (a)

(a) Into the detailed history of cancer, and an exposition of existing opinions of its origin, structure and progressive changes, it is not deemed necessary to enter in this place. Some additional light on the subject has been lent by the recent labours of Hodgskin, Carswell, Cruveilhier, Gluge, Muller and others. A good summary of the Anatomy, Physiology, Pathology, and Treatment of Cancer, by Dr. Walshe, will be found in an article in the *Cyclopædia of Surgery*, and subsequently brought out in a separate volume by Dr. J. Mason Warren, with additions. In the article "*Cancer*," in the *Dictionnaire de Médecine et de Chirurgie Pratiques*, and in the *Diction. de Médecine*, and "*Scirrhus*" in the *Cyclopædia of Practical Medicine*, the reader will find abundant details arranged in a methodical manner.

On the special divisions of cancer of the skin, treated of in the text,

765. *Causes*.—Cancerous tubercles have been known to be formed in the substance of the skin, in consequence of local irritation; but in by far the greater number of cases, these little tumours have appeared slowly, and without any assignable cause. Cancerous tubercles are rarely met with before the age of puberty; they even occur much more frequently between the fortieth and sixtieth years than at any other time, and in subjects of a bilious temperament, although even numerous instances of their development among the youthful, and persons in the flower of life, might be quoted. Cancer is occasionally a hereditary disease, and is often seen evolved under the influence of long-continued depressing moral causes. The disease is not contagious.

766. *Diagnosis*.—The tubercles of lupus, of Greek elephantiasis, and of certain forms of syphilis, are almost always indolent, and unattended with suffering; those of cancer, sooner or later, become the seat of severe lancinating pains. Cancerous tubercles differ in their appearance from warts; the cuticle is usually thickened, and cleft on the surface of these last, which are also almost always numerous and indolent, and never fall into a state of ulceration spontaneously. Those painful subcutaneous tubercles, which have been entitled *neuromata*, occasion, from their very commencement, pain of a much severer character than cancerous tubercles of the skin—pain which is likewise propagated to a distance, in the direction of the nervous twigs upon which they happen to be developed.

Dr. Walshe imparts little additional information from that given by M. Rayer, who is, by the way, largely quoted by Dr. W. The remarks of the latter on one of the varieties of cancer are not without interest.—I give them in the words of the author.

"From the uncertainty referred to has arisen some difference of opinion respecting the true nature of the disease termed 'chimney-sweepers' cancer.' According to our views, this affection may, or may not, be cancerous, and, in the latter case, may be so either primarily or secondarily; primarily, if it originate in true scirrhus infiltration or excrescence; secondarily, if the ulcer produced by simple irritation become the seat of scirrhus or encephaloid formation. Of the cancerous nature of the specimen, in which we discovered the following appearances immediately after excision, no doubt can be entertained. Four layers might be distinguished in the mass removed from the scrotum: 1, a stratum of firm laminar cellular membrane, presumed to be healthy; 2, the deep layer of the morbid structure, consisting of an indurated substance as resisting as fibro-cartilage, creaking like that tissue when the point of a scalpel was rubbed along its divided surface, and possessing a linear arrangement—the fibres being perpendicular to the base; 3, a stratum of much softer material, of yellowish-white colour, lobulated, and somewhat of a fungous aspect; 4, a viscid coating of ichor, of a brownish-gray tint. These layers, more closely examined, presented the following characters. 1. With a common lens, a distinct partition of the cellular layer, by white opaque septa, enclosing yellowish and more transparent matter between them, was plainly discernible. Under a microscope of 150 powers, a particle of this putative normal tissue was found to consist of cells, some irregularly shaped, others pentagonal, and containing a distinct nucleus with nuclear corpuscles. A number of minute bodies, without internal cavity, (granules of Müller,) floated free; in one part, an elongated mass, with exactly the appearance of the fibrous matter of carcinoma fasciculatum, presented itself; it had the transparent character of that product." 2. In the fibrous or linear part, caudate corpuscula, with or without nuclei and nuclear corpuscula, were abundantly seen. These were associated with cells of the description frequently referred to. 3. In this layer, a fibrillar stroma constituted a most remarkable feature. 4. In the ichor, we observed, in addition to nuclear cells, curved caudate corpuscles."

<sup>1</sup> This shows distinctly that the germina of cancer (for here they probably extend much beyond the part examined, which almost presented the grosser characters of the disease), are occasionally left behind in tissue, which appears at the time of operation to be perfectly healthy. A remark of the same kind has been made by Gluge: "It is not only," he says, "in the encephaloid tissue itself, of affected organs, that its globules are found; they are also to be discerned in parts apparently healthy; for example, in portions of encephaloid lungs, which still retain the property of crepitating."—(*L'Institut*, No. 191, Jan. 4, 1837.)

The tubercles of melanic cancer differ from pure melanosis developed in grains, by being accompanied with lancinating pains, which melanosis never is. Leucoid cancer has a characteristic appearance, which distinguishes it from every other disease. Mollusciform cancer cannot well be distinguished from the disease called molluscum, unless where symptoms, or other alterations of an unequivocally cancerous character, are observed at the same time.

The ulcers of lupus, of Greek elephantiasis, and of syphilis, do not occasion pain of the same description as cancerous sores, and are, moreover, accompanied with various phenomena which contribute to distinguish them. In other and more simple cases, the diagnosis may even remain for some time uncertain. I once saw a small fungous sore, nearly six lines in breadth, and of a cancerous appearance, situated towards the outer angle of the eye, below the level of the under eyelid, which had existed for a month, having followed a *spot* that had become excoriated; but the long continuance, and particular appearance of this sore, were solely owing to neglect of proper cleanliness, and to irritation kept up by the nails of the patient; for I succeeded in healing it up in the course of a month, by means of emollient applications, and the use of the simple tepid bath.

767. *Prognosis*.—It may be stated, generally, that cancerous tubercles of the face, lips, and *alæ nasi*, are less serious affections than cancer of the glands; when extirpated, the disease is also less apt to recur. Melanic tubercles, however, form a marked exception to this rule; the disease in this form being particularly apt to be reproduced. Cancerous ulcers of the face, trunk, extremities, genital organs, &c., are beyond the reach of art when they have extended so far as to make it impossible to remove with the knife or caustic, the whole of the parts which the disease has implicated. When a very large number of cancerous tubercles are developed in the skin, it may always be taken as evidence of the existence of a cancerous diathesis, which sooner or later will extend to the viscera, and prove inevitably fatal.

768. *Treatment*.—When one, or a very small number only of cancerous tubercles have been evolved within a short time upon a particular district of the skin, we have of late been advised to attempt their resolution by means of local bleedings, of emollient or narcotic applications, and the administration of gentle laxatives. I have little confidence in this mode of treatment, the value of which has been singularly over-rated; I have tried it several times, but without once obtaining the complete dissolution of a cancerous tubercle; forty leeches applied in the course of eight days around a tubercle recently evolved, failed to effect the slightest diminution in the size of this production; in one case only did a cancerous tubercle of the nose shrink temporarily under the influence of the abstraction of blood; in consequence of a cold it enlarged again, and the patient having died shortly afterwards of an acute disease, I was enabled to ascertain that the tubercle contained cerebriiform matter.

Dr. Recamier has given a case of cancerous tubercle in which cauterization and compression were employed with advantage. In the majority of instances, however, it is better, when the cancerous nature of a tubercle has been well established, to remove it with the knife at once. A multitude of cases show that tubercles of this description evolved in the skin of the cranium, of the face, and other regions of the body, may be extirpated with complete success. The existence of some lesion of the viscera or their membranes could alone contra-indicate such an operation. A multiplicity of tubercles need prove no obstacle to their removal, for they may all be taken away one after the other in a very short space of time, if no other symptom of a cancerous diathesis be present. When the wound which results from the extirpation of a cancerous tubercle cannot be healed by the first intention, I am of opinion that instead of dressing it simply, like a common suppurating wound, it is better to cauterize its surface with the acid nitrate of mercury, or even to cover it with the arsenical paste. Cancerous tubercles in a state of ulceration, in young or middle-aged subjects, may also be attacked with the scalpel, whenever it appears possible to remove the whole of the structures affected, and when the disease is not hereditary. After the operation, I should always recommend the use of caustic in these particular cases. And I have fancied that relapses were less frequent when, under such circumstances, a caustic issue was made in the arm or leg, either before or shortly after the operation.

769. When cancer of the skin, after having destroyed in succession this tissue, the subjacent cellular substance and the muscles, extends to the bones, to the cartilages, conglobate and conglomerate glands, or to the tissues in the vicinage of its primary seat, or when it occurs among the aged, or individuals who present marks of the cancerous diathesis, the disease can neither be successfully attacked by the knife nor by caustics. Nothing more can then be done, in fact, than to endeavour to assuage the acute and incessant pain which the patient endures. The necessity of employing anodynes, in large doses, for a great length of time, and the no less evident necessity of sparing the digestive organs the paralysis of their powers, induced by the habitual use of opium, led me to recommend, in these desperate cases, the application of small doses of the acetate of morphia to the surface of the sores, or of the corion at any point where it happened to have lost its cuticle: experience has satisfied me of the advantages of this mode of using the narcotic.

770. Many different medicines, of various degrees of activity, have in their turn been spoken of as calculated to modify the *cancerous diathesis*, to favour the resolution of cancerous tubercles, or to heal up cancerous ulcers. Arsenic, in one or other of its forms, has been tried internally by Loder, Lentin, Selle, Tode, and others; I have prescribed many of these myself, but in vain. I have also tried the preparations of hemlock, which have been lauded in this class of complaints, in doses of from one to two grains, for a year, in several cases of cancer of the skin and mammary glands; and, under the influence of this medicine, the disease appeared to me to advance more slowly than usual, and to be attended with less severe pain. I have tried the carbonate of iron in doses of half a drachm, a drachm, and even several drachms, for months together, without perceiving any good effect from the action of the medicine. Several experiments have been made with iodine; and, as usual, with the effect of arousing hopes at first, which have not been subsequently realized. Rust assures us that he has succeeded in curing radically, several cancerous affections of the lips, with the decoction of Zittmann;<sup>1</sup> were not these presumed *cancers*, syphilitic in their nature? Græfe<sup>2</sup> has given a case of very extensive cancer of the face and palate, which was much improved by creosote. We should, therefore, feel encouraged to enter upon new, and even bold attempts, to check a disease, which it is difficult to conceive, must necessarily and under all circumstances, remain incurable; the more especially when we remark the extraordinary success that has attended the introduction of several powerful medicines, in the treatment of certain syphilitic ulcers, the havoc committed by which is neither less extensive, nor their consequences less deplorable, than those of cancer. When called to give our assistance to the aged, however, and to those whose constitutions, although, perhaps, not seriously affected by the disease, have been injured by severe abstinence, by long courses of active medicines, or the shock, and after consequences, of a surgical operation, it is always well to bear in mind the following passage of Celsus, which has been often quoted, both by physicians and surgeons of ripe experience: “Quidam usi sunt medicamentis urentibus: quidam ferro adusserunt: quidam scalpello exciderunt; neque ulli unquam medicina proficit—excisa (carcinomata) etiam post inductam cicatricem tamen reverterunt, et causam mortis attulerunt—sed imponendo tantum lenia medicamenta, quæ quasi blandiantur, quominus ad ultimam senectutem perveniant, non prohibentur.” (Celsus. De Medicinâ, lib. v. sect. xviii.)

#### Historical Notices and particular Cases.

771. Hippocrates nowhere mentions cancer of the skin distinctly. Celsus<sup>3</sup> has left a most accurate account of the external characters of the disease. He has remarked on the great tendency of *καρκίνωμα* to relapse, after it has been extirpated by caustic or the knife. Paul of

<sup>1</sup> A comp. decoct. of sarsaparilla.—Tr.

<sup>2</sup> *Litré*. Art. Cancer: Dict. de Médecine, 8vo. Ed.

<sup>3</sup> Celsus. De medicinâ, lib. v. De carcinomate. “Id vitium fit maximè in superioribus partibus, circa faciem, nares, aures, labra, mammas feminarum—circa locum aliqua quasi puncta sentiuntur—circa eum inflatæ venæ—interdum simili his est quæ vocant *κνιδώματα*, aspredine quâdam et magnitudine suâ.” Celsus has also spoken particularly of the characters and treatment of cancer of the penis (lib. vi. sect. xviii. 3.) and the case he had in his eye, from one of the appearances he mentions, (incipit a nigritiæ,) would seem to have belonged to the *melanic* variety.

Ægina, in giving the characters of cancer, insists particularly upon two symptoms—"ægros maxime fatigans et perpetuo fere dolore affligens." Hafsenreffer<sup>1</sup> has given a good description of the cutaneous cancerous tubercle, and cancerous ulcer. Forestus,<sup>2</sup> under the title of *noli me tangere*, has detailed the symptoms of a tumour, probably cancerous in its nature, situated on the right cheek, and extending to the eye and nasal fossæ. According to Ledran<sup>3</sup> this title properly belongs to phagedænic cancers, regarded as incurable. I have already had occasion to state that lupus had been described under the same name. Paré<sup>4</sup> speaks of a plump hussy of goodly presence (*une garce potelée de bonne apparence*), who simulated cancer of the skin by dabbing her breast with a sponge dipped in a mixture of milk and blood.

Several varieties of cancer have of late been described in our medical journals, and systems of surgery, with great accuracy. A number of cases of cancer of the face,<sup>5</sup> of *fungiform* cancer of the skin, covering the calf of the leg,<sup>6</sup> groin, and forearm;<sup>7</sup> of cancer vulgaris of the scrotum;<sup>8</sup> of *melanic* cancer of the lips,<sup>9</sup> hands, finger,<sup>10</sup> face, &c.;<sup>11</sup> and of *globular* cancer,<sup>12</sup> will all be read with interest. *Chimney-sweepers'* cancer has only been observed and described in England.<sup>13</sup> I have myself given the first account of the *leucoid*, of the *mollusciform* and *disseminated encephaloid forms* of cancer.

772. The local treatment of cancer has been a subject of much research. The effects and advantages of *compression*, which was so much recommended by Dr. Young,<sup>14</sup> have been studied with great care by Dr. Recamier.<sup>15</sup> Some practitioners of great eminence, with Dr. Al. Monro<sup>16</sup> at their head, condemn *excision* entirely. Others, and especially Hill,<sup>17</sup> on the contrary, rely on this means as one very often successful; others, again, among whom Boyer deserves to be particularly mentioned, without rejecting an operation entirely, acknowledge the frequency of relapses, even in those cases which were, to all outward appearance, the most favourable for its performance. In another work<sup>18</sup> I have given an account of the greater number of the experiments which have been made with arsenic, administered internally and applied externally, in the treatment of cancer.

Several medicines—hemlock,<sup>19</sup> belladonna,<sup>20</sup> carbonate of iron,<sup>21</sup> iodine,<sup>22</sup> &c., have been held up as calculated to subdue the cancerous diathesis, and to cure cancer. The whole of these remedies, as well as the *cura famis*,<sup>23</sup> which has been advised with similar views, I have tried a very considerable number of times, but always with results very little satisfactory.

It were greatly to be wished that further experiments were undertaken under definite and well-determined circumstances, and that the results of these were faithfully detailed.

CASE CXXXIV.—*Cancerous tubercle of the lower lip. Removal and cure.* Anne Blasie, sixty-eight years of age, became a patient in the Hôtel Dieu, Feb. 14, 1826, on account of a cancerous affection of the lips. The disease had appeared eleven months previously, as a small tubercle, on the inner surface of the lower lip. This tumour, by and by, became covered with a scab, which the patient removed by working at it with the point of her tongue. The patient leads a very active life, going to bed soon, and rising very early in the morning. She had had herself bled a few days ago, and since then, thinks that the tumour of the lip has been less inflamed, and not so hard as before. The tubercle, at the date of her admission, is as large as an almond, hard and ulcerated on its upper part along the edge of the lip, the mucous membrane of which is destroyed in two different places. Usually indolent, this tubercle is at times the seat of acute shooting pains, similar to what are caused by the slight prick of a needle.

M. Sanson, surgeon of the Hôtel-Dieu, removed the tubercle with a single stroke of the flat curved scissors. The semi-lunar wound that resulted, healed rapidly, so that the patient was dismissed on the 4th of March, perfectly well, the lip presenting no deformity.

CASE CXXXV.—*Cancerous tubercle—ulceration—complications—death.* Madame \* \* \*, sixty years of age, consulted me towards the end of the year 1824, on account of a chronic laryngo-tracheitic affection, attended with loss of voice. Asses' milk, and a soothing plan of treatment, were recommended; and she afterwards went into the country to try the effects of the method in restoring her voice.

About the 15th of June of the year following (1825), she perceived a small tubercle, or wart, as she called it, on the prominent edge of the root of the nose. Another practitioner attempted to get rid of this wart by passing a ligature round its base on the 1st of July. This was not done without much difficulty, on account of the flat lenticular shape of the tubercle, which was of the same colour as the skin, with a black point in its centre, and nowise painful. The ligature at first caused little inconvenience, but at length, before the tubercle fell off, which happened on the 13th, great suffering. A sore, a little larger than a silver threepenny piece, surrounded by a great deal of inflammation, was left.

On the 16th of July the patient returned to Paris, when I saw her again. At this time there was on the median line of the root of the nose, an ulcer half an inch in breadth, rounded and prominent, and presenting a singular mixture of whitish, livid, and blackish points, upon its surface; this sore did not discharge, and formed the centre of an inflammatory circle, which spread to the lateral parts of the root of the nose. The appearance of this ulcer reminded me of that presented by fungoid cancers, and I proposed calling M. Dupuytren into consultation. This eminent surgeon could hardly be persuaded that the sore we had before us could have been developed in a month. It was agreed to cover the swollen parts with emollient and anodyne cataplasms, and to apply five leeches every day to the base of the sore, causing the bites to bleed as plentifully as possible, by the use of tepid fomentations. Forty leeches were in this way successively applied to the base of the tumour in the course of eight days; but no sensible abatement of the inflammation resulted. In consultation, a week afterwards, it was determined that nothing was to be expected from the antiphlogistic treatment: the swelling had rather increased than otherwise under it; and, reflecting that the progress of cancerous sores is seldom so rapid as in this instance, and conceiving it possible that the obstinacy of the laryngeal affection, which still continued, might be owing to something *specific*, Madame \* \* \* was put upon a course of the bichloride of mercury in solution, and decoction of sarsaparilla. These medicines, continued for two months, produced no good effect; on the contrary, the ulcerated tumour was more rounded and prominent than before, chapped in several places, and scarcely secreted any thing. The general health of the patient, too, seemed to have suffered. She therefore returned to a tranquil mode of life, took asses' milk, &c.; and I covered the ulcer with a little powder, composed of ninety-nine parts of calomel and one of protoxide of arsenic. This application produced the most singular abatement in the inflammation of the base of the tumour, and removed the disagreeable smell emitted by the sore. An operation being held inadmissible by the eminent surgeon consulted, and the patient herself having an unconquerable aversion to any thing of the kind, I resolved

on destroying the indolent fungus that rose from the surface of the ulcer, by means of the concentrated nitric acid. The patient felt no pain from the action of the acid, either at the time of the application or afterwards, so that on the following day I used the acid again, and more freely than at first. Neither did the patient, on this occasion, make any complaint at the time of using the acid; but next day, she felt some deep pricking pains under the small tumour. Five days afterwards, (Sept. 28,) a portion of the tumour, like the half of a large walnut, sloughed out, and the surface of the sore was reduced to a level with its edges. By and by, recourse was again had to the compound powder of calomel and oxide of arsenic, with which the surface of the sore was dusted over; and under this application, the neighbouring parts became much less inflamed, and the ulcer itself contracted, and even cicatrized over three-quarters of its whole extent. But while the cancerous sore improved, the chronic inflammation of the larynx and trachea extended to the bronchi, and even appeared in others of the mucous membranes; so that the patient, long confined to spare diet, lost her strength rapidly, and died on the 5th of April, 1826.

CASE CXXXVI.—*Mollusciform cancer. Cancerous formations in various parts of the body.* M. S. Duboille, aged forty-two, married, and a mother, had felt her health on the wane for the last three years and a half, having suffered from wandering pains of the abdomen, and the sensation of something like a tumour in the lower part of the left hypogastrium, a situation in which she felt rather severe lancinating pains from time to time. The right breast had begun to enlarge about a year ago, and was now hard, shrunk, and knotty, with a chain of enlarged lymphatic glands stretching from it, though it had never been very painful towards the axilla. In January, 1827, a number of tubercles made their appearance on different regions of the body, two of which soon became much larger than the rest, the one situated midway between the ribs and haunch bone of the right side; the other on the right scapular region. Many of the tubercles had precisely the appearance which is held characteristic of the non-contagious form of molluscum. The patient's skin was of a uniform pale straw colour. The belly was large, and the seat of deep lancinating pains. The evening after her entrance into the Hôpital de la Charité, the patient had a violent attack of bleeding from the nose, which was only stopped by plugging the nostrils. The patient having taken out the plugs, the hemorrhage returned next day, and the apparatus had to be replaced, while a small quantity of blood was taken away from the arm. The patient died a few days afterwards.

On inspecting the body of this woman, thirty-six hours after her death, the skin of the thorax was found beset by about ten small tubercles, scarcely rising above the general level, of a bluish cast in some instances, in others, of the same colour as the surrounding integuments; the smaller of these tubercles did not extend deeper than the skin, so that the inner or adhering surface of this tissue presented its ordinary appearance; opposite the larger tubercles, however, the texture of the skin was altered, indurated, and yellowish. The left mammary gland was healthy. On the posterior surface of the thorax, two tumours, of much larger size than any that have been mentioned, were observed. These were prominent, uneven, fungiform, and when cut into presented the following dispositions: The most external layer was yellowish, and in its general characters, approached the organic alteration which has been described under the name of scirrhus; the next layer consisted of the corion hypertrophied, but not otherwise changed. The skin of the abdomen, held between the eye and the light, showed a number of small reddish or livid tubercles, nowhere prominent; and the integument of the left arm presented two tubercles, of the same colour as the skin. These morbid changes in their first stage, and as they occurred in the smaller tubercles, appeared to consist of circumscribed simple hypertrophied patches of the corion; in the larger tumour, however, the more superficial layers of the corion presented an uniform yellowish tint, and a semi-transparency analogous to what is observed in scirrhus.

The right breast was hardly larger than that of the opposite side, but it was very hard, yellowish, and creaked under the scalpel, like a scirrhous mass. The colour here formed a striking contrast with the milky white of the left mammary gland. Running from the breast to the hollow of the axilla, there was a chain of lymphatic glands, reddish in colour, and rather voluminous, but not otherwise altered.

In the abdomen, the stomach exhibited a very remarkable morbid appearance. Its inner surface presented a great number of nipple-like eminences, analogous to the tubercles of the skin; they were in general of the size of a hazelnut, and, when cut across, showed that they consisted of four layers: the mucous coat, very much hypertrophied externally, the sub-mucous cellular tissue indurated, the muscular coat hypertrophied, and redder than natural, and the peritoneum, which was not sensibly changed. Three or four of these tubercles were ulcerated in their centre. The intestinal canal was healthy. The pancreas and liver were greasy. The spleen was hard, and in one part presented a mass either of cerebriform matter, or of discoloured fibrinous deposit. The left ovary, the size of a turkey's egg, consisted in part of cerebriform matter, and in part of a serous cyst. No other morbid alterations sufficiently remarkable to enumerate, were detected.

CASE CXXXVII.—*Leucoid cancer. Cutaneous tubercles. Cancerous alterations in a female aged seventeen.* Marie Patureux, sempstress, aged seventeen, of lymphatic temperament, had menstruated regularly for six months, when in the month of February, 1828, she began to feel lancinating pains in one of her thighs, and became aware of a tumour in this situation, nearly as large as a walnut. The application of twenty leeches relieved the pain for a time, but the tumour went on increasing in size; the thigh swelled, walking became laborious, and the patient entered the Hôpital de la Charité, where, besides the tumour on the thigh, another, occupying the umbilical region, was discovered. Rest was prescribed; a soap plaster, and, by and by, the inunction of some mercurial ointment, combined with the methodic compression of the femoral tumour, were tried. After remaining in the hospital a month, a number of small tumours, which I shall describe by and by, began to make their appearance on different parts of the body. She then left the house; but on the 14th September, became a patient in the Hôpital St. Antoine. The number of tumours had now very much increased; and, although three of these had acquired a considerable size before the patient became aware of their existence, to show us the mode in which they were generally evolved, she directed our attention to a number of small round bodies, about the size of large pins' heads, imbedded in the skin of the belly and thighs; these were not made visible by any projection above the level of the surface; they were quite immovable, and not painful to pressure. As the tubercles advanced, however, they rose above the general level, and, assuming an oval shape, very commonly appeared surrounded with a large pale red areola. They were then mostly of the size of a shilling, or rather larger. Here and there several appeared irregularly clustered together. The greater number were pink in the centre, and of a dull white in the circumference. Those of oldest formation, however, presented a brownish hue in the middle, which, instead of being raised, was flattened, and even depressed. The brown tint seemed to inhere in the cuticle, which could be detached in small plates from several of the tubercles. Lastly, the majority of the tubercles were traversed by a number (commonly four or five) of small tortuous venous branches, which, in case the tumour were prominent, proceeded from the base, to unite in the centre, and which, in case it were flat, were distributed almost solely around its circumference.

The tubercles were not accompanied with any pain: the surface of the right thigh was completely covered with them. They were also very numerous above the pubes; an irregular band of them stretched from the right inguinal region to the anterior and superior spinous process of the left os ilium. The skin of the abdomen generally, and of the bosom, was also thickly beset. Besides the cutaneous tubercles, a large tumour could be felt deeply imbedded in the substance of the right thigh, which was much swelled, and nearly a third more in circumference than that of the opposite side. On the right arm there was another morbid growth, of a rounded form, an inch and a half in diameter, and pointed in its centre, which fluctuated, and was of a livid red, slightly squamous, and occasionally moistened with a little exudation. The abdomen, in fine, was hard and tense, and seemed distended under the navel by a bulky tumour. The patient scouted every hint at the possibility of this last tumour being induced by pregnancy, so obstinately, that we were at first misled in our estimate of its nature, when we presumed it might

be similar to the others. By and by, however, the truth came out: the girl was pregnant, and the mistake committed might have been avoided by a recurrence to auscultation.

The patient's general health was at first satisfactory; but she soon began to droop and lose flesh. The cancerous nature of the complaint under which she laboured being recognized, made us fear for the worst. Arsenical medicines were tried for some short time, but these appearing to cause heat in the throat, and pain in the bowels, were soon discontinued, and leeches applied to relieve these symptoms. The patient became jaundiced at length, and was sinking fast, when, on the 11th of January, 1829, she was taken in labour, and died almost immediately after giving birth to a child, which lived but a few hours.

Inspected twenty-four hours after death, the body of the patient presented the jaundiced colour observed during life. The cutaneous tubercles, when cut into, appeared, in many cases, to be formed of the corion hypertrophied, the prolongations of this structure into the subjacent cellular membrane being much more largely developed than they are in the normal state. Some of the tubercles presented large drops of blood effused into the substance of the corion; others again were softened, and when squeezed between the fingers, a little purulent matter exuded from the cut surfaces. The tumour of the right arm consisted of a mass of cerebriform matter, softened, and tinged yellow like the skin. The subcutaneous cellular substance, which was very abundant, formed small white, hard and rounded masses, which creaked when cut into, under the several tubercles. The deep-seated tumour of the right thigh was composed of cerebriform matter, but very hard. The centre of the mass, as large as the fist, was traversed by the crural veins. Several small, hard, cancerous masses were detected in the upper part of the intestinal canal. The mesenteric glands had also evidently undergone alteration. The liver was healthy. The ductus cysticus and ductus choledochus were alike distended with bile; the latter was compressed by the extremity of the pancreas in a scirrhus condition, and this had caused the jaundice. The aorta was surrounded by a cerebriform mass of considerable size. The other viscera did not appear to be changed. The fetus, apparently in the seventh or eighth month of its uterine existence, was quite free of all appearance of cancerous affection.

CASE CXXXVIII.—*Encephaloid cancer of the scalp and pubic region; death.* Tyron, aged twenty-five, the mother of several children, observed in the month of April, 1826, that a small tumour, the size of a mulberry, had grown on her head, having been preceded for several weeks by constant and pretty severe pain in the parietes of the cranium. Towards the month of August this woman consulted M. Ollivier d'Angers, who discovered four mammillated tumours of a like description on the scalp, one of which was extirpated; but scarcely had the edges of the wound coalesced, when a new tumour sprang up, and speedily attained the size of a hazelnut. This tumour was uncovered with hair, of a pale-red colour, slightly flattened, hard and resisting, and the seat of acute intermitting pain. The other tumours were rather smaller, of a violet-red colour, hard, and also without any covering of hair; the skin that was stretched over them was of a pallid or bluish-white colour. The tumours only became painful when they had acquired a certain size. Two more of the tumours were subsequently removed by M. Boyer, one of which was rapidly reproduced, and, at the time I saw the patient first, bore the most perfect resemblance to a raspberry. At this period the patient appeared to be labouring under a purely local affection. The principal functions were performed with perfect regularity, and Tyron had all the appearance of a person in good health.

The indifferent success that had attended the two operations already performed, the repugnance of the patient to any further measure of the kind, and the obscure nature of the disease, led to the prescription of bleeding, and the use of simple emollients. Two of the tumours of the scalp became red and fungous, and a tumour of the same kind was evolved above the pubes. Symptoms of morbid alterations in the abdomen soon afterwards made their appearance. In the hypogastric region, a tumour, equal to the mass of the uterus in the fourth month of pregnancy, was discovered. There was no change in the state of the cervix uteri, however, to cause any suspicions of pregnancy; besides, the catamenia continued regular, though

scanty. This tumour was the seat of violent pain, and the patient became feverish and disturbed in her sleep. On the 8th of January all the symptoms of acute peritonitis were presented; the patient was bled, put on low diet, ordered to have diluents, lavements, &c., but in vain; she died on the 22d of January, 1827.

The body was inspected by M. Ollivier, who communicated the appearances to me, and sent for my more particular examination the tumours of the scalp. Three of these were completely subcutaneous, and as large as musket balls. The skin which covered them was naked, the hair bulbs having probably been atrophied under the effects of the compression they had undergone. The cellular substance surrounding these tumours was healthy. When dissected out, their surface was lobulated, which made them look as if they consisted of a number of smaller parts. When cut into, they were found composed of cerebriform matter, in a state of crudity. Other two fungous and vascular-looking tumours, which were not covered with integument, were also formed of encephaloid matter, but very much injected and softened. The bone under these last tumours was healthy. Among the hair of the pubes, a small red bleeding tumour, the size of a nut, also formed of encephaloid matter, was discovered. On either side of the umbilicus, a tumour of the same size and like composition, but less vascular, was found. The peritoneum, in a state of inflammation, contained about a pound and a half of a sero-purulent fluid. The lower or lesser pelvis was filled by a lobulated tumour, uneven on its surface, of a pale rose-colour, and as large as a child's head, lying between the uterus and rectum, which were respectively pushed by it forwards and backwards. When cut into, this tumour presented all the characters of the encephaloid tissue; several of the lobuli were softened, others were still in a state of crudity; every part of it had the same smell as the substance of the brain. The centre of the tumour appeared to be occupied by the left ovary; the broad ligament of the same part formed a very distinct band on the external surface of the tumour. Around this ovary, the morbid formation was clustered in the shape of lobular masses, most of which were of the size of hens' eggs. A lobulated encephaloid mass, as large as a hen's egg, was also found in the thorax, adhering to the right lung, which presented a peculiar structure: instead of being cleft transversely, as usual, it appeared divided longitudinally by a deep fissure. The head and spinal canal were not examined.

773. Having felt called upon in the course of this work to describe subcutaneous tubercles of a *syphilitic* and of a *scrofulous* nature, I conceive it will be well to quote a case of *painful subcutaneous tubercle*.<sup>1</sup>

CASE CXXXIX.—*Painful subcutaneous tubercle.* M. J. Roy or Fuque, aged forty-two, became a patient in the Hôpital de Cochin, 1st Oct., 1826, on account of the disease which Mr. W. Wood has denominated *painful subcutaneous tubercle*. The tumour in this case was situated in the posterior part of the thigh, was as large as a grape stone or a small pea, of an oval form, nowise adherent to the skin, and not only extremely painful when touched or pressed upon, but repeatedly during the course of the day, the seat of severe pain, which shot downwards from the thigh into the leg. The patient informed me that she had suffered for some time with severe darting pains in the seat of the tumour, before she discovered a small hard body, about the size of a large pin's head. It continued nearly stationary for several years, and attended with the same symptoms; it had finally grown gradually till it had attained the dimensions stated, accompanied with paroxysms of pain, more and more frequent, and more and more severe. The patient has now from two to fifteen paroxysms daily, which last from a quarter of an hour to an hour, often with such intensity, that tears are forced from the patient, though she appears to possess a great share of fortitude and much good sense. These paroxysms, which frequently came on spontaneously, were certainly excited by the slightest touch, so that the patient is very careful how she either lies or sits down, and now submits to the examinations of medical men with great reluctance, as she never fails to suffer severely from their manipulations. Each paroxysm begins with tingling and severe shootings, and with a feeling of extreme heat in the tubercle and skin which covers it. An instant afterwards the pain extends down the whole of the back part

<sup>1</sup> For a particular account of these tubercles, vide Descot. Diss. sur les affections locales des Nerfs, 8vo. Paris, 1825.

of the limb, from the tubercle to the heel, ending between the malleolus internus and the inner and under edge of the os calcis, without any diminution of intensity, through the whole of this course; if there were any difference, indeed, it was rather in the greater severity of the pain in the tubercle itself, the calf of the leg, and the inner side of the heel. The sole of the foot, and all the parts above the tubercle, have always been exempt from pain. In its extension, the pain did not seem to follow the course of any particular nerve; it was general, and diffused over the posterior part of the limb. The anterior aspect of the thigh and leg was unaffected. Active exercise always made the paroxysms more severe. These were also more than commonly acute on the approach of the menstrual period, and when any great change occurred in the state of the atmosphere, especially when it became cold and moist. During the paroxysm, the pain was almost constantly of the shooting kind, or appeared to extend in rapid pulses from the tubercle to the heel. When the paroxysms were long and severe, the feeling of heat was not confined to the tubercle, but extended to the whole of the back part of the thigh; although unaccompanied with febrile symptoms, they always left the patient exhausted and enfeebled. Various remedies had been tried, but without doing any good.

M. Guerbôis extirpated the tumour next day, October 2d, exposing it by a longitudinal incision, raising it by means of a hook, and taking it away along with a small portion of lamellar tissue, by which it was surrounded. The wound scarcely bled, and its edges, being brought together with sticking-plaster, united by the first intention. From the moment of the operation no further paroxysm of pain was felt, and by the 6th of the month, the patient felt completely relieved from the torture she had endured for eight years.

On the day of the operation, M. Ollivier (d'Angers) and I examined the tumour particularly. It was of an oval form, of the weight of six grains, smooth, and of a very slightly bluish-white cast of colour, very similar to that of made starch, without any thing of the pearly lustre of cartilage. The texture of the tumour was hard and solid, like that of the fibro-cartilages, from which it differed, however, in being homogeneous, in presenting no trace of fibres in any part; neither could any vessel or nerve be detected in its composition, even with the assistance of the magnifier. The cellular substance in which the tumour was enveloped, was also searched in vain for even the smallest branch of an artery or nerve. The tumour was not developed in the course of any nervous twig; neither can it well be imagined that it lay in the neighbourhood of one of the posterior subcutaneous branches of the sciatic nerve, to the compression of which all the suffering endured by the patient might be attributed; for the intermitting, extremely acute and lancinating character of the pain, could not be explained by this supposition. Looking at the bluish cast of the tumour, and all the circumstances attending its development, we were inclined to view it as a modification of scirrhus, rather than as simply cartilaginous.

#### ELEPHANTIASIS. (a)

Vocab. *Elephantiasis, Djuzam, Lepra Medii ævi, Lepra Taurica, Mal rouge de Cayenne.*

774. Elephantiasis is a serious chronic disease, characterized externally by shining and oily-looking dark patches, to which succeed irregular, slightly prominent, softish, and at first, red and livid tubercles, which by and by assume a dusky or bronze colour; these usually continue long indolent; they may terminate in resolution or ulceration; their most common seat is the face. They also often appear on the palatine arch; but the nose and ears, swelled and hideously distorted, are the parts of all others which suffer most frequently.

775. *Symptoms.*—Some writers inform us that Greek elephantiasis

(a) It will be seen that M. Rayer restricts this term to the disease known as leprosy, the Greek leprosy of the middle ages. By many writers it is applied to the other form of leprosy, or the Arabian, the prominent or chief feature of which is a swelled leg, (*Barbadoes leg*). This disease is described in a subsequent part of this volume at § 1331 *et seq.*

is usually preceded by a state of languor and depression both physical and moral. Robinson mentions this particularly as one of the most remarkable symptoms of the first period of the disease. The *spots* and *tubercles* which characterize the disease, when fairly formed, occasionally appear upon the skin, with acute febrile symptoms of some intensity—(development by *fluxion*, Th. Heberden). But the attack of the disease is more commonly gradual and slow (development by congestion, Th. Heberden). The evolution of the tubercles is sometimes preceded by a change of colour in the integuments, which in whites become sallow, bronzed, or of a hue which might be likened to that of the mulatto. In blacks, the *spots* are even deeper coloured than the skin; in whites they are yellowish or reddish, and slightly raised above the general level of the surface. Irregularly disseminated, like the patches of psoriasis *guttata*, the spots of elephantiasis look as if they were full of oil (Adams), or covered with varnish. Occasionally they are quite *insensible*; but more frequently, feeling is not quite absent in them, though they may still be compressed without pain. In the very first stage of their formation, they are now and then observed to be endowed with a greater degree of sensibility than the skin which surrounds them: by degrees this state, and the redness which has accompanied it, subside; the flush being followed by a tan or bronze colour; in every case, after having continued stationary during a period, the duration of which varies considerably, the spots are succeeded by tubercles, some of which are truly cutaneous, whilst others are evidently developed in the cellular membrane which lies under the skin.

The cutaneous tubercles of elephantiasis are small, soft, round, reddish, or livid tumours, the size of which varies between that of a pea, and that of an olive. They generally appear on every part of the face, on the nose and ears particularly, but are also, occasionally, though rarely, evolved on the legs only. When patients live under this infliction for a few years, the disease very commonly spreads to the whole body. The disease becomes even more and more marked. Of all the parts which are implicated, the face always bears the strongest traces of the havoc and deformity that characterize it. This seems to be generally puffed. The skin of the forehead, marked by numbers of deep transverse furrows, is beset with many tubercles, the superciliary ridges, swelled, and furrowed with oblique lines, are covered with nipple-like projections. The hair of the scalp, that of the eyebrows, and the cilia, are lost. The lips become thick and shining; the chin and concha of the ear enlarge, and become thickly covered with livid tumours; the lobe and alæ of the nose are in general even more seriously altered than the other parts of the face; the nostrils are irregularly dilated; lastly, the cheeks are swollen, and the whole of the features, enlarged and distorted by the puffing of the subcutaneous cellular membrane, acquire a character of the most frightful deformity. Arrived at this stage, elephantiasis sometimes remains stationary; and then the skin alone seems implicated; the principal functions are performed with perfect regularity.

The time which elapses between the appearance of the first tubercles and the development of those which succeed them, varies extremely; in general, however, they are rapidly evolved; they never acquire a very large size. At a subsequent period, commonly after several years, the greater number of these tubercles inflame, and are either resolved or suppurate. Ulceration is preceded by an acute inflammatory state, during which the tubercles, and the integuments surrounding them, become hot and red. The sanious pus of the tubercles which become softened, dries up speedily, and forms adhering, brown or blackish scabs, which rarely rise above the level of the skin. Sound cicatrices are occasionally formed under these scabs; but this termination is extremely rare.

776. When Greek elephantiasis appears before the age of puberty, the development of the beard, and of the hair upon the genital organs and axillæ, is often checked. In some patients the axillæ and pubes are covered as usual with hair, but the beard is wanting, or a few straggling hairs appear upon the throat in situations where no tubercles are evolved. In adults, the beard, and axillary and pubic coverings, and occasionally, but more rarely, that of the scalp, have also been observed to be lost. I have already said that the sensibility of the skin might be blunted or increased; sometimes it is not at all changed.

777. On the upper extremities the tubercles follow the same course

in their evolution: less numerous in general than on the face, they appear more particularly on the outer and posterior aspects of the forearms. The hand is almost always swollen, but is rarely the seat of tubercles; it is commonly of a livid tint, with less of the bronze cast than the other parts of the body. The same phenomena are observed to take place in reference to the lower extremities and feet. The space in the sole, included between the heel and heads of the metatarsal bones, filled with swollen cellular membrane, causes the foot to appear quite flat. The tubercles of the buttocks are rather large; those of the sole are flattened. Ulceration of the tubercles of the legs is always slow of healing; the phalanges are occasionally stricken with sphacelus, especially when the disease, complicated with important lesions of internal organs, is tending to a fatal termination. The trunk of the body is seldom affected with tubercles.

778. The mucous membrane of the mouth, the velum palati, uvula, amygdalæ, pharynx, and nasal fossæ, very commonly also present tubercles, but less voluminous than those of the skin; a longitudinal band of tubercles is frequently seen extending from the superior incisor teeth backwards along the roof of the mouth to the uvula. The lingual veins are occasionally observed to be varicose. An inflamed state of the pituitary membrane gives rise to the secretion of a sero-purulent fluid from the nostrils, to pain of the frontal sinuses, and finally to caries of the cartilages and turbinated bones of the nose. The voice becomes hoarse, nasal, and then is lost. The affections of the organ of hearing in elephantiasis do not extend beyond the external auricle. This part is enlarged, deformed, of a livid colour, and commonly beset with tubercles. The sense of smell, almost uniformly deranged even from the commencement of the disease, is always destroyed entirely when it has attained a certain stage; that is to say, when the pituitary membrane, covered with tubercles, ulcerates, and pours out a profusion of fetid secretion. The eyes, except the deformity caused by the loss of the cilia, are seldom affected either externally or internally. Although the arch of the palate and the lining membrane of the mouth are frequently thickly beset with small tubercles, developed in the mucous follicles of this tissue, the sense of taste generally remains intact. The pharynx at length, is usually covered with tubercles, but the œsophagus is seldom thus affected. When the patient has not been put upon a lengthened course of purgatives or arsenical preparations, the stomach and intestines commonly perform their functions satisfactorily. Yet in the bodies of those who have died while labouring under Greek elephantiasis, the follicles of Peyer have been found very much developed, as well as intestinal tubercles ulcerated, or on the point of becoming so, small cicatrices, and enlarged or tubercular mesenteric glands (Larrey). The liver and spleen have not been observed to be morbidly affected. In accordance with the affection of the voice during life, a thickened state of the mucous folds of the larynx, tubercles upon the chordæ vocales, and occasionally ulcers which had destroyed the thyro-arytenoid ligaments, have been discovered after death. Neither is it uncommon to observe small ulcers of the mucous membrane of the trachea. The lungs have generally some crude or softened tubercles scattered through their substance. Three patients affected with elephantiasis, whose bodies I have examined, after their demise, presented this alteration of the lungs. Others, who have died at a less advanced stage of the disease, have shown unequivocal traces of pneumonia. The organs of circulation and of innervation present nothing peculiar, so long as the disease continues limited to the skin.

Authors are not agreed in regard to the influence of Greek elephantiasis on the organs of generation. According to some, the disease always arrests the evolution of these organs when it occurs before puberty; and when the attack occurs after this period, it causes them to fall into a state of atrophy (Adams). Pallas also informs us that the Tartars affected with elephantiasis show a distaste to sexual intercourse. All the patients I have had an opportunity of seeing myself, however, had the genital organs very well developed. On the other hand, none of them were tormented by the *libido inextinguibilis*, mentioned by some writers, particularly by Vidal and Joannis, as a frequent concomitant of elephantiasis. Niebuhr relates that a leper of the Lazaretto of Bagdad, a prey to the venereal appetite, succeeded in communicating his disease to a woman of the town, who was in consequence admitted into the Lazaretto to him. This patient was

perhaps affected with lues venerea and syphilitic tubercles of the skin. (a)

The organs of locomotion are remarkably enfeebled in elephantiasis, although this is not a constant symptom of the disease. If it has begun before puberty, the patient continues weakly and gradually becomes deformed; if, on the other hand, manhood has been attained before its invasion, and the subject be in other respects well constituted, the affection of the muscular system is only observed to come on by slow degrees, and follows the current of the disease. The lesions of the osseous system, described by some authors, and denied by others, are admitted on the strength of the solitary case related in the dissertation of Ruette. To sum up, Greek elephantiasis appears to affect especially the skin, the mouth, the nasal fossæ, and the organs of the voice and of respiration.

779. Robinson, who studied elephantiasis at Calcutta, reckons two species of the disease; one, the tubercular, the characters of which I have just detailed (775-778), the other distinguished by the occurrence of broad tawny patches, of considerable extent, shriveled or wrinkled on the surface, *insensible*, attended with slight desquamation of the cuticle, and a peculiar deformity of the hands and the feet, and ending in extensive ulceration, which causes a loss of soft parts, greater or less in amount. This is the elephantiasis *anesthesiaca*,<sup>1</sup> the same disease described under the name of *Baras*, by Avicenna, and which has been observed by Winterbottom. Vidal tells us that he has seen individuals labouring under elephantiasis, whose sense of touch was blunted, not only in the extremities, but over almost the whole surface of the body, though they still suffered much from internal pain.<sup>2</sup> (b)

(a) Mr. Peacock, (*Edinb. Med. and Surg. Journ.*, 1840,) in his account of the tubercular form of elephantiasis in the island of Ceylon, coincides with Ainslie, who describes the loss of power and wasting of the testicles as of invariable occurrence in the latter stages of the disease. In some cases these glands could scarcely be detected, and in the case of a young man, then 25 years of age, who had been attacked with the disease before he was 14, the signs of puberty had not developed themselves. Mr. Peacock admits, however, that where the disease has been of much shorter duration the sexual feeling was certainly not impaired.

(b) The symptoms of the more aggravated form of elephantiasis are well described by Mr. Brett (*On the Surgical Diseases of India*). He calls the disease *lepra tuberculata virulenta*.—"An individual labouring under this complaint usually presents himself in the following condition: A general torpor seems to pervade his system, so that his sensations of pleasure and pain are considerably impaired. Instead of that excessive propensity to venery which they are generally supposed to possess, they have usually little or no inclination for such

<sup>1</sup> From a priv. and ἀνίσθησις sento.

<sup>2</sup> On the subject of anesthesia in elephantiasis, the authors who have written on the lepra of the middle ages, must be consulted. The greater number of these recommend the skin to be pricked, to ascertain whether it be sensible or not. Ferrius describes, as the first degree of elephantiasis, the case of a man fifty-one years of age, whose skin was marked with black or livid spots, *sensu nullo aut obtuso præditæ*; and in his general description of the disease, he says of those who are affected: *in his sensus torpescit*. Paré tells us—"Véritablement je me suis souvent trouvé à l'épreuve des ladres, et entre tous les signes dignes d'être bien notés, cestuy-cy m'estoit commun, c'est que les ayant piqué d'une grosse et longue espingle au gros tendon qui s'attache au talon, et voyant qu'ils n'en sentoient rien, bien que j'eusse poussé l'aiguille fort avant, je conclus que véritablement ils sont ladres." (Paré. Œuvres, liv. vii. chap. ii.) More modern writers have also particularly mentioned the diminution of sensibility in the disease denominated elephantiasis. Cleyer notices the symptom in his account of the elephantiasis he observed at Java. According to Schilling, elephantiasis is distinguished by two principal characters: a change in the colour of the parts affected, and insensibility of the skin. Hahn, in speaking of a patient labouring under elephantiasis, whose skin, besides tubercles, was covered with white squamæ, says—"Plena *anæsthesia* est in cute sinistri genu, quæ non tantum, quatenus exstat, sed profundius pungi, inscio ægro, potest." This insensibility, he observes, was especially remarked over the old patches of the disease, which were of a dusky hue, and slightly prominent. Winterbottom divides the elephantiasis which he studied among the negroes on the west coast of Africa, into three species, or rather three degrees:—1st. Demadyang, in which the skin is only discoloured and insensible; 2d. Didyan (Juzam), in which there were ulceration and loss of the phalanges of the fingers and toes, swelling and ulceration of the lips and alæ nasi. 3d. Baras, in which the same symptoms occur, but of greater intensity, with ulcerative destruction of the throat and structures of the nose. Robinson describes a variety of anesthesiac elephantiasis with discoloration of the skin, which he observed in the East Indies, and which Bateman conceives to be the *Baras* of the Arabian writers. Dr. Fuchs has given the details of two cases of elephantiasis *anesthesiaca*.

780. *Anatomical Researches*.—Elephantiasis is a disease which is very seldom seen in Europe, and opportunities of instituting inquiries into the morbid anatomy of the affection occur still more rarely. All the inquiries that have been instituted, however, tend to show that those who are the subjects of the disease, almost always fall victims to acute or chronic inflammatory affections of the organs of voice, of respiration, and of digestion. I shall, by and by, give the history of a case of elephantiasis, with the whole of the very accurate details of the post-mortem appearances. Vidal saw one patient affected with elephantiasis die of a pleurisy; a second succumbed, after having suffered extreme oppression in his breathing, which was preceded by the drying up of his ulcers; a third was carried off by a putrid fever; a woman sank under the sequelæ of her confinement.

781. *Causes*.—First observed in Egypt, then in Italy during the time of Pompey, elephantiasis subsequently extended, and has since been seen in the four quarters of the globe. It spread over the whole of Europe like an epidemic during the middle ages, especially about the period of the Crusades; and at this time, houses destined for the reception, or rather for the confinement of lepers, were established in great numbers.<sup>1</sup> Since the commencement of the 17th century, this

indulgence, though there are exceptions to this, where it exists in a diminished degree only. The pulse is slow, not small, but heavy, 'as moving through mud.' There seems to be a sort of stagnation in the process of nutritive vitality. The bowels are generally constipated. The patient's face is bloated. His forehead, nose, lips, and ears become swollen; his nostrils expand; his eyes appear sunk and fiery, the tone of his voice is altered to a loud and nasal sound; the skin, especially of the extremities, is harsh and scaly, resembling a case of ichthyosis. He is subject to profuse perspirations, especially when exposed to the sun; these are confined to the trunk, not the slightest moisture permeating the surface of the scaly extremities. He is often distressed with thirst and a sensation of internal heat. The knees are stiff, and their motions contracted. The hairs generally fall from the brows, the beard, the pubes, and axillæ, &c., or they are seen stunted and dried up for want of moisture. His breath is fetid, and his perspiration rank and offensive. The blood drawn by venesection is very dark. A kind of dry gangrene pervades the fingers and toes, which are generally eaten away, and drop off at the first phalanges; these sores then generally cicatrize over without any rete mucosum, and the next joint becomes invaded by a renewal of the ulcerative process. It is singular to observe that notwithstanding these extensive sores, they can wear hard shoes, which are seen saturated with the sanious ichor that exudes from these ulcerated surfaces. The disease progressively advances, eating through the ankles and wrists, and performing slow but certain and successive dismemberments, every revolving year bearing some trophy of this tardy but gradual march of death, till at last the vitals become affected. During all this, a sleepy inertness overpowers his mind, and 'seems to benumb and almost annihilate every faculty, as well of the soul as of the body, leaving only sufficient sense and activity to crawl through the routine of existence.' In the last stages of the complaint, the flesh gapes with long sores, the mouth, nose, and brain become exposed to its ravages, and death at length terminates this loathsome existence. He is usually cut off by the supervention of diarrhœa. It is astonishing, however, to witness how long the victim lingers, from twelve to twenty years being no uncommon duration. During the greater part of this period he has a good and even voracious appetite, and moves about from village to village."—*British and Foreign Med. Rev.*, pp. 424-5, vol. xii.

<sup>1</sup> Between the 11th and 16th centuries, an immense number of hospitals for lepers were to be found in every country in Europe. The numbers of these houses, however, have been over-rated, through a false interpretation of a passage of Math. Paris (*Hist. Angl.* ad ann. 1244. Ducange, *Glossaire*, Art. Lazaret). Still they must have been very common in certain provinces of France. Thus Henry II., Duke of Normandy, caused a superb edifice, for the reception of lepers, (*grande maladrerie*), to be erected near Caen, in the year 1160. This building is now a *maison de détention*. We have also accounts of the *maladreries* of Mondeville, Cagny, Argences, Troarn, Rupierre, Varavielle, Ranville, &c., so that it would appear there was no burgh or commune which had not its special *maladrarium*, *misellarium*, *ladrarium*, or hospital for lepers. (Delarue, *Hist. de la Ville de Caen*, 8vo. Caen, 1820.) Into these houses, individuals affected with ulcers and other chronic diseases of the skin, were also at length received. (Vide G. Horst. *Obs. Med.*, lib. vii. obs. xviii.) P. Foreest. *Obs. Chirurg.*, lib. iv. obs. vii. Riedlin. *Linnæ Medic.*, vol. iii., an. 1677.

dreadful disease has disappeared from almost all the districts of our continent which it formerly ravaged; and Greek elephantiasis, at the present time, is a disease confined to the equatorial or inter-tropical regions of the globe. Much more common among the poor than the rich, it principally attacks those who are in indigence, and strangers after a residence of longer or shorter duration. The disease has been studied by Pococke in Asia Minor, by Prosper Alpinus, and Messrs. Desgenettes and Larrey in Egypt, by Bruce in Abyssinia, Marsden in Sumatra, Marshall in Ceylon, Robinson and Ainslie in India, and Bergeron in Cayenne. It has also been seen in the Antilles, in St. Domingo, Martinique, and New Orleans, on the west coast of Africa, and the islands that lie to the southeast of this continent, Bourbon, the Isle of France, Madagascar, &c.; so that it seems demonstrated that a generally high temperature, joined to a humid and variable state of the atmosphere, is a condition extremely favourable to the development of elephantiasis. Nevertheless, it is well ascertained, that the disease prevailed in the year 1686, in the Faro Islands,<sup>1</sup> which lie to the southwest of Iceland, in the Northern Ocean. (a) Greek elephantiasis has also been seen in France among natives of the country: Vidal, Valentin, and Fodéré, have observed it at Martignes and Vitrolles; Delpech informs us that it is frequently seen at Roussillon, especially in the neighbourhood of Elsne. It is, however, still a question, whether the disease originated in these situations, or has not rather been, as all circumstances would lead us to believe, imported thither and continued hereditarily. The same uncertainty prevails in regard to the origin of the elephantiasis which occurs on the plains of Arragon.

Other causes have been stated, the influence of which on the development of Greek elephantiasis is less apparent. The stagnant waters of marshy districts, the moist heats of autumn, low and sheltered situations, filthy habits, bad food, exposure to wet, &c., have one after another been set forth as adequate to produce the disease; but the whole of these causes occur combined in places where Greek elephantiasis has never been seen. Though inadequate to excite the disease, however, they may unquestionably favour its development, and keep it up in certain districts.

Arætaus, Galen, Schilling, Forest, &c., and in later times, Darwin and Cullen, have held that Greek elephantiasis was contagious. Had the disease truly this character in the olden times, when it prevailed epidemically in Europe? The cases observed in India by Robinson and Ainslie (*Medico-Chirurg. Trans.*, vol. x.), in Madeira by Adams and Heberden, the few I have myself seen in France, where I have observed West Indian Creoles living in the midst of large families without communicating the horrible malady to a single individual, and the concurring testimony of all observers, lead to the conclusion that Greek elephantiasis is never communicated by an individual affected, to an individual in health—that the disease, in a word, is not contagious. One of my pupils, M. Raisin, jun., has oftener than once, and for several days in succession, worn the clothes of a person affected with elephantiasis, without suffering the slightest inconvenience. Many facts prove that Europeans have contracted this disease during a residence in the East and West Indies. Women labouring under elephantiasis have produced children who have never suffered in the same way; but the fact of the hereditary transmissibility of the disease is one not less certainly ascertained. After the most careful study of the affection in the Lazaretto of Madeira, both Adams and Heberden are of opinion, that not only is the disease transmitted hereditarily, but that it occasionally descends through several successive generations. The researches of Dr. Ainslie in India tend to confirm the views of these excellent observers. M. Alibert tells us that he had met with two women who inherited elephantiasis from their parents.

In the Lazaretto of Funchal, the majority of the individuals affected with Greek elephantiasis had not yet attained the age of puberty.

(a) Greek elephantiasis or leprosy, is met with along the western coast of Norway. It is represented by Dr. Danielssen as hereditary, but not contagious. A similar disease has lately appeared in New Brunswick, and is described by Mr. Skene (*Med. Gaz.*, 1844).

<sup>2</sup> De Chamseruc et Coquereau. *Recherches sur l'état actuel de la lèpre en Europe*, &c.; *Mémoires de la Soc. Roy. de Méd.*, t. v. p. 199.

From the other documents examined by Adams, it would appear that in the course of a century, five hundred and twenty-six men, and only three hundred and seventy-three women had been received into that establishment, a difference of nearly a third in favour of women. M. J. C. Soarès, of Marscilles, informs us that, of a hundred individuals attacked with Greek elephantiasis in the Brazils, ninety are of a sanguine or bilious-sanguine temperament.

782. *Diagnosis*.—It is of importance to distinguish accurately between Greek elephantiasis and Arabian elephantiasis, lepra and certain syphilitic affections.<sup>1</sup> Arabian elephantiasis never commences primarily in the skin; even when it follows a confluent lichenous eruption, or a chronic eczema; these affections are evidently causes not elements of the disease. Arabian elephantiasis is observed at the present time in countries under every latitude; Greek elephantiasis, on the contrary, is scarcely seen save among individuals who have lived in one or other of the inter-tropical European colonies, or who are natives of these regions, or who have inherited the disease from their parents. As to Greek leprosy (*lepra vulgaris*), characterized by rounded and pretty broad squamous patches, depressed in their centres, enclosed within a raised reddish circle, and scattered over the surface of the body, it has really nothing in common with elephantiasis save the distinctive epithet.

783. Greek elephantiasis has been maintained to be a mere modification of syphilis; but elephantiasis, besides that it was described long before we have any mention of syphilis, has been observed in many instances when there could be no suspicion of venereal affection, either of recent date or older standing. Further, the blotches and tubercles of syphilis have by no means the same appearance as the tuberculations of elephantiasis. Those of elephantiasis have a shining brownish tint, and oily look, and are attended with a general puffiness, and occasionally with a great degree of insensibility of the skin in their vicinity. The tubercles of syphilis, again, are red or livid, hard, developed in the substance of the corion, clustered together, and almost always consecutive to venereal ulcers of the genital organs; very different, therefore, from the soft, tawny, irregular tubercles, separated from each other by deep fissures, proper to Greek elephantiasis. Lastly, in those rare cases in which Greek elephantiasis is characterized, not by yellowish blotches and oily-looking tubercles, but by fungous and sanious sores, resting upon soft and flabby bases; these are not less distinct from ulcers of syphilitic origin, for the most part so well marked by their indurated and sharply cut but irregular edges, and their grayish bottoms of variable depth. The tubercles of cutaneous cancer, or of lupus, cannot be confounded with those of elephantiasis.

Neither of these is attended with the loss of the hair of the parts they affect, with the development of tubercles on the arch of the palate, or any material alteration of the voice; they have, in addition, peculiar and very constant characters, extremely different from those of Greek elephantiasis.

784. No one now thinks of simulating Greek elephantiasis, although this seems to have been done occasionally in former times.<sup>2</sup> The serious nature of the disease has been noted by every writer who has seen it since the time of Aretæus. Despite the praises that have been lavished on certain medicines, almost all the well-marked and inveterate cases of the disease are incurable. Those who are attacked with it before the age of puberty, commonly die between their twentieth and twenty-fifth year. Those who contract it later in life, may drag on a painful existence for some considerable time. Some have been seen presenting all the outward symptoms of the disease for more than twenty years, without any notable disturbance of the principal functions of the system. The fatal termination is almost always owing to the sequelæ of inflammatory affections of the organs of the voice and respiration, and of those of digestion.

785. *Treatment*.—The treatment in Greek elephantiasis should be directed with a view to prevent the development of tubercles; to favour the cicatrization of sores; to obtain the resolution of such spots and tubercles as exist, when any have been formed; and to

<sup>1</sup> When elephantiasis (*lepra*) reigned epidemically during the middle ages in Europe, those who are suspected of being affected underwent an examination, the model of which may be found in Horstius, Fernelius, Paré, &c., and those pronounced lepers, were shut up in one of the houses appropriated for that purpose.

<sup>2</sup> The case given by Paré deserves to be particularly referred to. Liv. xxiv. chap. viii.

check the progress of chronic inflammation of the larynx, lungs, stomach and intestines, if it has already occurred, or to prevent it entirely, in case it has not yet made its appearance. To attain these ends, removal into a mild and temperate climate has been recommended, and many persons affected with elephantiasis, have quitted intertropical countries for the south of France and Italy, but in general without deriving any benefit from the change. The practitioners of the Antilles are in the habit of sending their patients to the island of Desiderada, remarkable for the mildness of its climate, and the excellence of its fruits, a twofold recommendation, which, it is presumed, should tend to modify the constitution favourably, and to retard the natural course of the disease. Patients should pay the greatest attention to personal cleanliness, and change their linen frequently; they should take gentle exercise, and their spirits must be kept up by the constant presence of some devoted friend or attendant.

Besides the morbid alterations of the skin, some patients exhibit unequivocal symptoms of chronic inflammation of the pharynx and stomach, of the larynx, trachea, and occasionally of the lungs. These ought to be put upon the use of mucilaginous drinks, with a diet consisting of milk, white meats, veal, chicken, or turtle broth, &c. As to the specific properties of the viper in this complaint, modern observers are mostly agreed in regarding them as fabulous.<sup>(a)</sup> Other patients affected with elephantiasis show no symptoms of any serious disorder of the larynx, trachea, lungs, or intestines. In the majority of these cases, I have preferred recommending bland diet, and a regular plan of life, to prescribing a course of active medicines, often uncertain in their primary effects, and occasionally dangerous in their secondary or remote consequences. It cannot surely be a matter of indifference, whether or not individuals are put upon a course of cantharides, of arsenic, of decoction of mezereon bark, &c., who, from all concurring testimony, are known commonly to die at an early age, of some inflammatory gastro-pulmonic affection.

Heberden informs us that he cured a patient in five months, who had taken antimony and mercury fruitlessly for seven years. The medicine employed was a mixture of an ounce and a half of powdered cinchona bark, and half an ounce of powdered sassafras root, made into an electuary with simple syrup, of which the patient took a piece, the size of a nutmeg, twice a day. He, at the same time, rubbed his arms and legs, night and morning, with a mixture of an ounce of oil of tartar, two ounces of sal ammoniac, and eight ounces of brandy. Blisters were also applied between the shoulders. Several cases seem to prove the utility of the muriate of gold, administered in doses, gradually increased from the tenth to the fourth of a grain, during several months, by way of friction, under the tongue. These cases, however, it is much to be regretted, are still very far from satisfactory. Our Indian practitioners have spoken of the *asclepias gigantea* as a kind of specific. Playfair has published an interesting account of the therapeutic effects of this plant, in the first volume of the Transactions of the Medical Society of Calcutta; and Robinson (*Med. Chir. Trs. of Lond.*, first part), thinks that it may be useful in anesthesiac elephantiasis. Sarsaparilla and squill have also been recommended to attention. Turner and Vidal have seen tubercles resolved under the use of alkaline frictions. The tubercles and stains of the disease may be destroyed by the application of caustic when they are not numerous; but it almost always happens that new tubercles are developed in other situations. The discussion of the tubercles of elephantiasis has also been attempted by means of the sulphur, the vapour, and the sea-water douche, ammoniacal frictions, &c.; but the whole of these various remedies have been attended with very uncertain results. The baths recommended by some authors have been held useless by

(a) M. Sigaud (*Du Climat et des Maladies du Bresil*, pp. 389-93) gives the details of the case of a Brazilian who, having suffered for more than four years from leprosy in its worst form, determined to try the effects of the bite of a rattlesnake. The wound was received between the first joints of the little and ring fingers, at ten minutes before twelve (noon), and at half-past eleven the following morning, the man was dead, after great suffering. No autopsic examination was made, owing to the rapid decomposition and extreme fetor of the body. Ten hours after the bite, there was a great depression of the tubercles on the arms and face.

others, as Walesius and M. Cassan. Robinson has advised the application of blisters to the insensible patches of elephantiasis *anesthesiaca*. The bi-chloride of mercury internally, and mercurial frictions externally, have been employed in elephantiasis without success. The various preparations of arsenic have been particularly upheld, for their powers for bringing about the resolution of the tubercles of elephantiasis. But patients have frequently been found to droop and then to die, under the fever which these medicines are apt to light up. In two cases, which were watched by M. Raisin with particular attention, the Asiatic pills,<sup>1</sup> taken regularly for a short season, had soon to be given up on account of the irritation of the gastro-intestinal membrane they occasioned, without benefiting a single symptom of the disease for which they were prescribed.

The whole of these various and fruitless experiments but too forcibly remind us of the accuracy of the prognosis pronounced by Hollerius,—confirmata elephantiasis non curatur (de Morbis internis, p. 64, de elephantiasi).

It is from the labours of the practitioners of the European colonies established in intertropical countries, that science looks for new light in regard to Greek elephantiasis and its treatment. (a)

#### Historical Notices and particular Cases.

786. No mention is made of the collection of Hippocratic writings of elephantiasis. Some interpreters, however, insist on the affection being there indicated under the name of the *Phœnician disease*.<sup>2</sup> The poet Lucretius,<sup>3</sup> forty years before the time of Celsus,<sup>4</sup> first speaks of elephantiasis, and he assigns Egypt as the country where it occurs. Celsus gives the principal characters of elephantiasis, and adds that the disease is scarcely known in Italy, but very common in certain other countries. Galen supplies us with several particular but imperfect cases of elephantiasis, with a view to demonstrate the value of the flesh of the viper; in another place he adds that the disease is common in Alexandria.<sup>5</sup> Aretæus<sup>6</sup> has left a very accurate picture of the symptoms of elephantiasis. The sole objection, indeed, that can be raised to this description of the disease, which is much more detailed than that of Galen and Celsus, must be made on the score of certain forced comparisons and contrasts, the end of which, however, is to explain the origin of the various denominations given at

(a) The various preparations of iodine, and the iodide of mercury and arsenic, merit a careful trial in elephantiasis. If the treatment begun at an early period of the disease, we may hope for success. "In Hindostan, arsenic is the remedy most generally employed, but it is associated with the mudarr (*Asclepias gigantea*) to which Playfair, Robinson, and others have ascribed great virtue. The most accredited form is the following: oxide of arsenic, 55 grains; mudarr powder, 4 ounces and 80 grains; black pepper, 9 ounces: the whole well beaten at intervals for four days, made into a mass with water and divided into 800 pills. Not more than two pills should be taken daily, which are equal to about a seventh of a grain of arsenic. Mr. Marshall treated 200 cases with nitric acid, a drachm in a pint or a pint and a half of water daily; above one third were cured and the remainder were greatly benefited. The Hindoo physicians place their patients during treatment on the following diet: all kinds of game, Sushtiká rice, and Urhur."

<sup>1</sup> Compounded of white oxide of arsenic and black pepper.—Tr.

<sup>2</sup> *φαινική νόσος*, printed in the ordinary editions, evidently by mistake, *φαινικα*. Mackius, in his edition of the works of Hippocrates, fol. Vienna, 1743, has restored the proper reading, which Foesius had only ventured to correct in a note. Galen speaks of a *φαινική νόσος* by which, probably, elephantiasis is meant. M. Alexandre, in his Greek dictionary, quotes Herodotus as his authority for the phrase *φαινική νόσος*, which he translates lepra. There is another passage of Herodotus where lepra and leuce, *λεπρα*, *ἡ λευκή* are mentioned together, the latter term is probably employed in the same sense as it is used by Hippocrates. (Herod., lib. i. p. 59. Bd. in fol. Francof., 1606.)

<sup>3</sup> "Est elephas morbus qui propter flumina Nili.

Gingitur Ægypto in mediâ neque præterea nusquam.

(De Rerum Natura, lib. iv.)

<sup>4</sup> Medicina, lib. iii. sect. xxv.

<sup>5</sup> Galeni Opera. De arte curativâ ad Glauconem, lib. ii. De canero et elephantiasi: "In Alexandria quidem elephantis morbo plurimi corripiuntur propter victus mobum et regionis fervorem. At in Germaniâ et Mysiâ rarissima hæc passio videtur. Et apud Scythos, lactis potatores, nunquam fere apparuit."

<sup>6</sup> Aretæus. De causis et signis morborum. Fol. Ludg. Batav., 1735, p. 69. De elephantiasi.

different times to the disease, such as leontiasis, satyriasis, and elephantiasis. Pliny<sup>7</sup> recapitulates the principal characters of elephantiasis, and tells us that the disease indigenous in Egypt (*Ægypte peculiare hoc malum*), had not been seen in Italy previous to the time of Pompey. The opinion of the contagiousness of elephantiasis, which we find announced in Herodotus and in Galen, is more strongly insisted on by Cælius Aurelianus,<sup>8</sup> who recommends the isolation of those affected with it as a measure necessary to the public health. He also speaks of the advantages which may be derived from blood-letting and purgatives in its treatment. Paul of Ægina,<sup>9</sup> in discussing elephantiasis, dwells more especially on the general hygeiastic measures adapted to strengthen the constitution. Not one of these Greek or Latin authors, except Herodotus, has assimilated elephantiasis with lepra or leuce.

The Arabian writers have described elephantiasis under the name of *juzam*, which their translator have rendered by the word *lepra*. Avicenna<sup>10</sup> rehearses the phenomena already signalized by the Greek and Roman authorities, and particularizes several symptoms of an alarming nature. Several historical writers and others<sup>11</sup> have left us ample documents in regard to the lepra of the middle ages. Hensler,<sup>12</sup> in these latter times, has made their accounts the subject of his particular studies. Lepra is known still to have prevailed in Europe during the fourteenth and fifteenth centuries. Guy de Chauliac, Fernelius, Paré, Vesalius, Horstius, Forestus, &c.,<sup>13</sup> may each be consulted with profit for information upon the lepra which prevailed epidemically during this latter period.

Observations have since been extended, and the disease has been seen in most parts of the globe. In France<sup>14</sup> elephantiasis has been studied by Raymond, Joannis, Ruette, Vidal, Fodéré, Valentin, and others; in Spain<sup>15</sup> very recently by Fuchs, who has given us a map of the various places in which he met with the disease in traveling along the shores of the Mediterranean, and who has studied the anesthesiac variety with particular care; in Belgium and Holland by P. Forest;<sup>16</sup> and in Russia by Martius.<sup>17</sup> In Asia Minor the disease

<sup>11</sup> Theodorici, a physician of Bologna of the thirteenth century, has given a good description of the symptoms of *lepra* (elephantiasis), of which he reckons four varieties. 1st. *Lepra elephantina*; a livid colour of the face and whole body, loss of the eyebrows, atrophy of the muscles between the thumb and fore finger; slow course of the disease. 2d. *Lepra leonina*; a citrine tint of the surface, *rotunditas avilorum*; alteration of the voice: formation of tubercles, &c. 3d. *Lepra tyria* (lyrienne); puffing of the eyelids, face, legs, loss of the nails, &c. 4th. *Lepra decalvans* (alopecique) loss of the hair, leucophlegmatic phenomena; hemorrhage from the nose and gums, ecchymoses, &c. Chirurgia Guidonis, Bruni, Theodorici, &c., fol. Venet., 1519.

<sup>12</sup> Ph. Gabr. Hensler. Vom abendländischen Aussatze im Mittelalter, &c.; on the western leprosy of the middle ages, with an illustrative and historical supplement. 12mo. Hamb., 1790. In his first part, Hensler has collected the greater number of those passages in the older writers, especially of the middle ages and of Arabia, that bear upon the subject of elephantiasis; but these are, after all, the mere materials of history, and required a very different arrangement to make them generally useful, from that they have received at the hands of Hensler. Of this truth conviction is easily obtained, by turning to page 369 of the work, where he confounds the Arabian elephantiasis or Barbadoes leg, Vitiligo, the fourth impetigo of Celsus, certain squamous affections and pellagra, one with the other. The judgment of the physician is not here combined with the erudition of the scholar. But the period at which Hensler wrote, may undoubtedly be charged with the sin of much that is faulty in his works: the admirable disquisitions of Willan upon the diseases of the skin had not yet appeared; Hensler was without a compass on an unknown sea; but he evidently wanted that spirit of penetration which catches a glimpse even of things unknown, and that acute judgment which bids us pause, when others of the mental powers are about to enter upon an erroneous path.

CASE CXL.—*Greek elephantiasis; improvement after several attacks of erysipelas.* B \* \* \* was born in Guadaloupe in the year 1807, of healthy parents, of French origin, inhabitants of Pointe-à-Pitre. B.'s father died in Guadaloupe of fever, never having had elephantiasis; his mother resides in Paris in the enjoyment of good health. B \* \* \* was suckled by his mother, as were his two brothers, both established in Guadaloupe, and said to be of sound constitution. Madame B \* \* \* cannot tell how her son became affected by elephantiasis. She had, indeed, seen many persons labouring under the disease in Guadaloupe, where it is believed to be contagious: but she believes she is correct when she says, that her son never had intercourse with any one so affected. As to the contagiousness of the disease, Mad. B \* \* \* observes that she and her son had never lived apart; that during the earlier stages of the disease he frequently slept in the same bed with her; and that since this period, she and his other relations have frequently embraced him without fear and without inconvenience. She adds that the food of the family where she lived, at Pointe-à-Pitre, like that of the inhabitants at large, consisted in great part of the fish caught in the neighbouring seas, on account of the high price of butcher's meat. A physician of the country, whom she had consulted, appeared to ascribe a certain influence to this kind of living in the production of her son's disease.

Under the age of nine years, B \* \* \* suffered only from the indispositions common to children; he was even remarkable for his fresh and healthy complexion. At this time, however, and without known cause, several blotches (taches) and red or yellowish spots (boutons) appeared on the thighs and loins, and subsequently on the face and different other regions of the body; the skin, from having been white, now acquired a colour similar to that of the mulatto; and tubercular

tiasis. But our author adds certain symptoms, that make the lepra taurica appear as a variety of this disease. He tells us, for instance, that left to itself, the lepra increases in severity every year. First year, livid spots; second, spots larger and blackish; third, pruritus, ardor, tubercula; fourth, pains in the joints, tubercles, squamæ, general symptoms, enlargements of the glands; fifth, ulceration of the tubercles; sixth, spreading ulcers of the skin and of the mouth, aggravation of the general symptoms—death. This is the usual termination of the lepra taurica, which only appears among the populace.

growths, analogous to those which now present themselves (16th Sept., 1024), were evolved on the face and ears. Sarsaparilla was tried for forty days, then thirty of the *médécines de Leroy*, which distressed him greatly, but all without doing any good to the disease, or changing the state of the skin. Madame B \* \* \* and her son embarked for France in 1822. During the passage the disease became considerably worse. At Blois, where they took up their residence on their arrival, B \* \* \* underwent another course of tisan of sarsaparilla, and of artificial Barèges baths, but without benefit. A few tepid baths, taken subsequently, seemed to prove serviceable. On his arrival at Paris, B \* \* \* became a patient at the fourth dispensary, on the 16th of September, 1824, and I had an opportunity of seeing him for nearly two years afterwards. On his admission, B \* \* \* was seventeen years of age, and of low stature. His form was European, but the colour of his skin almost that of a mulatto. The face and extremities were covered with tubercles; the face, more severely affected than any other part, looked generally swollen. The forehead, which was rather high, was beset with flattened and slightly prominent tubercles, from four to five lines in diameter, and of the same bronze-like colour as the skin. There was neither scab nor cicatrice upon it to indicate that the tubercles had ever suppurated. It was crossed by deepish transverse furrows. The skin of the rest of the cranium was free from tubercles, and was covered with strong, straight, black hair; the hairs of the eyebrows were black and scanty. The eyes and eyelids presented no alteration in form, colour, or dimensions. The cilia were distinct but not strong. The nose was large, and very much flattened, and in its general configuration approached that of the negro. A great many small tubercles were clustered upon the alæ of the nose, the surface of which appeared mammillated or lobular. Two months afterwards, the lobe and neighbouring parts were covered in the same manner. The tubercles in these situations were so numerous, that they formed, as it were, one continuous irregularly mammillated mass. Many of these small tubercles, which at first presented the same colour as the skin, became inflamed in succession, and covered with little brownish and strongly adhering scabs; and when several in the vicinity of each other were thus affected, they were all hidden under a uniform incrustation, formed by the union of the lesser scabs. After this kind of inflammatory process had subsided, which was not till a year had expired, the lobe and alæ nasi appeared contracted, and have since continued of diminished magnitude. The lips were thick, somewhat shining, and beset with several tubercles. The chin and cheeks were swollen, and under, and in the thickness of the skin, a number of flat-shaped and slightly prominent tubercles could be distinguished. The conchæ of the ears were much larger than in their natural state. They were swollen, and imbedded in their substance under the skin; a certain number of tubercles, similar to those just described, could be felt. These various alterations gave a particular and hideous character to the physiognomy, but still the countenance bore no resemblance to the head of a lion.

The skin of the neck and trunk was not bronzed like that of the face, being nearly of the same colour as the skin of a young European, and was free from tubercles. The upper extremities presented the following alterations: on the left arm, three or four tubercles only could be felt; they were, however, very numerous on the corresponding forearm, covering its dorsal aspect especially. Some of these tubercles were no more than two or three lines in diameter, others were two and three times larger. Several small tubercles, rising above the level of the skin, and developed in its substance, were also seen on the back of the hand and near the wrist. The smaller tubercles, the size of which did not exceed that of the papulæ of prurigo, were in general prominent, and appeared to be evolved within the substance of the skin; the larger ones, which were like big peas, seemed more deeply situated, and bedded among the subcutaneous cellular tissue. The whole of the tubercles were of the same colour as the skin, and under the finger, felt exactly like little indurated lymphatic glands. Some of these tumours remained stationary for several months, several inflamed and ended in resolution, and others suppurated and became open sores, which never showed any disposition to extend either superficially or in depth; the discharge they poured out was sanguinolent and tenacious, so that the linen of the patient and

the dressings stuck readily to their surface. The secretion dried into brownish or black crusts; those that covered the larger tubercles became prominent, and looked like those of rupia; those that followed the smaller tubercles about the wrist were oval-shaped, and scarcely exceeded the level of the skin. Under the scabs, a cicatrice was slowly formed, which continued of a livid red colour for several months. On the right arm, which was slightly paralyzed in its muscles, nearly the same appearances and phenomena were observed as on the left. The hand was constantly half shut, its integument swollen and indurated, and subsequently stiff and shining.

The lower limbs were slender and weakly, and the patient sometimes complained of a feeling of tension in them. Walking was fatiguing, and running next to impossible. On the thighs the tubercles were not numerous, but in general large. One, situated over the trochanter, ulcerated, and was followed by a pretty broad cicatrice; another, on the buttock, became covered with a brown scab, larger than a shilling, which, when removed, disclosed a sore, with sharp cut and not very highly inflamed edges. In the groin of the right side, an enlarged lymphatic gland, the size of an almond, was discovered. The legs were more thickly covered with tubercles than the thighs. The ankles were swelled; the soles of the feet puffy, and occupied here and there with several, broad, flat and distinct tubercles. The skin here was red and shining at first, but by and by, became pale and wrinkled or puckered in appearance.

The hair, although strong on the scalp, was wanting on the other regions of the body on which it usually appears, at the age which B \* \* \* had now attained; and two years later (1819), there was not a single hair upon the cheek, chin or lip. Between 1818 and 1819, a few scattered hairs did make their appearance on the pubes and axillæ only, situations in which no tubercles had been evolved.

As to the functions of the skin, they appeared much less altered than its structure. Generally, it still preserved its sensibility even over the tubercles; the sense of touch was only blunted in the soles of the feet, which, as I have said, were swollen and tense, and in the right hand, the extensor muscles of which were in a half paralytic state: still the sensibility, even of these parts, could always be aroused by pinching the skin.

Besides the tubercular affection of the skin, and the puffing in places of the subcutaneous cellular tissue, there existed several other alterations which deserve to be mentioned. Along the middle of the palatine arch, for instance, there extended a band of small tubercles, which became regularly broader as it stretched from the incisor teeth towards the uvula and velum palati molliis. Several of these tubercles, of the same colour as the mucous membrane under which they were evolved, inflamed subsequently at different times, and ended in the formation of small yellowish ulcers two or three lines in diameter, which, after continuing stationary for a season, cicatrized like those of the skin. The uvula was enlarged and full of small tubercles. Several were also visible on the pendulous velum. The mucous membrane covering them was very little or not at all inflamed. The only other part of the mouth on which I perceived any tubercles, was the upper surface of the tongue, where there were three or four. Deglutition was easy; the belly was soft, nowise painful, and the organs included within it performed their functions freely. The thorax was pretty well developed; the voice was hoarse, husky and sniveling; the patient felt no pain in the larynx; but for some time had laboured under an habitual cough. An examination of the chest enabled me to detect a slight bronchitis. The affection proved temporary, and the lungs subsequently appeared to be free from all morbid affection. The organs of circulation were in the normal condition. The subcutaneous veins were neither more nor less developed than usual.

With the exception of smell, the senses were possessed in perfect integrity. Ever since the nose had become covered with tubercles, and the disease had extended to the palatine arch, the patient had continued subject to a constant coryza, or cold in the head; this was probably owing to an affection of the mucous membrane of the nasal fossæ, similar in kind to that of the skin and arch of the palate, the consequence of which was an almost complete loss of the sense of smell. B \* \* \* is naturally of a lively disposition, and his conversation is that of an intelligent man. He has a taste for drawing; and since his right hand has become paralyzed, he has even attempted

to gratify his taste by using the pencil with the left. The organs of generation are well developed, and do not appear to have been in any way affected by the disease under which he labours. In 1819, the right testis had not yet descended into the scrotum. That of the left side was of the usual size. No circumstance leads to the belief that B \* \* \* is more insensible to the sight of women than young men of his age; but neither does any particular in his conduct give room for suspecting that he is at all influenced by the *libido inextinguibilis* of which certain writers speak.

In the treatment of this disease, I had recourse at first to the anti-phlogistic system. At various intervals during the course of several months, I covered the face with leeches. The day after each application a little swelling was apparent; but this always subsided in a few days, and left the face what it had been before the bleeding. About a hundred leeches were used in this way, without any improvement, but without detriment. The tepid bath and diluents did not appear to exert any more powerful influence in resolving the tubercles. The digestive organs of the patient seeming to be healthy, I resolved, not without a certain degree of repugnance, on giving the pills of white oxide of arsenic and black pepper (pil. Asiatiques) a trial; and M. Chevalier had them prepared for me, according to the long and singular formula of the memoirs of Calcutta. B \* \* \* took one of these pills, containing the one-sixteenth of a grain of the protoxide of arsenic, daily; after the forty-eighth he began to show unequivocal symptoms of gastro-enteritis. I therefore ordered the medicine to be let off, and returned to the use of the tepid bath and mucilaginous drinks.

At this time B \* \* \* was advised by some one to whom the nature of his disease was probably not well known, to undergo an anti-venereal course, and with this view, he was entered a patient of the Hôpital St. Jacques, on the 11th of March, 1826. But the enlightened physician of that establishment at once perceived the kind of complaint with which he had to do, and no mercurial medicine was prescribed. During his stay in this hospital, on the 24th of March, B \* \* \* had a violent attack of erysipelas of the face, attended with delirium, and a train of other serious symptoms. The inflammation was treated by emollients, two bleedings from the arm, and two blisters to the thighs. B \* \* \* left the Hôpital St. Jacques some time afterwards, and I discovered that the erysipelas had had a very marked and far more favourable effect on the tubercles of the face than any of the remedies I had formerly prescribed. In the first place, the tubercles of the auricle had disappeared, having ended in resolution; the skin, become less brown in its hue, was soft and wrinkled; secondly, several tubercles of the cheeks and chin, and all those of the forehead, save two, were resolved; the lips were not so thick, the nasal fossæ less obstructed, and the voice less hoarse and suppressed; thirdly, many of the tubercles of the alæ nasi, still numerous, were covered with brownish and adhering incrustations; fourthly, the tubercles of the arms and thighs were less numerous than they had been before the erysipelas of the face; several had ended in suppuration, and were now covered with a small blackish scab; fifthly, the hair and eyebrows, which had fallen out in great part after the erysipelas, soon began to shoot again, and before long, appeared at least as thick as ever; sixthly, the tubercles of the palate were in the same state as formerly. I advised B \* \* \* to restrict himself for the present to the use of diluents and the tepid bath. In the month of September, 1825, he was a second time attacked with erysipelas of the face; and, after an interval of four days, with varicella, but suffered less on this occasion. Both of the affections got rapidly well, under the sole use of diluents and pediluvia. At the end of October in the same year, B \* \* \* was a third time seized with erysipelas of the face, which got well as the others had done. These last two attacks of inflammation had a much less obvious influence than the first in bringing about the resolution of the tubercles. Yet the greater number of those of the face had now disappeared; those that remained, had been but lately developed on the nose, and had not been implicated in the inflammation. One circumstance, particularly worthy of notice, is that during the invasion of the erysipelas, and the whole period of the febrile reaction which accompanied it, the tubercles of the extremities became red and hot, as if each of them had been attacked with acute inflammation; it was always as a consequence of this kind

of excitement, that the resolution of those tubercles which disappeared, was accomplished. The knowledge of this physiological phenomenon led me, in the beginning of 1826, to attempt to arouse the indolent tubercles of the extremities, by means of friction with an ointment of the hydriodate of potash. This was first tried on the arm, and had the effect I wished: the whole of the tubercles inflamed; several ran into ulceration, and were followed by small cicatrices; others ended in resolution. This inflammatory process was attended with so much pain, that the patient expressed his decided repugnance to my proposal to try the effect of the same procedure on the lower extremities.

From this time the disease was left to itself. Fresh tubercles went on making their appearance, nearly in the same proportion as others disappeared. B \* \* \* became a patient in the Hôpital St. Louis, in August, 1826. In September, he was attacked anew with erysipelas of the face; the febrile reaction with which it was accompanied, was still felt by the tubercles of the extremities, which, as in the previous attacks of the same kind, became hot, red, and evidently inflamed. B \* \* \* died in February 1827.

CASE CXLI.—*Greek elephantiasis. Various and unavailing modes of treatment.* Death. M \* \* \*, a native of New Orleans, was sprung of parents in easy circumstances. At the age of eleven, a number of blotches, of a pale yellow colour, and little apparent at first, were observed on the thighs and forearms: these were ascribed to the heat of the weather, and no attention paid to them. Two years afterwards, these spots were both more numerous and more conspicuous, and were now pronounced *scorbutic* by the physician who was consulted. Another year elapsed, during which the blotches extended to the face, and a number of small tubercles were evolved in the substance of the skin. A glass of the expressed juice of endive, water-cress, lettuce, and other herbs, was ordered by his physician every morning fasting, and a glass of a decoction of sarsaparilla and the woods, twice during the course of the day. This treatment did no good. The disease made constant progress during the next year; tubercles were evolved at the entrance into the nostrils, which caused a very copious secretion of mucus; the *face began to swell insensibly*; the feet were readily excoriated, and healed with difficulty. M \* \* \*, feeling himself full of life and vigour, thinking little of his ailment, and reckoning on the strength of his constitution, gave himself up, without restriction, to the pleasures of the field, of the table, and of Venus. It was only in the spring of 1821, that he again put himself into the hands of his medical attendant, who prescribed whey, a sudorific tisan, the warm, and, occasionally, the artificial sulphureous water bath, made by the addition of the sulphuret of potash, at a high temperature. These means were followed by no amendment. The patient indulged in his usual habits through the succeeding winter. In the spring of 1822, M \* \* \* applied to another practitioner, who gave him hopes of a speedy cure, from a tisan of sarsaparilla, carrot, &c., saponaceous baths, Belloste's pills,<sup>1</sup> and lotions of althea thrown into the nostrils. During the three or four months that this system was followed, several flesh blotches appeared.

In despair at seeing his infirmity increase, M \* \* \* now resolved to undertake his ease himself; he purchased Leroy's book,<sup>2</sup> and began taking an emetic one day and a purge the next; he then rested a few days, and repeated the medicines; allowing a few more days to pass by, he returned to his vomit, &c., and so on for twenty days continuously. A great degree of weakness, emaciation, and some pain of the stomach were the only results of this emeto-purgative plan of treatment. In the spring of 1823, M \* \* \*, with the advice of one of the physicians he had already consulted, tried a tisan of the leaves of the plantago psyllium internally, and the inunction of the sulphur ointment to the arms only. Four months of this system did no good. M \* \* \*, from having been of a lively turn of mind, was now subdued and melancholy. In the course of the same year, 1823, M \* \* \* put himself under the care of a quack, from whom he took a stone bottle (dame Jeanne) and a half of a medicine, the composition of which was a profound secret; but having accidentally broken one of his large bottles, M \* \* \* found about three pounds of garlie in

pieces, and a glass and a half of antimony at its bottom. This medicine was as unavailing as every thing else. During 1824, M \* \* \* took sea-water baths without benefit, and next year left his native country for France, where he landed on the 15th of May (1825), and immediately came on to Paris. There he entered a Maison de Santé, where he underwent an *anti-syphilitic course*, and at the same time took simple and vapour baths. One of the sub-maxillary glands now inflamed and suppurated. An *anti-scorbutic* plan of treatment was next proposed but rejected by the patient. Under another physician, however, he passed through a course of iodine, and some time afterwards began taking the *pilules Asiaticques*, which, soon causing gastro-intestinal disturbance, had consequently to be suspended. The iodine was tried again at different times. On the 1st of September, 1825, the patient was in the following state:

The face was beset with tubercles, and had a puffy appearance; the complexion was of the dark or bronze colour which distinguishes the mulatto; the scalp was white and showed no tubercles; the skin of the forehead was in the same state as that of the face, bestrewn with tubercles; and, further, furrowed with deep wrinkles. The superciliary ridges were covered with similar tubercles, very numerous, and much crowded, yet without being confluent. Their surface was traversed by oblique folds, which gave them a mammillated or nipple-like character; they projected considerably above or beyond the orbit. The hair of the eyebrows had almost all fallen out; the eyelids were swelled and hard at their edges; the whole of the eyelashes had been lost. The nose was large and much flattened; the nostrils were dilated, misshapen, and ran upwards. An immense number of tubercles were clustered on the *alæ nasi*, the surface of which was knobby and uneven; on the lobe and neighbouring parts they were so numerous that they formed a continuous irregularly mammillated mass. Several of these tubercles which had been inflamed, were covered with small brownish crusts, and the little sores, which secreted the matter that formed these, were long of healing. The cheeks were swollen and also beset with tubercles, though not so thickly as the nose. The lips were large, thick, shining, and covered with tubercles; the chin was likewise swelled, tubercular, and mammillated at the point. A few hairs of the beard appeared here and there, in those parts especially where the skin was merely brown without being affected with tubercles. The ears, in like manner enlarged and tumid, stuck out from the head, and were of a dusky-violet hue, but not occupied by any tubercles. The skin did not present the bronze-like and morbid hue of which mention has been made, lower than the inferior part of the neck. The integument of the trunk was extremely white and fine. The hands, especially the fingers, were swelled; and the colour of their backs, as also of the outer aspects of the forearms, was the same as that of the face. Several brown patches and bands, which stretched down along the angles of the ribs, were apparent on the lower and outer extremities of the shoulder. The skin of the thighs and legs was of a dark-brown. The feet were so much swelled that the patient appeared plain soled.

The arch of the palate was beset with a band of small tubercles, less bulky than those of the skin, but more numerous; they formed a kind of mammillated band, stretching along the median line. The upper part of the pharynx was visibly beset with tubercles. The mucous membrane of the nasal fossæ seemed to be affected with chronic inflammation, and poured out an abundance of purulent secretion. The sense of smell was almost extinct; hearing and sight were enfeebled; taste was perfect, and it was not remarked that touch was blunted. The voice was rough, delivered through the nose, and, at times, almost suppressed.

The organs of generation were in a normal state; the pubes covered with hair, as well as the axillæ, and in a slight degree the breast also. M \* \* \* exhibited nothing of the libidinous appetite mentioned by some writers on elephantiasis. During his stay at Paris, he avowed that towards the sex he felt precisely as other young men of his age.

The patient passed the winter without submitting to any kind of treatment. He went little abroad, and often continued in bed all day. He could not now run rapidly; a great sense of weakness in his limbs compelled him to stop; the slightest pressure caused excoriations and ecchymoses; and the least contusion of the legs was

<sup>1</sup> Compounded of mercury extinguished by rubbing, aloes, scammony, and some opium.—*Tr.*

<sup>2</sup> The *Bachan's* domestic medicine of the French, it is presumed.—*Tr.*

followed by a sore, which was very long of healing. In the month of May, M \* \* \* consented to another mode of treatment proposed to him: *a diaphoretic tisan; frictions along the spinal column, with an ammoniacal liniment; and cauterization of several of the tubercles of the face with the incandescent iron*: all that were thus treated suppurated and soon cicatrized. In September, M \* \* \* complained of violent pain in the right side of the chest, and two days afterwards he expectorated some blood. He was bled to twelve ounces, and felt relieved. The blood abstracted was buffy. He did not recover completely, however; the slightest departure from the strictest regimen caused painful indigestion and sleeplessness. October 24th, the patient had another attack of pain in the right side; fifteen leeches were applied to the part, which did little to relieve him; he coughed a great deal, and expectorated little. The tongue was red, foul, and marked with white streaks. A week afterwards, a number of leeches were applied to the epigastrium. The appetite had now failed; the bowels were obstinately confined. All that was done proved of little avail in relieving the symptoms. The expectoration became purulent, pectoriloquy was detected on the right side, and the patient lost flesh and strength rapidly.

The tubercles of the face were now for the most part in a state of suppuration; the ears were no longer livid or swollen; the hands were emaciated and brown, instead of violet as they had been. November 30th, a profuse diarrhœa succeeded the obstinate constipation which had continued till this time. On the 1st of December the patient became delirious, and on the 3d he expired.

The body was opened, twenty-four hours after death, in the presence of M. Rayer,<sup>1</sup> and of M. Gaide, his pupil. The skin of the face alone bore traces of the elephantiasis under which the patient had laboured whilst he lived. The greater number of the tubercles had been cicatrized, shrunk away, or had ulcerated of themselves. The left side of the chin, to the lower lip, is of a livid or sallow and yellowish hue. Several small striæ are observed on this lip, along the edge, where it joins with the mucous membrane of the mouth, from which the cuticle, in a semi-pultaceous state, is readily removed. The skin of the chin presents a few irregularly circumscribed, nipple-like eminences, covered with cuticle, or hidden by slight squamæ, under which the corion has a slight reddish tint, and appears in some places softened to various depths, in a very remarkable manner. Incised perpendicularly it appears hypertrophied, and on the sides of the chin, is at least two inches thick; by scraping with the scalpel, and still better by maceration, the softened portions of the corion are readily removed. The bronze tint of the skin is not owing to any deposition of pigmentary matter upon the surface of the papillary body; for a perpendicular section through it shows the corion itself to be altered, and the colour to be a consequence of changes undergone in its intimate structure. The integument of the point of the nose, softened in a less degree than that of the chin, is the seat of a number of ulcers of different depths; the surface of this region is covered with a whitish layer, owing to augmented secretion from the sebaceous follicles. This layer removed, a considerable number of small projecting points, of a pearly white, are perceived, which are nothing more than the extremities of the minute epidermic prolongations, that dip into the cavities of the follicles, and form little tubercular offsets, that may be drawn out; after which the skin appears to be perforated by a multitude of conduits, capable of receiving the head of a large pin, which may then be made to penetrate to the depth of nearly a line into the corion. The integument of the forehead and cheeks was covered here and there with a small incrustation, which had followed the ulceration, suppuration, or use of the actual cautery. The same alterations existed in several places of the limbs.

The nasal fossæ, connected together by the almost entire destruction of the septum, presented the following alterations. The mucous membrane completely destroyed in some places, left the bones of the nose exposed; in several places it was covered with a pretty thick layer of muco-purulent matter, in others it was softened and whitish, and here and there was coming off in irregular flaps of small extent. When the muco-purulent layer was removed, a considerable number of small nipple-like projections were exposed, from which little filiform bodies, from half a line to a whole line in length, could be

extracted, formed, in all likelihood, by the concrete fluid of the follicles. In the mouth, two superficial sores, a line and a half across, were discovered on the tongue; these were the only morbid appearances which this organ exhibited. The anterior aspect of the velum palati mollis was slightly whitish on the left side, and was beset on its edges with a number of very small ulcers. The anterior paries of the pharynx, through its whole extent, but especially superiorly, was of a peculiar dull white colour; its free surface was covered with irregular small mammillæ, a number of which could also be traced along that of the œsophagus, projecting, on an average, about a line and a half beyond the level of the mucous membrane. Between this indurated and mammillated state of the mucous membrane of the pharynx and œsophagus, and the morbid alterations of the skin, there was a very great analogy. The mucous membrane of the larynx was lined on its inner surface by a purulent or pseudo-membranous deposit, of considerable thickness, and easily removable with the back of the scalpel. Under this layer, the mucous membrane appeared to be much paler than it is in the normal state. It was also every where thinner than usual, and presented an ulcer two lines in length by one in breadth, which exposed the crico-arytenoid muscle of the right side. The posterior aspect of the epiglottis was possessed by a number of very minute sores, like those of the pendulous velum of the palate. The edges and apex of this organ, everywhere the seat of ulceration, were of a very decided grayish colour. At the place where the epiglottis is continuous with the larynx, and above the margin where the mucous membrane of this part joins that of the pharynx, a small quantity of black matter was observed to have been deposited. The trachea was not sensibly altered, and the bronchi did not exhibit any morbid changes other than the communication of a few of these tubes with the tubercular cavities which I am about to mention. The subcutaneous cellular tissue of the anterior part of the right side of the neck was infiltrated with pus. Several lymphatic glands in the vicinity were enlarged, of a yellowish-gray colour, and softer than natural.

The right lung was much more affected than the left, and its superior lobe was thickly beset with small miliary tubercles, especially upwards, where there was a cavity large enough to hold a pigeon's egg. Between the tubercles the substance of the lung was of a reddish-brown colour, and a good deal indurated. The inferior lobe was affected in the latter way, and showed no signs of tubercles. The left lung contained a good many tubercles, and several small cavities. It adhered slightly to the pleura; on the right side the adhesions were more extensive and stronger, and the pleura contained about a couple of pints of sero-sanguinolent fluid.

The heart, soft and small, was unaltered. The mucous membrane of the stomach, somewhat thickened near the pyloric end of the organ, was, on the contrary, extremely thin near the cardiac extremity, and, in some places, appeared to be even entirely destroyed. Almost the whole surface of the viscus was covered with very distinct vascular ramifications. A vascular injection of the same kind was visible through the whole extent of the intestinal canal, which was also ulcerated in three different places, and the mucous membrane softened in the lower part of the colon. The liver was healthy, as were the kidneys, and the mesenteric glands, and the spleen. The external organs of generation were of the usual size. The glands of the groin were very much enlarged, and, when divided, they had the consistence and appearance of greasy liver.

#### ARTIFICIAL TUBERCULAR INFLAMMATIONS.

787. The bite or sting of many insects, such as the wasp (*vespa*), gnat (*culex pepiens*), bug (*cimex lectularius*), spider (*aranea*), &c., is generally followed by acute circumscribed inflammation, which frequently assumes the tubercular shape. These affections have, for the most part, a particular appearance; their causes, too, are generally known.

788. The sting of the wasp and hornet is more painful than that of the common bee, and often occasions an erysipelatous inflammation. When the sting has been left in the skin it should be extracted as quickly as possible, and a compress of linen dipped in cold water or

<sup>1</sup> M. Raisin is the narrator of this case.

a saturnine solution applied to the part. We are assured that the sting of these insects has occasionally been followed by very serious consequences.

789. The bites of *gnats* are very commonly succeeded by small circumscribed indurations, with surrounding œdematous swelling and redness. The itching occasioned by gnat-bites, is to be allayed by an ether or vinegar wash. In the south of Europe, and in warm latitudes generally, these insects are so troublesome that the inhabitants have to defend themselves during the night by surrounding their beds with a musquito-net.

790. But it is after the bites of the common *bug* that the skin appears to be covered with an eruption of a truly tubercular nature. In spite of all that can be done in some hospitals, this insect, secreted in the bedsteads, especially if they be of wood, in the flooring, or in the partitions of the building, torment the patients during the night, and hinder them from closing their eyes. I have seen patients whose throats, bosoms, and limbs were covered with a copious eruption of lenticular tubercles from this cause, each of which presented a central point, marking the seat of the puncture.

791. The *flea* (*pulex irritans*), which commonly occasions a little red spot with a deeper central point, also gives rise to tubercular-looking elevations in individuals with a fine and highly irritable skin.

792. The *spider*<sup>1</sup> sometimes causes a red and prominent spot, the irritation of which may be relieved by simply washing the part with cold water. The *tarentula* (*aranea tarentula*) causes accidents of a far more serious description.<sup>2</sup> The harvest bug, and other insects that pierce the skin, also occasion severe itching, which is soon followed by large papulæ, or small reddish or yellow tubercles.

793. There are several other accidental tubercles which approach still more closely to the true tubercular inflammations of the skin, both in their appearance and tardy progress. One of my pupils of a sanguine lymphatic temperament, whilst dissecting, chanced to scratch the back of his hand, and in the place there was shortly afterwards developed a flattened, reddish, and irregular circumscribed tubercle, which continued during several years, in spite of all that could be done to effect its discussion. I have oftener than once seen leech-bites, and the slight use of caustics, succeeded in individuals of scrofulous constitution, by indolent, reddish tubercles. Nipple-like tuberculations are also occasionally seen following small-pox, and blisters after they are healed up.

## SYPHILIDA, SYPHILIDES.

### Vocab. Syphilis.

794. By the term Syphilide, I understand every alteration of the outer integument of the body which is produced by a general venereal affection of the system. Alterations of the skin of this kind are commonly associated with one or several other secondary symptoms of lues venerea, and, in the great majority of cases, are consequences of a contagious specific inflammation of the external organs of generation. They consist of exanthemata, bullæ, vesiculæ, papulæ, squamæ, and tubercula, which almost in every instance are evolved upon bases of a reddish-yellow, or copper colour. They also occur in the shape of cutaneous ulcers with yellowish or grayish bottoms, sharply cut edges, and occasionally possessing the phagedænic or spreading character. They show themselves, in fine, as special affections of the papillæ, and of the nails and hair.

795. In the epidemic syphilis of the 15th and 16th centuries, venereal eruptions occurred so commonly a short time after infection, that the disease was regarded as a contagious affection of the skin: at the present day, and indeed for a long time past, these eruptions have been much less frequent, and have always appeared at an epoch much

more remote from the receipt of the poison than they did formerly. This circumstance is explicable from the disease during several ages having been transmitted almost exclusively by the intercourse of the sexes without primary general infection. If the extreme frequency of primary or local venereal symptoms at the present day be considered, cutaneous eruptions may even be said to be rare. It would appear that in consequence of the great number of transmissions, the venereal poison had lost something of its original energy, and that its general effects on the system had in consequence become less common. It is certain, moreover, that the poison is neither so readily transmitted nor possessed of such virulence at every period of the existence of the sores and discharges by which it is propagated.

796. The study of the syphilides cannot be entered upon absolutely, and independently of the other symptoms of syphilis, whether these precede, accompany, or follow the eruptions of the skin which characterize them. It is impossible above all to study the venereal eruptions apart from the primary symptoms to which they succeed after an interval of shorter or longer duration. The necessity of considering the primary and secondary symptoms together, becomes the more imperative when we are aware of the fact that venereal eruptions do not appear with similar frequency after every variety of primary symptom, and that this or that form of eruption succeeds this or that species of contagious inflammation of the organs of generation.

797. These relations of the venereal eruptions or syphilides to contagious and virulent inflammations of the genital parts, scarcely suspected before the syphilitic epidemic of the 16th century, very obvious during the prevalence of that pestilence, when the eruption occasionally appeared at the same time as the affection of the genitals, and generally before the end of the fourth or fifth week thereafter, have become much less strikingly and obviously connected of late, when it is usual for several months at least, and often for several years to elapse between the occurrence and the cure of primary symptoms on the one hand, and the appearance of secondary infections on the other.

798. Carmichael has sought to connect exclusively the appearance of certain venereal eruptions with the occurrence of particular primary symptoms. This view has been successfully attacked by Rose, Guthrie, Bacot, Hennen, &c., yet it would be going too far to say, that no particular secondary symptom was more especially associated with one form of primary symptom than another.

799. Primary symptoms.—The number, nature, and characters of the primary symptoms of syphilis have of late years been subjects of pretty smart dispute among medical men, whence the necessity of studying these symptoms, both in themselves and with reference to the general infection, to the end that their relations to the various forms of venereal eruption, and other secondary symptoms may be the better understood.

800. The primary symptoms of syphilis are, 1st.—Syphilitic gonorrhœa; 2d.—syphilitic inflammation of the glans penis; 3d.—the simple syphilitic ulcer (two varieties); 4th.—the indurated syphilitic ulcer (the Hunterian chancre); 5th.—the phagedænic syphilitic ulcer; 6th.—the gangrenous ulcer; 7th.—the bubo.

The whole of these affections are due to one cause, and are of the same essential nature;<sup>3</sup> they arise from, and are reproduced the one

<sup>3</sup> "Six amis, après un repas peu frugal, eurent tous commerce avec la même fille qui leur donna à tous la vérole. Elle se manifesta chez eux avec des symptômes différens; deux eurent des chancres et des poulains; deux autres la chaudepisse; le cinquième eut un chancre; et le sixième un seul poulain." (Vigaroux. Observ. et remarques sur la complicité des sympt. vénér. avec d'autres virus.)—"M\*\*\*, négociant d'une ville maritime, voyageait depuis deux mois sans avoir exposé sa santé avec aucune femme. Lorsqu'il fut arrivé à Paris, il fit la connaissance d'une jeune fille, avec laquelle il cohabita. Après huit jours il me fit appeler, et je lui trouvai le prépuce et le gland couverts de chancres profonds et douloureux. Je visitai aussitôt la jeune personne qui n'avait qu'un écoulement, encore était-il fort peu abondant. Elle est restée sous nos yeux pendant tout le traitement de M\*\*\* et malgré les recherches les plus exactes, il ne m'a pas été possible d'apercevoir d'autres symptômes." (Obs. de Cullériér, citée par M. Lagneau. Exposé de sympt. de la malad. vénér. in 8o, 5e ed. 1818, p. 30.) Hennen relates a similar case. (Military surgery, 3d ed. 8vo, p. 534. Lond., 1829.) (a)

<sup>1</sup> Dict. des sc. med. Art. Abeille.

<sup>2</sup> Baglivi. Dis. de anatome, morsu et affectibus tarentulæ. Opera omnia, p. 60, 4to. Lugd., 1745.

(a) In the above note Cullériér, cited by Lagneau, tells of six men having been inoculated after intercourse with the same female, two having chancres and buboes, two gonorrhœa, the fifth a chancre, and

by the other at certain periods of their existence, but not with like activity nor in similar proportions. (a) Inflammation of the surface of the glans, and simple sores are so often associated that Carmichael believes them to be produced by a particular morbid poison.

the sixth a bubo alone. This writer gives also the case of a person from a distant city, having, after his arrival in Paris, cohabited with a young girl, from whom he contracted numerous deep and painful chancres in the glans and prepuce; although the surgeon in careful examination was unable to detect any thing more than mere gonorrhœa in the female herself.

The explanation of cases of this nature is, after all, not difficult without our still admitting an identity of the gonorrhœal and chancreous in proper syphilitic virus. The person who communicated the two diseases had them both. Some have been infected with the one, some with the other, while some, again, have entirely escaped. M. Ricord has shown that chancres often exist deep in the vagina or in the *os uteri*. "I believe" says Mr. Herbert Mayo (*Lectures on Syphilis in Med. Gaz.*, 1839), "from observation that such chancres, not external in women may remain for months in an indolent and unprogressive state. I attended a gentleman for three successive chancres which he had caught, at intervals of a very few months, from the same woman, who would have it that she was in perfect health. At last she consented to allow me to examine her, when I found two small ulcers within the external labia which got well under mercury. The story of the Portuguese opera dancer, mentioned by Dr. Ferguson, and already quoted, is doubtless to be explained in the same way.

"This woman had inoculated several with chancres; but she herself continued on the stage for many months afterwards in apparently good health.

"A man labouring under a slight gonorrhœa, as it may be called, but without any chancre in the glans or prepuce, has sometimes inoculated a female, with whom he cohabited, with true syphilis. Careful examination in such a case has revealed the existence of a chancre just within the meatus, and explained the apparent anomaly."

(a) As I have elsewhere stated, I believe this position to be untenable. Desirous to avoid discussion, and not to occupy space by needless details, I shall merely repeat on this occasion the condensed view presented elsewhere.

"In detailing the causes of urethritis, I mentioned that gonorrhœa was produced, principally, by the contact of virus resulting from morbid secretion of the mucous surface of the urethra in males and of the vagina in females. I adverted to that other opinion, that the disease was also caused by the matter secreted from chancre. At the present time we have small reason for adhering to this last notion, disproved as it is by careful observations and experiments. The fallacy of the belief in the chancreous origin of gonorrhœa was kept up by the fact of an urethral discharge, accompanied by symptoms of irritation, following the introduction of the matter from chancre into the urethra. But more careful inspection showed that in this case there was true inoculation, and that an ulcer was formed in the meatus, the irritation and discharge from which simulated and were taken for gonorrhœa. We are authorized, in the existing state of our knowledge on this subject, to reject the opinion of Hunter, who tells us, as a reason for giving small doses of mercury in the case of gonorrhœa, 'it is always necessary to have in view the possibility of some of the matter being absorbed and afterwards appearing in the form of a lues venerea.'

"Inoculation affords the true test in this question, as clearly proved by M. Ricord (*A Practical Treatise on Venereal Diseases*, &c.). He has shown that the matter of gonorrhœa never produces chancre, nor does the pus of chancre give rise to gonorrhœa, when each respectively has been applied to the surfaces and tissues in which these diseases are developed in common. 'The gonorrhœal secretion, applied to the mucous membrane of the eye, has never produced chancres of the conjunctiva or eyelids, nor has the muco-purulent secretion of gonorrhœal ophthalmia ever produced chancres by inoculation, or otherwise, although the eyelids are susceptible of being injected by chancre. We may add, that the muco-pus of balanitis, &c., the consequence of an impure coition, or produced artificially by an irritant,

801. *Syphilitic gonorrhœa*.<sup>1</sup>—This is a contagious inflammation of the urethra, glans, and prepuce in the male, of the vagina and occa-

has never furnished a result by inoculation, and that these affections, therefore, cannot be followed by symptoms of constitutional syphilis whenever they have existed without chancres.

"Without, in this place, entering into the discussion and history of all the symptoms which have been attributed to gonorrhœa, there are two which are pretty frequent and regular, as consecutive symptoms; these are buboes (yet far less frequent than after chancre) and swelled testicle (epididymite).

"I have ascertained by inoculation, that the pus from buboes which are consequent on gonorrhœa, does not inoculate, even should they terminate in suppuration, which is rarely the case: they otherwise partake only of the nature of an engorgement or simple abscess, whose characters frequently correspond to strumous and not syphilitic affections.

"As to swelled testicle, which still more rarely suppurates, the pus never produced any thing by inoculation.

"The observations made upon gonorrhœa, during my researches upon inoculation, lead to the following propositions:—

"I. The matter of a gonorrhœa, applied to a healthy mucous membrane, causes gonorrhœal inflammation so much the more easily the nearer it approaches the purulent form, and therefore, contrary to the opinion of Wathely, the less mucous its nature.

"II. Under no circumstances can it produce chancre; but as an irritating matter, like that of coryza, for instance, it may excoriate the skin, with which it remains some time in contact, but it never produces a specific ulcer. Convinced of these truths, which were so often verified, one of my pupils, M. Léon Ratier, often inoculated himself with the muco-pus of gonorrhœa upon the skin of the forearm, without any results.

"III. The consecutive, undoubted, and regular symptoms of gonorrhœa, do not furnish an inoculable pus.

"IV. The symptoms of constitutional syphilis are not the consequence of gonorrhœa. In all the cases in which authors mention that it was an antecedent, the frequency of which precisely corresponds with that of masked chancres (chancres larvés), the diagnosis was not correct; the diseased surfaces not having been examined.

"V. Lastly, the only correct means of diagnosis, in the present state of science, is inoculation. Every gonorrhœa which is tested by inoculation in its various periods, without producing any result, is only a simple affection, and incapable of communicating syphilis, whether primary in another subject, or constitutional in the one first affected."—*Bell & Stokes' Lectures*, &c., pp. 634-5, vol. i. 3d edit.

<sup>1</sup> There is no mention made in any part of the writings of Hippocrates of a painful and contagious flux of the genital organs. Celsus speaks of a *nimie profusions seminis*, but not of a *blenorhagia*, or flow of mucus (*De re medicâ*, lib. iv. sect. xxi); Swediaur, and several other writers, have interpreted this passage amiss. Neither does Galen treat of more than a flow of the seminal fluid: *Igitur gonorrhœa instrumentorum seminis affectio est, non pudendorum* (*De Gonorrhœa priapismo*, &c., in the treatise, *de locis affectis*, lib. iv. cap. vi). It would appear consequently that the Greeks and Romans were unacquainted with syphilitic blenorhagia.

We read, however, in a book much anterior to any of the writings quoted, *Leviticus* to wit, chap. xvi., some very strict ordinances relative to men labouring under a *flow of semen*, and it seems much more probable that the question here is of a true blenorhœa than of a flux of the seminal fluid, an infirmity far too uncommon ever to have been made the subject of any sanitary law. It is very likely, therefore, that blenorhagia was frequent among the Jews. In Europe it was certainly rare before the end of the middle ages. Brassavolus (*De morbo Gallico*) and Fernelius (*De morbis contagiosis*, lib. ii. cap. xiv.) are generally allowed to have been the first who described gonorrhœa as an effect of the morbid poison *lues venerea*, and Astruc assures us, and his is the opinion of Fallopius, that venereal gonorrhœa was not observed during the earlier periods of the epidemic of the 16th century (*Astruc de Morbis Venereis*, 4to. Paris, 1738, p. 77).

More recently, Fr. Balfour (*De Gonorrhœa virulenta*, 8vo. Edinb., 1767), and W. Ellis (*An Essay on the cure of venereal Gonorrhœa and Gleet*, 8vo. Lond., 1771), started the opinion that clap and pox were perfectly distinct diseases, and this opinion has been since espoused by Duncan, Ehrman, Lafont-Gouzi, Hernandez, and others. On the other hand, T. Bayford (the Effects of Injections into the Urethra, &c., 8vo. Lond., 1772) about the same time as Ellis, and subsequently, Preteau (*Consid. prat. sur la gonorrhée virulente*, 8vo. Paris, 1815) have maintained the identity of the cause of gonorrhœa and syphilis.

For my own part, the development of venereal eruptions after syphilitic gonorrhœas and the engenderment of venereal sores by the contact of gonorrhœal matter, and the contrary, induce me to believe that these several affections are different effects of the same cause. As to non-syphilitic blenorhagias, I conceive them at the present day to be extremely rare. I have, however, seen true discharges from the urethra in

sionally of the urethra in the female. In the male this affection is announced by the secretion of a yellowish or greenish-white fluid with scalding and pain in making water, and involuntary and frequently repeated erections. This of all the primary symptoms of syphilis is that which is most frequently observed at the present day.

802. In the female attacked with syphilitic gonorrhœa, the inflammation may extend from the vagina, where it begins, to the urethra, the cervix uteri, and pudenda; it is occasionally accompanied with excoriation of the labia majora and minora. In its acute state, this inflammation gives rise to a flow of yellowish or greenish fluid, which, inoculated by the intercourse of the sexes, reproduces the same, or some other form of venereal disease.<sup>1</sup> This character distinguishes syphilitic blenorhœa from leucorrhœa, and every other form of discharge, such as that which depends on a rheumatic or arthritic cause, the irritation of teething, &c., to which these parts are subject.

803. In the male, the venereal swelled testicle, the swelling of the prostate and Cowper's glands; in the female, the inflammation of the uterus or of the ovaries; in both the ophthalmia, (a) the iritis and gonorrhœal arthritis, are the secondary mischiefs of most frequent occurrence; but severe erysipelas and even gangrene have been observed attacking the glans and prepuce in a few rare and very bad cases.

The buboes occasionally observed along with gonorrhœa are generally less serious than those which accompany syphilitic sores, or which are developed during their treatment. Venereal arthritis is more common after gonorrhœa than any other form of primary symptom.

804. *Cutaneous eruptions*, secondary to gonorrhœa, are rare: they occur especially in a much smaller ratio than after syphilitic ulcers, whether superficial or deep. Yet I have seen every form of syphilide as consequences of gonorrhœal infection. Considered in regard to their relative frequency, they may be arranged in the following order:—papula, exanthemata, psyraciacus pustules, squamæ, syphilitic tubercles.

805. Syphilitic gonorrhœa, treated by means of rest, cooling diet, local and general baths, occasionally by the local, and even by the general abstraction of blood, and in its latter stages by the balsam of Copaiba, or Cubebs pepper, gets well in general between the twentieth and thirtieth day. Neglected or mismanaged, the disease is apt to be followed by stricture of the urethra, &c. After the discharge has ceased I am in the habit occasionally of prescribing the pills of Beloste, or of Sedillot<sup>2</sup> for a time, with a view of modifying the constitution, and of preventing secondary mischief.

806. *Syphilitic blenorhœa of the glans*.<sup>3</sup> A muco-purulent con-

(a) Gonorrhœal ophthalmia requires a very bold and vigorous practice—the chief points of which will consist in early and free blood-letting, and the application of stimulants and astringents to the eyes. The nitrate of silver is the preferred article on these occasions.

children cutting their teeth (Mem. sur les inflam. non-virulentes des membr. muq. des org. de la générat. des enfans, 8vo. Paris, 1821); and I have met with several cases of arthritic discharges, upon which Bell (on Gonorrh. Virulenta, &c., 8vo. Edinb., 1793), Swediaur (Tr. des Mal. Vener., pp. 56, 60), Barthez (Tr. des mal. Goutteuses, t. ii. p. 324) and Cuecon (Rec. period. de la Soc. de méd., t. ix. p. 156) have published interesting observations. With regard to the epidemic blenorhœagias that sometimes prevailed, I refer to the remarks of Blas (Obs. Chirurg. Med., Magd., 1731), and of Winkler (Rec. period. de litt. méd., étrangère, p. 152).

<sup>1</sup> Hunter thought that gonorrhœa could produce chancre, and *vice versa*. Bell disputes this opinion, and informs us that, in an experiment in which the matter of gonorrhœa was placed between the prepuce and glans, the disease that followed was clap, whilst the poison of a chancre, inserted into the urethra, produced a sore of the same description. I believe that matters turn out most generally as Bell has stated them; but his experiment does not by any means prove that the matter of gonorrhœa can never produce a chancre. According to Carmichael, not only will gonorrhœa not produce chancre, but gonorrhœal infection will be followed by eruptions of a different order from those that succeed chancre. The erroneousness of this assertion has to my mind been demonstrated. Hunter (on the venereal) gives two cases of general infection (ulcers of the throat, pustules), happening after gonorrhœa, and M. Lagneau relates the case of a young man who, eight months after having had gonorrhœa, was attacked with ulcers of the velum palati, lenticular tubercles over the whole surface of the body, and incrustations of the hairy scalp. Vide also Lombard. (Cours de Chirurgie Pratique sur la maladie vénérienne, t. ii. p. 50).—Swediaur. (Traité complet des mal. syphilitiques, 8vo., 7e éd. 1817).—Fabre. (Traité des mal. ven., 4e éd., p. 47.)

<sup>2</sup> The blue pill—that of Beloste being combined with aloes and aromatics—that of Sedillot being made with the blue ointment, gum, and sugar.—Tr.

<sup>3</sup> Sydenham describes this affection: "Ipse vidi virulentam hujusmodi materiam

tagious discharge from the surface of the glans and inner aspect of the prepuce, of a vivid red generally, and in some places denuded of their epithelium. This discharge, which is transmissible by sexual intercourse, may give rise to other venereal symptoms. (b) In this disease the discharge is not poured out from every point of the surfaces of the glans and prepuce, but from irregular, highly inflamed, and occasionally excoriated patches, upon which M. Desruelles has sometimes seen false membranes deposited, which subsequently formed adhesions.

807. Syphilitic blenorhœa of the glans and prepuce requires to be carefully distinguished from an increase of the secretion poured out by the sebaceous follicles of these parts, and from accumulations there of the fluid of the follicles, through neglect of cleanliness. It must also be distinguished from eczema of the glans and prepuce, in which the discharge, more serous in its qualities, is independent of all venereal indication, whether primary or secondary.

Blenorrhœa of the glans is sometimes associated with urethral gonorrhœa, and with simple venereal ulcers of the penis; when it occurs without such complications, it may be cured in a few days by attention to cleanliness, and the use of cold lotions with the extractum saturni.

808. Blenorhœa of the glans, without complication, is very rarely followed by secondary symptoms; when cutaneous eruptions have been seen to succeed the affection, it will almost always be found to have occurred associated with gonorrhœa, or venereal sores.

809. *Primary venereal sores*.<sup>4</sup>—These sores occur under five differ-

(b) The remarks, made in a former note, on the difference between urethral or common gonorrhœa and chancre, apply to syphilitic blenorhœa of the glans (*balanitis*). This latter is caused by gonorrhœal virus and neither causes nor is induced by chancrous matter.

per substantiam glandis porosam exudare, non per urethram ejectam, nulloque ulcere vel glandem occupante vel præputium. (Opera medica, 4to. Geneva, 1769, t. i. Epist. ii. p. 205.) J. Vercelloni also mentions it. (De pupendorum morbis et lue venerea tetra biblion. Asti, 1716, 8vo.)

M. Desruelles has given a good account of the affection, and is the first who speaks of the variety with pseudo-membranous deposits. (Of two hundred and ten men attacked with the disease, fifty had it in the simple form; one hundred and fifty-five had it complicated with gonorrhœa or ulcers.)

Astruc saw a young man labouring under ophthalmia, from having carried his fingers, impregnated with the matter of a blenorhœa of the glans, with which he was affected, to his eyes. (De morbis veneris, lib. iii. cap. iii. De gonor. spuria.)

<sup>4</sup> A loose interpretation of the descriptions left us by the Greek and Roman writers, of ulcers of the genital organs, neglect of the writers of the sixteenth century, imperfect details of cases, and purely hypothetical notions in regard to the predisposing and essential causes of these ulcers, have conspired to introduce confusion into the determination of their species, and accounts of their several characters. Had the study of anterior works not been neglected, we should not have had certain appearances, observed and described previously to the use of mercury, attributed to its exhibition, and distinctions made with care by the practitioners of the sixteenth century, would not have first been held as impossible or useless, and subsequently been reproduced, from new data, by the more accurate among the observers of later times.

Hippocrates mentions, but does not describe, ulcers of the pudenda. (De naturâ muliebri, sect. v. ed. Foes. p. 582.) Celsus gives a careful account of phymosis, and of simple, phagedenic, and gangrenous ulcers of the glans and prepuce; but he does not say that these sores are contagious, or followed by secondary consequences. (De re medica, lib. vi. sect. xviii. 2-4.) Galen speaks of ulcers of the penis and pudenda (de locis affectis, lib. vi. cap. vi.—De compos. pharm. secund. locos, lib. ix.), but is much less complete than Celsus.

Lanfrancus (Chirurg. magna et parva, fol. 1490, tom. iii. cap. ii.), and Gulielmus de Saliceto (Chirurgia, fol. 1476, lib. i. cap. xiii.), in the thirteenth century, are the first who speak of ulcers and pustules of the glans happening *post coitum cum feda muliere*. In the fourteenth century, Bernard Gordon, Guy de Chauliac, and Arnaldus de Villanova, severally make mention of sores contracted *propter decubitus cum muliere feda*.

During the height of the great syphilitic epidemic at the end of the fifteenth and beginning of the sixteenth century, contagious sores of the genital organs were observed and commented on as one of the symptoms of the disease, by great numbers of writers. (Casp. Torella.—De ulceribus in pudendagra tractatus.)

Fallopius has left a good account of venereal ulcers. He distinguishes three kinds, which very evidently correspond with the three species described with great care in these latter days by Carmichael:—"Signi cariei benignæ sunt: primum enim suboritur pustulæ quædam parvæ et candidæ, quæ quidem non excedunt crassitatem unius grani panici minimi; pustulæ erumpunt; his ruptis remanet ulcusculum rotundum, in medio habens punctum candidum, penetrans, aliquantulum simplex, vel duplicatum; aliquando tota corona glandis inficitur hujusmodi ulceribus, quandoque simul copulantur, et ex duobus, vel tribus, vel quatuor unum fit, ita ut sit veluti linea cingens, et coronans glandem; ista est sine dolore; levis et moderatus pruritus; facillime cedit medicamento (this is the simple sore of Carmichael).—Secunda species sævior est, ista est et genus quoddam ulceris rotundi, sed in medio non adest punctum album; adest livor in ulcere, et labra leniter attoluntur, purpureo colore infecta; aliquantisper

ent forms: 1st, the simple sore; 2d, the indurated sore (the Hunterian chancre); 3d, the phagedenic sore; 4th, the gangrenous sore; and 5th, the venereal sore becomes cancerous. They have the common and essential character of being produced by the same morbid poison, and of being followed by venereal eruptions, and other secondary symptoms of various character.

810. Ulcers are less common than gonorrhœa as the primary symptoms of venereal infection. They are divided and distinguished from one another by their progress and appearance; their cause and their secondary consequences separate them from every other description of sore, accidental or factitious, affecting the organs of generation. All are not alike severe: the phagedenic and the gangrenous ulcer occasion local mischief, often of a serious nature; the indurated sore, or Hunterian chancre, is healed with greater difficulty than the simple ulcer. As to the relative frequency and extent of secondary symptoms after each, opinions are divided, and data are yet wanting upon which accurate conclusions may be formed. I have fancied that secondary mischief was both more frequent and more severe after the indurated sore than any other form of local affection.

811. The simple venereal ulcer.—(*Venerola vulgaris*, Evans; the common chancre of several French pathologists.) Primary sores, acute in their character, contagious, arising from local infection, the edges of which are neither callous nor deeply indurated. These are the most common of all the forms of venereal ulcer.

Simple sores present several varieties in their appearance, their number, their seat, their course, and their continuance.

812. A variety of the simple ulcer is occasionally observed on the glans and inner surface of the prepuce, the bottom of which, before long, becomes raised, and, as it were, fungous (*ulcus elevatum*). When these sores, which are seldom seen in greater numbers than two or three together, are evolved on the inner surface of the prepuce, or upon the body of the penis, they begin in the shape of a small pustule, that continues for a day or two; a slight scab is then formed, which, on being thrown off, leaves exposed a small excavated ulcer, of a round or oval figure, and surrounded with some redness. The bottom of this sore begins to fill up in the course of the second week, and at a later period rises gradually above the level of the surrounding integuments, presenting a smooth surface of the usual colour of a simple wound, but without granulations, and having something of a *fungous appearance*. It is when the sore is in the latter state that patients commonly first seek advice.

813. Other simple sores (common chancres) are evolved behind the corona glandis and on the parts of the prepuce immediately contiguous to it. In this case there are almost always several sores, generally four or five, and I have counted as many as fifteen, when they have all the look of an eruption. *First period* (*excavated pseudo-membranous state*). Each of these sores begins as a little red spot, which is soon replaced by a yellowish-white point that might be covered with the head of a pin. In the course of a few days this

profundum est hoc ulcus (this is the sore of the *pustular venereal* of Carmichael).—Ultimo in loco est pessimum et valde malignum ulcus, non rotundum, sed varia figura figuratum, ac variis depictum coloribus, livido, purpureo, etc.; callosa habet labra, serpit sævissime, et aliquando nome conjunctam habet, hoc est putredinem (this is the phagedenic ulcer).<sup>2</sup> (G. Fallopi de morbo Gallico tractatus, cap. 82; de tribus cariei gallicæ speciebus.)

Carmichael (an essay on venereal diseases, 2d ed., 8vo., London, 1825), has presented us with an excellent description of *primary venereal ulcers*, and I have adopted his species. Mr. Evans (Path. and Pract. rem. on ulcerations of the genital organs, 8vo., Lond., 1819), has united under the name of *venerola vulgaris* or *ulcus elevatum*, the two first species of Carmichael, (the sore which he believes proper to the *popular venereal disease*, and that which, according to him, precedes the pustular form of the malady), and has contended for the *phagedenic state* being regarded as an evidence or effect of a constitutional taint. M. Desruelles has distinguished venereal ulcers into *simple and complicated*; he thinks that the differences observed in their appearance are due to diversity of seat, and to merely accidental circumstances. Hennen (Principles of Military Surgery, 3d ed. 8vo., Lond., 1819), is also of opinion that the different appearances presented by venereal ulcers, are owing to their variety of situation, on the outer or on the inner surface of the prepuce, behind the corona glandis, on the frenum and on the body of the glans. Boyer distinguishes venereal ulcers into benign and malignant; the latter comprehend—1st, the *callous chancre*; 2d, the *gangrenous ulcer*; and 3d, the *ulcer* which has a fungous and cancerous appearance.

<sup>1</sup> These sores are indicated by Fallopius under the name of *cariei benigna*. Of late Carmichael has described two appearances as characteristic of ulcers proper to two distinct forms of lues venerea—the *popular* and *pustular*. Mr. Evans speaks of them under the title of *venerola vulgaris*. Carmichael has published several cases of these sores in the Lond. Med. Gaz.

point attains the dimensions of a large hemp seed, and acquires the form of a small, slightly excavated ulcer. Its bottom is covered with a yellowish-white, very adherent substance; its edges slightly inflamed, not prominent, are neither hard nor callous, and its base is not indurated. When several of these little ulcers are in contact by their corresponding edges, they run together, and a broader and frequently irregular pitted ulcer, with the same general characters, is the consequence. When they appear near the origin of the frenum, if this part is accidentally torn, they spread in the direction of the rent, so as to form a slight superficial furrow, the bottom of which is covered with a yellowish-white substance. These little sores occasionally form a kind of ring around the outer opening of the prepuce, and if they chance to run together, a succession of ulcerated arcs or portions of circles succeeds. Sores of this description are occasionally evolved in succession during the course of the week following the appearance of those first developed. *Second period* (*excavated state, without false membrane*). Towards the end of the second, or beginning of the third week, and occasionally even sooner, the bottom of the ulcer rises, the edges, that were slightly swollen, sink, and cicatrization is completed in the course of the fourth week, under the influence of the antiphlogistic plan of treatment, without other assistance than the application of the nitrate of silver to those sores whose granulations shoot beyond the level of the general surface.

The appearance and the course of these *benign ulcers* may be modified by neglect of cleanliness, by fatigue of body, the application of irritating dressings, &c. Their surface then becomes dusky, and apt to bleed, their edges are hard and prominent, and the period of their cicatrization is longer of arriving. The mean duration of the ulcers of this class varies between three and six weeks; but this, too, may be modified by the state of the constitution, the manner of living, &c. The ulcerative process and the extension of the inflamed areola appear to stop as soon as granulations begin to be formed.

These sores are frequently accompanied with blennorrhœa of the glans, with urethral gonorrhœa, and with phimosis. They have also been seen accidentally complicated with gangrene or with phlegmon of the prepuce.

814. These ulcers may be caused by the matter of gonorrhœa, and the fluid they secrete has the power of reproducing them.<sup>2</sup>

815. I have seen this variety of venereal sore appearing on the inner surface of the prepuce under the guise of two small eminences covered with a layer of yellowish and very adherent matter, and bathed with pus. These projections, when they had lost this pseudo-membranous covering, at a later period, presented the fungous appearance of which I have spoken above.

816. I have observed every variety of venereal eruption and venereal growth as consequences of these two varieties of primary sore. Carmichael believes that nodes occur very rarely after them.<sup>3</sup>

817. Simple venereal ulcers occasionally present yet another appearance: after the detachment of the layer of grayish adherent matter observed on their surface during the first period, they sometimes assume a reddish-brown hue, and their edges become prominent and sharp. Sores of this kind are not excavated out of the glans or prepuce, like the Hunterian chancre; their bottom, on the contrary, is on a level with the surrounding parts, or is even raised above them.

This peculiar appearance of the simple ulcer is commonly seen when the outer surface of the prepuce, or body of the penis, is the part affected. Several of these sores frequently form a circle around the orifice of the prepuce; and after they get well, are often followed by a phimosis which is only remediable by the operation.

The progress of these simple raised sores is generally slow; they seldom show any disposition to extend superficially or to penetrate

<sup>2</sup> Two men visit the same woman labouring under gonorrhœa; one of them contracts clap, the other *venerola vulgaris*—Evans. Three experiments of this gentleman go to prove that the matter of these sores is more contagious when they are in their first stage, in the excavated state, than afterwards when the discharge from them is purulent.

<sup>3</sup> In a thousand cases of *popular venereal disease*, Carmichael assures us he had not met with a single instance of well-marked exostosis, nor any of those deeper affections which are so common in the other forms of venereal disease. The results of my observations differ from those of Carmichael. I have several times seen exostosis following ulcers of the description in question.

deeper. They vary in size from that of a split pea to that of a shilling. The elevation of their edges gives them an excavated appearance, which they exhibit for two, three, four, and even a greater number of weeks. This elevation of their edges distinguishes them from simple ulcers of corona glandis, which commonly heal up without presenting this kind of circular swelling. These ulcers with raised edges never have the smooth and prominent surface peculiar to the fungous sore. They are distinguished from the *indurated* ulcer (Hunterian chancre) by the want of the callous edge, and base of cartilaginous hardness. They differ from the phagedenic ulcer in having a well-defined margin, and a surface which is not irregular, and as it were eroded, as well as by being unaccompanied with the acute pain that always attends the progress of the eating ulcer.

The mean duration of ulcers with *prominent* edges is greater than that of the simple sores which do not become fungous, and the edges of which do not get separated from the subjacent parts, which are commonly seen on the corona glandis. I have observed every variety of venereal eruption after these ulcers with prominent edges.<sup>1</sup>

818. The antiphlogistic mode of treatment is applicable in the majority of cases of *simple* venereal ulcer. Under the combined influence of rest, especially of rest in bed, low diet, the tepid bath, emollient topical applications, and bleeding when the inflammation runs high, these ulcers always improve, and commonly heal up entirely within from twenty to thirty days. By touching the fungous sore with sulphate of copper, its cure is often expedited. Sores of the body of the penis are frequently found to heal more rapidly when they are dressed during their second period with the unguent. *oxidi zinci*, or of the hydrarg. *nitratum*. In this stage I am also of opinion that alterative doses of one of the preparations of mercury, and purgatives generally prove useful. Carmichael in addition recommends antimonials.

Carmichael tells us that he has used caustic with success to the simple sore in its excavated state. B. Bell was of opinion that this practice was apt to cause buboes.

819. The cicatrices of primary venereal ulcers of the organs of generation are generally small, slightly depressed, of a bluish-white colour, and frequently numerous on the corona glandis. Save in those cases in which the frenum is destroyed, they do not occasion any evident deformity. Previously to complete cicatrization, the neighbouring parts, and the prepuce especially, continue puffy and enlarged, often for a very considerable length of time, but those livid indurations are never seen under the cicatrices which are occasionally observed after *indurated* ulcers.

820. The *indurated syphilitic ulcer*,<sup>2</sup> the *Hunterian chancre*. This form of sore occurs much more rarely than the *simple* venereal ulcer. It is commonly seen on the glans penis. It is constantly circular in a greater or less degree in its form, excavated, without granulations, and covered with a whitish adhering matter. Its base is callous, its edges hard and thick. This hardness and thickening are primary, very accurately circumscribed, end suddenly, and do not blend with, or melt gradually into, the surrounding parts. This character of induration is not limited to the edges of the ulcer in question, but extends over the whole surface of the sore, and frequently spreads beyond it. Ulcers or chancres of this kind are often seen, the extent of whose ulcerated surface is trifling in comparison with that of the induration.

<sup>1</sup> According to Carmichael this kind of ulcer must be very different from the first variety; he adds, that in every case of the second variety to which he could attach constitutional symptoms, they were essentially different from those that followed the first. He relates several interesting cases: Case 9th, ulcer with raised edges on the outer surface of the prepuce; ulcerated bubo with raised edges; phlyzacious pustules.—Case 10. Body of the penis encircled by a series of ulcers with raised edges; an ulcer on the external surface of the prepuce; five weeks afterwards, phlyzacious pustules, and a hard and indolent bubo.—Case 11. Ulcer extending from the back of the penis to the pubes, with raised edges, covered with a thick and adhering matter; seven weeks afterwards, eruption of phlyzacious pustules, pain, ulcers of the throat, &c.

<sup>2</sup> John Hunter is generally supposed to have fixed the characters of this ulcer; but they had been described with great exactness long before: "Interdum in virgâ, nonnulla ulcera cum duritie et callositate que sanari exacte nequeunt, perpetiuntur, quod morbi gallici certum signum est, maxime vero cum in inguine præcesserit apostema, quod bubonem dicunt." (Aloysii Loberæ, de morbo gallico, tractatus.) Massa had equally well indicated this character: "Ulcerâ virgæ quæ sunt mala cum duritie callosâ" (Aphrodisiacus, p. 46). Still John Hunter has particularly insisted upon the circumscribed hardness of the edges and of the base of this ulcer, the characters of which he has well described. (On the Venereal Disease, 4to. London, 1786.)

Carmichael informs us that he has met with *primary indurated tubercles* without ulceration; this form of primary syphilitic affection is exceedingly rare: by questioning patients we almost invariably discover that a small sore had been formerly situated in the same place as the induration, and that it had only healed up within a few days.

821. When the *indurated chancre* is developed on the body of the penis; the ulcer is not in general excavated; it is of a dusky or livid colour; its bottom is on a level with the surrounding parts; its edges and base are always less hard, less callous than those of the same description of sore evolved upon the glans. The size of this ulcer occurring on the body of the penis varies from that of a sixpenny to that of a half-crown piece, or rather less; the sore, indeed, has been seen extending completely round the member. Its edges are but slightly raised; the induration of its base is easily recognizable by the touch, but is never so strongly marked as in the *indurated ulcer* of the glans.

822. Phymosis and inflammation of the prepuce complicate the *indurated* sore or chancre more rarely than the other forms of ulcer; and when this complication does occur it is almost always owing to some accidental circumstance.

823. The duration of the *indurated ulcer* is on an average from five to six weeks. After the first inflammatory symptoms have subsided, the administration of mercury causes this ulcer rapidly to assume a favourable appearance. When this medicine is not employed, the livid tint of the ulcer often alternates with a slight tawny colour; the induration of the base obviously increases, and the ulcerative process commences anew. The *indurated ulcer* or Hunterian chancre, however, gets well locally without mercury. This ulcer often leaves a circumscribed callous and livid induration behind it, which was particularly noted by the writers of the sixteenth century.<sup>3</sup> After getting completely well, this sore is generally followed by a broad and deep cicatrix, which on the glans is commonly single.

824. This variety of ulcer is usually readily distinguished. Simple sores, after being repeatedly irritated, may indeed present, accidentally, some degree of swelling, and a slight induration in their circumference; but this induration does not convey to the same amount the sensation of positive hardness which is perceived when the edges and base of the Hunterian chancre are touched. Farther, this accidental induration of simple sores does not end abruptly at their circumference as in the *indurated ulcer*, but is lost gradually and imperceptibly amidst the surrounding parts.

The *indurated ulcer* differs from those of a phagedenic and gangrenous character, not only in its appearance, but in being for the most part free from pain, and in the slowness with which it spreads. And yet, when the *indurated ulcer* has spread over a considerable extent of surface, and it is situated on the body of the penis, its livid and dusky appearance bears some analogy to that of the phagedenic ulcer; it may, however, be distinguished from this last by its elevated edge and the hardness of its base. The progress of the *indurated ulcer*, moreover, is, as I have said, slow, and within a few days acquires a tawny aspect. In the gangrenous syphilitic ulcer, again, eschars are continually formed until the part affected is destroyed.

825. Syphilitic eruptions of the skin are more frequently observed after the *indurated ulcer* or Hunterian chancre, than after any other primary symptom; they occasionally even make their appearance during its existence.<sup>4</sup> Carmichael tells us that he has never seen any other than *exanthematous* and squamous eruptions succeeding this form of sore; I have seen eruptions possessing various other elementary forms, and tubercles perhaps oftener than any other.

826. Consecutive ulcers also occasionally show themselves in the mouth, on the velum palati, &c. Periostoses and exostoses, too, may follow the *indurated ulcer*, events which are very often preceded by an obvious derangement of the constitution.

827. The *phagedenic syphilitic ulcer*.<sup>5</sup> I have never had an oppor-

<sup>3</sup> "Callosa cicatrix...mobilis loco, crassa, livida, dura, et rotunda...aliquando quidem veluti nervus post cariem remaneat qui durus per pudendum percurrat... Symptomata nondum curati morbi gallici." (G. Fallopiæ. De cicatrice callosâ, cap. 87.—Aphrodisiacus, p. 816.)

<sup>4</sup> Carmichael. Op. cit., case xlix. "Phymosis, discharge under the prepuce; ulcer of the size of a bean, of a livid colour, with callous and slightly raised edges, situated on the body of the penis; syphilitic exanthema during its continuance" (Roseola annulata). I have observed several analogous cases.

<sup>5</sup> Fallopius has clearly described this ulcer, § 788.—Torrella also distinguishes it

tunity of seeing this ulcer in its earliest stage, and I do not know whether it begins in the shape of a solid elevation, of a vesicle, or of a pustule, or whether or not it passes immediately into the phagedenic state. Carmichael states that he has seen a great number of phagedenic ulcers, and assures us that in two or three cases, these sores, before acquiring the decidedly phagedenic character, were *excavated* and covered with a white adhering film.

The phagedenic ulcer has an eroded aspect; its surface presents no granulations, and the soft parts that surround it are not callous nor indurated. It sometimes spreads with great rapidity, and commits much havoc in the space of a few days. At other times it creeps slowly onwards, healing even on one side and advancing on another. It most frequently attacks the penis first, but as regularly spreads to the prepuce, which it often destroys entirely; and it may continue its ravages until the whole of the glans has fallen; when this happens, the ulcer commonly stops suddenly and makes no further progress. The occurrence of hemorrhage occasionally brings about a favourable change, and the bleeding in this case is sometimes so profuse as to soak the linen and bedding of the patient; Carmichael was on one occasion compelled to pass a ligature around a vessel which had been eroded. In some rare cases the destructive process has not stopped until the whole of the penis was destroyed.

According to Carmichael this ulcer has one very peculiar character; it is that of its frequent occurrence upon parts which it has primarily affected, but which it had not destroyed completely.

828. The *phagedenic* syphilitic ulcer may be readily distinguished from all the others of this class. It presents the phagedenic character at so early a stage, that this circumstance ought to suffice for its distinction from the other ulcers which become phagedenic *accidentally*, which they do most generally from excessive stimulation. These sores thus *rendered* phagedenic are much more common than the sore that is primarily so. M. Desruelles<sup>1</sup> has given a particular account of its characters: "From the time," says he, "that a common sore passes into the phagedenic state, the patient feels uneasy; his skin becomes hot and dry; his pulse is sharp and frequent; he complains of thirst; his tongue is red towards the point; the sore is affected with a sensation of intolerable heat and itchiness, succeeded before long by one of burning pain, as if a lighted coal were applied to the ulcer; shooting twinges are further felt from time to time, as if a sharp and burning body were passing rapidly through it. These painful sensations extend to the penis; the edges of the sore swell; an intense degree of redness extends widely around it; the bottom is covered with a grayish or blackish, uneven and very adhering membrane; the ulcer extends both in breadth and depth. These phagedenic ulcers destroy the glans and frenum with rapidity; they have been observed to destroy the penis by layers as it were; their progress is announced by the formation of a grayish or blackish false membrane, or of a putrescent layer, which is observed each time the sore is dressed, and which is renewed repeatedly; the patient then loses his appetite, his countenance changes, &c. &c." With phagedenic ulcers of this kind, the phagedenic sore described by Welbank must be assimilated.<sup>2</sup>

The *phagedenic* differs from the *indurated* ulcer in its external characters, and also in the circumstance that far from being improved like the latter by the administration of mercury, it is, on the contrary, made

from other venereal ulcers. "Ulcers virulenta a corrosivis non differunt nisi secundum magis et minus.... et si talis corrosio non multum profundetur, tunc tale ulcus dicitur *ambulationna* (Aphrodisiacus, p. 536. Torella. *De ulceribus in pudendagra*)—George Sydenham describes *phagedenic* syphilitic ulcers, (*Epistola ii. responsoria* v. i. p. 207.) but these are consecutive ulcers. Carmichael has given a very good description of the phagedenic ulcer. Evans, with many other pathologists, has considered the *phagedenic* and gangrenous character of venereal ulcers as connected with a peculiar morbid state of the constitution. According to him, this constitutional derangement is of two kinds: 1st. A febrile state, or at least a pulse both hard and full, without any remarkable frequency. 2d. An anadynamic state. These two states may exist in the same patient at different periods of the disease. Evans relates two cases which prove that phagedenic and gangrenous ulcers may be communicated by connection with persons only affected with simple ulcers of the genitals. (J. Evans, *Pathological Remarks on ulcerations of the genital organs: appendix on phagedæna and sloughing*, 8vo. London, 1819. Case 3d, p. 124.)

<sup>1</sup> Desruelles. *Seconde mémoire sur les maladies vénériennes* (Recueil des mémoires de méd. chir. et phar. milit., t. xxvii. p. 165).—*Ibid.*, t. xxv. p. 99.—Obs. d'un ulcère situé sur le prépuce, devenu phagédénique sous l'influence du mercure.—Lagneau, exposé des sympt. de la maladie vénérienne, 8vo. Paris, 1818, 5e ed. pp. 96-98. Obs. d'un ulcère simple devenu phagédénique par un traitement local excitant.

<sup>2</sup> Welbank, on sloughing phagedæna. (Med. Chir. Transact., vol. xi. p. 361.)

worse and more rebellious by such a plan of treatment. The phagedenic differs from the *gangrenous* syphilitic ulcer in this, that the destruction of parts is not accomplished as in the latter, alternately, by gangrene and erosion, but always in the latter mode. Phagedenic sores, however, may *accidentally* become gangrenous,<sup>3</sup> and present the twofold mode of destroying parts mentioned.

829. Carmichael conceives that buboes are more infrequent after the phagedenic than after any other form of syphilitic ulcer; and he adds, that the buboes which do occur in its train, have their edges loosened<sup>4</sup> and irregular, and that they can only be healed up after being pared off or destroyed by caustic.

830. Every form of secondary symptom, and every variety of cutaneous eruption are observed to follow the phagedenic ulcer,<sup>5</sup> but I have not had an opportunity of witnessing a sufficiently great number of cases of this kind of sore, nor of eruptions following in its train, to condescend upon any statement of their relative frequency; the whole of the published data, indeed, up to the present day, are inadequate to furnish grounds for such a computation.

831. Carmichael inclines to believe that it would be advantageous to touch phagedenic ulcers with caustic at their very outset. Whether this practice has been enforced or not, recourse must afterwards be had to the antiphlogistic treatment: rest in bed, emollient cataplasms, soothing and narcotic lotions, local or even general blood-letting in proportion to the degree of pain, inflammation and fever, the warm bath, &c. Antimonial medicines, in nauseating doses, have also been recommended by Carmichael, according to whom the scarification of the edges of the ulcer occasionally affords great relief. M. Desruelles has sometimes obtained the same good effects by applying leeches upon the middle of the ulcer. At a subsequent period, when the part affected is no longer painful, when the sore, though it may be spreading in one place, shows a tendency to cicatrize in another, its surface may be advantageously touched with a solution of the nitrate of silver. When any bands extend from one part of the ulcer to another these must be destroyed.

832. After their cure, phagedenic ulcers always leave broad and deep cicatrices behind them. They rarely get well before the end of the second month, and the treatment may even extend over the fifth month.

Phagedenic and gangrenous ulcers are the great causes of those deformities and mutilations of the external organs of generation oftentimes observed after syphilitic affections. The glans and prepuce are sometimes seen eroded in the most singular manner, and are occasionally destroyed altogether. When this has happened, a small tubercle, which marks the orifice of the urethra, is seen upon the extremity of the stump. The external organs in women, after having been affected with ulcers of the same description, also present unseemly cicatrices which furrow or pucker the surface of the labia majora. The irregular, eroded and deep appearance of the cicatrices distinguishes them from those left by the other varieties of primary syphilitic ulcer.

833. When a phagedenic sore is accompanied or followed by syphilitic eruptions or secondary syphilitic ulcers, mercury must never be used till all febrile symptoms have subsided, which is announced by the desquamation of several of the patches or tubercles.

834. The *gangrenous syphilitic ulcer*.<sup>6</sup>—This ulcer is still more

<sup>3</sup> Carmichael. Case 36. Phagedenic and gangrenous ulcers; consecutive ulcers on the abdomen.—Case 42. Phagedenic and gangrenous ulcer; scabs on the thighs and head; ulcers on the lip.

<sup>4</sup> Carmichael. Case 17. Phagedenic ulcer and bubo.

<sup>5</sup> Carmichael. Case 21. Phagedenic ulcer followed by thickening of the perios-teum.—Case 23. Phagedenic ulcers followed by prominent scabby ulcerations.—Case 24. Phagedenic ulcers followed by ulcers on the forehead.—Case 25. Phagedenic ulcers followed by pustules on the face and body, with ulcer of the velum palati.—Case 28. Phagedenic ulcers followed by pains in the joints, by a large tubercle, and ulcerations.—Obs. 29. Phagedenic ulcers followed by pustules, scabs, and swelling of the testis.—Obs. 30. Phagedenic ulcers followed by pustules and scabs.

<sup>6</sup> Celsus (*De re medicâ*, lib. vi. sect. xviii. p. 4) and Paulus Ægineta (*De re medicâ*, lib. vi. 57) have described a gangrenous ulcer of the penis, but they do not say that this ulcer arises from infection, that it is contagious or followed by secondary symptoms. The bishop Palladius, who lived in the fifth century, relates that a hermit, named Heron, after an habitual intercourse with a dancing girl, was attacked with a carbuncle (anthrax) upon the glans. G. Torella, in a chapter, *De ulceribus putridis*, describes the gangrenous syphilitic ulcer. (*De ulceribus in pudendagra tractatus*.)

Swediaur assures us that a gangrenous affection has been observed in the north of the United States, which attacks the virile member and makes rapid progress.

destructive and serious than the phagedenic; it is very seldom that we have occasion to observe its commencement. The first symptoms are attended with so little pain that the patient pays little or no attention to them. According to Carmichael, a small black spot, very similar to a lead drop, both in size and colour, is the first indication of this ulcer. The practised eye detects a small gangrenous eschar in this state. This continues to enlarge on the succeeding days, and occasionally attains three or four times its original dimensions before a line of separation is established between the sphacelated and living parts. When the line of demarkation is formed, we do not find under the slough, as in simple gangrene, a granulating ulcer of good appearance, but a gnawing phagedenic sore, which commences the work of destruction in another manner, and possesses all the virulence, if not, perchance, all the rapidity of the gangrenous process which preceded its formation. Some days afterwards the affected parts are attacked with acute pain, become of a bluish colour, and within a day or two are again covered with a new eschar. In this way, by a succession of eschars and erosive processes, the disease often continues to extend until the whole penis, scrotum, pubes, and perineum, are destroyed or denuded in the male, the labia majora, orifice of the vagina, skin of the perineum, verge of the anus and sides of the buttocks in the female. The pulse under these circumstances generally beats from 100 to 130 in a minute, and when the ulcers are extensive the tongue is dry, brown, and even black, as it is in the advanced stages of severe dothinerteritic affection.

Should the *gangrenous syphilitic* sore have been happily arrested in its progress, and a portion only of the penis been destroyed, particular attention is required to keep the orifice of the urethra sufficiently pervious after the cicatrization of the sore; for without this it is very apt to be left so much contracted as to oppose a great obstacle to the free evacuation of the bladder.

835. It is of importance to distinguish this gangrenous syphilitic ulcer from the gangrene which occasionally happens to the glans in consequence of a paraphymosis.<sup>1</sup> It is also essential to distinguish the syphilitic ulcer, primarily gangrenous, from the gangrenous state which occasionally and accidentally complicates different other ulcers of venereal origin.<sup>2</sup> In the first case, a phagedenic sore is seen which advances by eroding, and causing eschars so long as the specific cause of the disease exists, whilst in the second, the sore is observed to be covered with granulations as soon as the eschar is thrown off. This specific gangrene must also be carefully distinguished from the simple gangrene with which the genital parts of young girls are occasionally attacked.

836. When the syphilitic gangrenous ulcer has made considerable progress, the prognosis is very unfavourable. If one-half of the penis be already destroyed, the most skilful treatment seldom succeeds in arresting the destructive process and saving the remainder of the member; but if a portion of the prepuce or of the glands only be affected, we may hope, with judicious measures, to arrest the further progress of the mischief. An excellent stimulating application under these circumstances is Venice turpentine or balsam of copaiba, mixed with two parts of olive oil, according to Carmichael, who has often seen very extensive ulcers of the penis and integuments of the groin, which were extending rapidly, checked by one or other of these applications, and made to assume a granulating and healthy appearance under its continued use. The same writer informs us that no advantage is to be derived from the application of emollient cataplasms to these ulcers. When the eschars were considerable, terebinthinate applications, or a lotion consisting of one part of tincture of myrrh, and seven parts of camphor mixture, was employed with excellent effect in destroying the fetor of the eschars and in favouring their detachment; but unfortunately these measures do not hinder their production. Change of air and residence in the country were followed

in every case by the happiest consequences, and so intimately convinced is the author I am quoting of the utility of this measure, that his first advice to invalids is usually to get into the country.

He has never seen any advantage from the administration of bark; on the contrary, he has observed the sores rather to spread more rapidly than before. Opium and conium in large doses seemed to produce good effects. Mercurials in every shape are injurious during the whole of the gangrenous period. When the ulcer is healing, however, recourse must be had to them in order to modify the constitution.

837. Secondary syphilitic symptoms, and particularly cutaneous eruptions are very frequently observed to follow the gangrenous primary sore; this, indeed, is one of the principal characters of this ulcer.<sup>3</sup>

838. The *degenerated syphilitic ulcer* (the *cancerous syphilitic ulcer* of some writers).<sup>4</sup> This ulcer is not primary; it is a mere degeneration of some other, and particularly of the *simple* and of the *indurated* ulcer, upon which fungous excrescences have made their appearance. The patient then suffers very severe pain; the part affected swells enormously; the glans is destroyed by the progress of the ulcer, and the penis presents the appearance of a kind of cauliflower, flattened and attached to the pubes.

839. These *degenerated* syphilitic ulcers must be distinguished from the *primary* sores of the penis which begin in the form of small flat tubercles, not painful at first, and which may become ulcerated shortly after sexual intercourse. This distinction, which positive information in regard to the circumstances that preceded the appearance of the ulcer, on the form and aspect which it presented in its earliest stages, occasionally enable us to make, is of so much the more importance as mercurial preparations, mentioned by some practitioners as the touch-stone, are generally injurious in cases of cancerous disease.

840. It is commonly agreed that the general and local abstraction of blood, the exhibition of opium both internally and to the parts affected, emollient topical applications, the tepid bath and the antiphlogistic regimen are the means best adapted to check the progress of this species of ulcer.

Some surgeons imagine, and I am of their opinion, that independently of this antiphlogistic treatment, it is often advisable to take away the fungous surface of this description of ulcer, and that there are cases in which it is even proper to remove the whole of the diseased parts with the knife.<sup>5</sup>

Should there be any symptoms at the same time of general infection, it would be necessary to attempt a modification of the constitution by the administration of alterative doses of the blue pill, &c.

These degenerated syphilitic ulcers, happily of rare occurrence, are frequently fatal. I am not aware that any secondary syphilitic symptoms have been observed after their cure.

841. *Syphilitic Bubo*.—A bubo is a tumour, developed in the inguinal region, and accompanied with a greater or less amount of

<sup>3</sup> Carmichael: obs. xxvi. Ulcer of the body of the penis, of a gangrenous appearance, followed by an ulcer on the upper lip, pains in the joints, flat coppery tubercles.—Obs. iii. Phaged. ulcer of the gland ready to become gangrenous, followed by a superficial ulcer of the pharynx and with thickening of the periosteum.

<sup>4</sup> The following case is from the work of M. Lagneau. "H. portait depuis quelque temps un chancre superficiel, qui avait résisté à l'emploi des topiques émoulliens. Il consulta un chirurgien, qui lui prescrivit des frictions mercurielles et cautérisa l'ulcère avec le vitriol bleu et la pierre infernale. Ce traitement étant sans succès, un second médecin fut appelé: il ordonna un pansement tout aussi peu rationnel avec l'eau phagédénique, et le malade ajoutait encore à ces mauvais effets en cautérisant lui-même son chancre avec le vitriol bleu. Dès-lors l'ulcère prit un mauvais caractère, devint rongeur et couvrit bientôt tout le gland, dont le volume s'était énormément accru; il rendait un ichor fétide et les bords en étaient renversés. Le malade entra dans cet état à l'hospice des vénériens, où il fut pansé avec les émoulliens et les calmans. Mais le mal était trop avancé pour qu'on en obtint la guérison; il se développa une tumeur lymphatique dure et indolente à la base de la verge, laquelle jointe à un engorgement semblable de l'un des cordons spermatiques vint contrarier l'amputation de l'organe déjà projetée." Lagneau, op. cit., p. 96.

I have also seen a case of cancer of the prepuce, with enlargements of the glands of the groin, which had followed an ulcer of the glans, which had been considered and treated as syphilitic; amputation was not had recourse to, and the patient died. M. Devergie has related several cases of venereal ulcers which had become cancerous after a stimulating plan of treatment. (Clinique de la maladie syphilitique. Paris, 4to, 1826, p. 88, et sequent.)

<sup>5</sup> M. Devergie relates three cases of these degenerated ulcers, in which amputation was performed either by himself, M. Boyer, or M. Gilbert.

Hunter has described the mortification produced by paraphymosis. Swediaur has noticed that gangrene appeared sometimes in the genitals of individuals, who, being attacked with gonorrhœa, took the putrid fever.

Carmichael, op. cit., p. 291, (phaged. vener. disease, or sloughing ulcer,) gives a good description of the syphilitic gangrenous ulcer.

<sup>1</sup> M. Desruelles has related a remarkable example of it: Mem. de Méd. Chir. et Pharm. Militaire, t. xxv. pp. 208-162.

<sup>2</sup> The gangrenous ulcer shows itself in those who have been under a course of mercury for several weeks. (Carmichael. Op. cit., obs. xv. xvi.)

pain, after impure sexual intercourse. These tumours most generally accompany or follow other primary syphilitic symptoms; but there are cases on record, the accuracy of which is unquestionable, which prove that buboes may make their appearance as primary symptoms of venereal infection.<sup>1</sup> (a)

842. This species of bubo differs from the inflammatory and sympathetic enlargement of the lymphatic glands of the groins, observed in some cases of gonorrhœa, in the circumstance of the latter usually becoming resolved, and not giving rise, like the former, to venereal ulcers after ending in suppuration, which is their usual termination. It must also be distinguished from the adventitious inflammation of the lymphatic glands of the groin produced by a blow, or violence of any kind, by the inflammation of a toe, by a wound or ulcer, a boil or a carbuncle on the leg or thigh, an abscess in the plevi, &c. In conclusion, it is easy to distinguish the syphilitic bubo from the gangrenous bubo of plague, from those inflammations of the glands of the groin which are occasionally observed in women who have just lain in, in individuals attacked with Barbadoes leg, or in scrofulous subjects.

843. Syphilitic buboes, in their earlier stages, are to be treated upon the antiphlogistic system generally, and by means of the topical application of ice; when matter is formed, they ought to be opened early; after the cessation of inflammatory symptoms, mercurial preparations become extremely useful. (b)

844. Cases of primary bubo are of such rare occurrence, that opportunities have still been wanting, duly to study the form, the frequency and the duration of the syphilitic eruptions and the other secondary symptoms to which they give rise.

845. The venereal poison may be transmitted to nurses by newborn infants labouring under syphilitic sores of the lips and mouth.<sup>2</sup> The local and primary symptoms which are observed around the nipples of nurses infected in this way are almost always ulcers; occasionally, however, flat tubercles are observed around the nipple in these circumstances.

846. New-born infants<sup>3</sup> sometimes present, from the very moment

(a) The test by which to determine the true character of bubo, is stated by M. Ricord to be inoculation. If the bubo be venereal, the pus in it will give rise to chancre and its sequences; but otherwise not.

(b) A succession of blisters with intervening dressings of lint moistened with a solution of bichloride of mercury, and then a simple poultice or cooling lotion, or a solution of opium, is the latest French practice. Both by hospital and army surgeons, it has been found to be very successful.

<sup>1</sup> Fallopius has observed bubo as a primary symptom of venereal affection: Nam solet oriri bubo (Gallicus) absque gonorrhœa et carie (Gabrielis Fallopii de morbo gallico tractatus, cap. 90. De bubone gallico.—Aphrodisiacus, t. ii. p. 819, in-fol. Lugduni Batavorum). Massa had already mentioned consecutive bubo. (Et sequitur apostemata inguinum.—Aphrodisiacus, p. 146.)

We have often seen, says Mr. Desruelles, inflammation of the glands in men who had neither at the time nor previously laboured under any other venereal symptom. In this case the inflammation of the glands does not usually show itself till a somewhat remote period from the date of infection. The shortest period I have known for the incubation of bubo is from eight to ten days, and the longest from thirty-five to forty days. (Second memoir, loc. cit. p. 274.) I have myself observed several examples of these primary venereal buboes. If patients be not carefully questioned, one might imagine them to be much less frequent than they really are, for patients often present themselves for the treatment of a bubo after the cure of a simple syphilitic ulcer.

<sup>2</sup> "Videmus plures infantulos lactantes, tali morbo (gallico) infectos, plures nutrices infecisse. (Jacobi Catanei de morbo gallico tractatus, cap. iii.—Forestus. De lue venerea, lib. xxxii. obs. ii.—Hunter, op. cit. p. 413.)

<sup>3</sup> Schenck quotes the case of a woman whose husband was attacked with syphilis, and who was delivered of a child covered with scabby sores. (Obs. medic. lib. vi. De lue venerea, ibid. vi. obs. 5.) Rosen speaks of a child which came into the world entirely covered with ulcers and scabby pustules. The father had died several months before its birth of an inveterate lues, and the mother also died of the same disease shortly afterwards. (Maladies des Enfants, p. 314.) One of my pupils, M. Desir, delivered a woman of a child whose body was covered with a tubercular syphilitic eruption. Berlinghieri was wrong (Traité de la maladie vénérienne, trad. par Alyon, 8vo., Paris, 1800) in stating that the child had not contracted syphilis before its birth. Doublet says, and with truth, that a child may be born affected with syphilis. Swediaur says that this very rarely occurs; he relates two instances, however. "A woman having apparently been affected by constitutional syphilis which had never been radically cured, gave birth to a child evidently labouring under the symptoms of this disease, which it communicated to its nurse, who was in perfect health (t. ii. p. 9, 116).—A dragoon had a syphilitic ulcer in the throat; in this state he cohabited with his wife; she became pregnant, and was delivered of a child, which showed, some weeks after its birth, a syphilitic ulcer in the same place that had been

of their birth, but more frequently several weeks or some months afterwards, eruptions and other syphilitic symptoms. Among these some may be regarded as contracted by the infant in its passage through the infected genital organs of the mother (of this number are ophthalmia and blennorrhœa of different descriptions); others are evidently the result of a constitutional infection transmitted hereditarily (tubercles, pustules, ulcers, &c.).

847. It is generally thought now that the nurse labouring under a syphilitic affection of the genital organs does not transmit the disease by giving suck, if there be no specific disease of the nipples (Girtanner, Van der Haar, Hunter, &c.); others, however, are of a different opinion.<sup>4</sup>

848. The syphilitic poison is most commonly communicated by sexual relations; but it may be transmitted by the application of the virus to a part that is excoriated, or the epidermis of which is very thin.<sup>5</sup>

849. Syphilis may be transmitted by the inoculation<sup>6</sup> of the matter of primary sores, or if gonorrhœa, by means of one or more punctures with the point of a lancet.

This experiment, however, does not always succeed: Bertin and his colleagues of the Hospice des Vénériens<sup>7</sup> constantly failed in their numerous attempts to produce the symptoms of syphilis, by inoculating the matter of venereal gonorrhœas, of primary chancres, the discharge of the virulent ophthalmia of children, or by placing these matters in contact with the surface of mucous membranes. In contrast with these experiments, which humanity brands as infamous, and no love of science will justify, are to be placed those cases in which medical men, practitioners in midwifery, &c., have accidentally inoculated themselves with syphilis.<sup>8</sup> (a)

850. To conclude, towards the end of the 15th, and beginning of the 16th century, a syphilitic disease appeared as an epidemic in Italy, France, Spain, &c.<sup>9</sup> This disease spread not only in consequence of the intercourse of the sexes, but from simple contact of the person,<sup>10</sup> and even by means of the air, as other contagious epidemic diseases do. Since this epoch epidemics analogous in their nature have been

(a) See the summary of M. Ricord's experiments and observations on this point in a preceding note.

affected in the father (op. cit. t. ii. p. 9).—Mahon admits that children may be born with unequivocal symptoms of syphilis (Considérations sur les symptômes de la maladie syphilitique des enfans nouveau-nés.—Mem. soc. méd. d'émulation, t. ii. 59.—Ibid., t. iii. p. 27). Hunter speaks of a woman covered with venereal pustules, who was delivered of twins, both of whom had pustules on their bodies when born, and who died soon after. (Op. cit. p. 310.)

<sup>4</sup> Potus lactis mala qualitate infecti, dato quod nulla cutanea infectio appareat (Jacob. Cutanei, op. cit. cap. iii). Gardien. Traité d'accouchemens, 8vo. Paris, 1807, t. iv. p. 189.

<sup>5</sup> "Per oscula vero facile recipitur hic affectus, quoniam vibratio illa et linguarum conflictus caliditatem auget; linguæ rarescunt (Brassavola, de morbo gallico liber. Aphrodisiacus, p. 673).—Cullérier, Swediaur, etc., have seen primary venereal inflammations of the navel, of the mouth, of the rectum, ears, etc. Syphilitic eruptions have been known to appear after the transplantation of a tooth. See Hunter (op. cit. p. 418).—On diseases occasioned by transplanting teeth, which have been supposed to be venereal, who, in his remarks on the case related by Watson, seems to me to have made use of little conclusive arguments.—Swediaur (op. cit. lib. ii. p. 16).

<sup>6</sup> A man who had venereal pustules on different parts of the skin, was inoculated in those parts which were exempt, with the matter of a chancre as well as with that of his own ulcers. The wounds which were impregnated with the matter of the chancre, became well characterized chancres, but the others healed up. I have frequently repeated this experiment, and the effects have always been the same. Having inoculated a person with the matter of a true venereal ulcer which appeared upon the tonsil, and with the matter of a gonorrhœa, the matter of the gonorrhœa produced a chancre; that taken from the ulcer of the tonsil had no effect. (Hunter. Op. cit. p. 390.)

<sup>7</sup> Bertin. Traité de la maladie vénérienne chez les enfans nouveau-nés, 8vo. Paris, 1810.—Prem. partie, p. 52-58.

<sup>8</sup> Swediaur. Op. cit. t. ii. pp. 11, 15. A young soldier affected with gonorrhœa inoculated himself accidentally with the matter of the discharge, by touching a slight wound on the chin with his fingers which were soiled with it; shortly after, considerable psudracious syphilitic eruption, beginning on the face and extending over the whole body; two months afterwards, ulceration of the throat, pains, &c. (Delpech. Chir. Clinique, 4to., t. i. p. 335.)

<sup>9</sup> Upon this memorable epidemic, consult the collection published by Ludovico Luvigini: Aphrodisiacus sive de lue venerea, fol. Lugduni Batavorum, 1728, and the supplement given by C. G. Gruner: Aphrodisiacus, sive de lue venerea, in duas partes divisus: quarum una continet ejus vestigia in veterum monumentis obvia; altera quos Aloysius Luisinus temere emisit scriptores, fol. Jenæ, 1789.

<sup>10</sup> "Evenit ei dormiendo in eodem lecto cum fratre suo infecto (Gaspari Torrellæ Consil. quartum).

observed to prevail partially (vide Scherlivo, Morbus Anglicus, &c.); in these the infection was general, and followed by all its effects.

851. In other cases of infection the disease appears to be local, at least in several individuals, and during a certain time. In effect experience has shown that many primary symptoms, particularly blenorrhœa of the glans and gonorrhœa are very seldom followed by general constitutional infection. But on the other hand, the number of cases in which symptoms of general infection have occurred after the cure of primary venereal ulcers, is so considerable, as to prove that the treatment of primary symptoms can only be held as complete when, by its means, the general system is guarded against the liability to secondary contamination. Unfortunately this desirable end has been attained by none of the methods of treatment hitherto pursued; and opinions are even at present very much divided in regard to the efficacy of the mercurial and the non-mercurial treatment, with one or other of which all the rest may be assimilated.<sup>1</sup>

852. *Secondary symptoms.* These symptoms are extremely varied: but I shall confine myself almost exclusively to the consideration of the venereal affections of the skin (syphilides), besides which, we have ulcers of the mouth, throat, nasal fossæ and other parts, affections of the bones and periosteum, of the articulations, of the eye, &c., all of which have peculiar characters.

853. The alterations produced in the integuments by the venereal poison may be classed under one or other of the elementary forms of cutaneous inflammation and its consequences: 1st. *Syphilitic exanthemata*; 2d. *Syph. bullæ*; 3d. *Syph. vesiculæ*; 4th. *Syph. psudracious* and *phlyzacious pustulæ*; 5th. *Syph. papulæ*; 6th. *Syph. squamæ*; 7th. *Syph. maculæ*; 8th. *Syph. tubercula*; 9th. *Syph. secondary cutaneous ulcers*; 10th. *Syph. cutaneous excrescences*; 11th. *Syph. onychia*; 12th. *Syph. alopecia*. These various forms of disease occur at the present day nearly in the following order of relative frequency: Tubercles, squamæ, papulæ, excrescences, exanthemata, secondary cutaneous ulcers, phlyzacious pustules, psudracious pustules; alopecia, onychia, bullæ, vesiculæ. I shall describe them in the order I have followed in treating of the other cutaneous eruptions, and according to which I have named them first.

854. The *syphilida* or *syphilitic cutaneous eruptions*, except in a few exceedingly rare instances, are only observed at the present day after the occurrence of primary symptoms of greater or less severity. During the epidemic of 1495, eruptions on the skin were occasionally the first symptoms of the venereal disease observed.<sup>2</sup> The disease, however,

<sup>1</sup> The objectors to mercury maintain that under the influence of antiphlogistic treatment and non-mercurials, the cure of primary symptoms is more prompt, and the malady thus cured less rarely followed by secondary affections. In aid of this assertion, they quote the account of experiments made in Sweden during five years, upon sixteen thousand nine hundred and eighty-five patients, the result of which showed, that relapses or secondary symptoms occurred in the following proportions: 1st. After the treatment by means of low diet (without mercury) of seven and a half per cent.

2d. After local treatment or other methods (without mercury), of seven per cent.

3d. After mercurial treatment, of fourteen per cent.

4th. After the treatment by cinnabar fumigations, of twenty-two per cent. (Bullet. Univers. de Ferussac, t. xiii. p. 152). M. Desruelles obtained results very similar. To these conclusions I might oppose those come to by Dr. Hennen, a partisan of the non-mercurial treatment, who declares notwithstanding "that secondary symptoms supervene more frequently, and at shorter and more determinate periods, after the treatment without mercury, than when the mercury has been used." But on the other hand he affirms, that after treatment without mercury the secondary eruptions have not been very severe, that they have not ulcerated, that they were easily cured, and that the bones of the nose or other parts were never affected with caries. (Hennen, op. cit. p. 535.) He says, besides, that iritis is more frequent after the non-mercurial treatment, and that in this case mercury may be resorted to with success (p. 555). According to his calculations, of nineteen hundred and forty individuals treated without mercury, ninety-six have had secondary symptoms; about one in twenty, in the interval of nearly two years.—Of twenty-eight hundred and twenty-seven individuals treated with mercury, and who presented a greater proportion of the Hunterian chancre than the preceding number, fifty-one had secondary symptoms; about one in fifty-five (p. 551, and following). With respect to the primary symptoms, the results obtained are similar to those of M. Desruelles. The mean length of the treatment without mercury was 21 days, with mercury 23 days. The results obtained by M. Rose (Trans. of the Med. Chir. Soc., vol viii.) are still more unfavourable to the treatment without mercury; for he assures us that secondary symptoms took place in a third of the cases treated in this manner. In the York hospital and some others, the proportion of individuals presenting secondary symptoms was less unfavourable—one in six; but in all the cases the rarity of affections of the bones and the mildness of the secondary symptoms generally have been remarkable.

<sup>2</sup> Cum multi laborent et laborarunt tali ægritudine (morbo gallico), qui nunquam in virili membro, aut in vulvâ quicquam passi sunt, et nihilominus omnes ferè ægrotabant partes corporis, ut in multis vidi, qui erant infecti ulceribus, doloribus, aposte-

even during this epidemic, very generally showed itself upon the external organs of generation before appearing upon other regions of the body.<sup>3</sup>

855. The title of *incubation* is given to the interval that elapses between the date of infection and the appearance of the eruption, or the attack of fever which in some case precedes its evolution. Syphilida sometimes make their appearance<sup>4</sup> during the continuance or very shortly after the invasion of primary symptoms.

856. Most commonly, however, it is after several months, and even after several years have elapsed from the date of an apparent cure of every primary symptom, that signs of secondary infection, and especially of venereal eruptions, make their appearance. (a) In the epidemic of the 15th and 16th centuries, these eruptions, when they supervened upon local affections of the genital organs, like all the other secondary symptoms, occurred in general much earlier than they do at the present day.<sup>5</sup>

857. Syphilitic eruptions are sometimes preceded by *febrile* symptoms,<sup>6</sup> which often cease as soon as the eruption is accomplished, but which also occasionally continue during a longer or shorter period of time afterwards. Frequently, too, patients complain before these eruptions of nocturnal pains in the bones or joints; they are, farther, very commonly attacked with ulcers in the throat before their appearance. The duration of these precursory symptoms varies from one to two or three weeks or more. A vapour bath or violent exercise seems often to hasten the outbreak of the eruption.

858. Whatever the elementary form of the syphilitic eruption, it very uniformly shows itself upon the external organs of generation, about the verge of the anus, on the face, especially on the forehead and angles of the mouth, on the back, &c. Syphilitic eruptions have a *peculiar colour*, the shades of which vary from a violet red to an earthy yellow,<sup>7</sup> but which is commonly characterized by the general term *coppery*.

859. Syphilitic eruptions are almost always accompanied by different other secondary symptoms; and they occasionally alternate with one or several additional symptoms of venereal infection.

860. Syphilitic eruptions generally display a great tendency to ulceration, which often assumes peculiar characters; this circumstance was observed very long ago.<sup>8</sup>

(a.) The period between the appearance of primary syphilis and the occurrence of secondary disease varies. It may be two weeks; more commonly it is two or three months, and, as stated in the text, even longer. The stationary nature and occasional suspension of all the secondary symptoms are well described by Dr. Colles.—(*Practical Observations on the Venereal Disease and on the Abuse of Mercury*.)

matibus, et pustulis, quorum pudendum nihil patiebatur.—tres hoc anno curavi ego pueros, unum ætate trium annorum, alterum, ætate sex annorum, et erat puella, tertium undecim annorum, isti non sumpserunt lac infectum—neque coiverunt. (Massa. De morbo gallico, cap. ii.)

<sup>3</sup> Morbus gallicus est pustulæ ex varia humorum corruptione generatæ, propter nimiam aëris in calore atque humiditate præsertim intemperiem, pudenda primum, deinde reliquum corporis, cum magno plerumque dolore occupantes. (Leonici. De Epidemia quam Itali morbum gallicum vocant.)

<sup>4</sup> Syphilitic exanthema sometimes occurs during the treatment for chancre. Papulæ and spots are also sometimes formed a short time after the appearance of primary venereal ulcers. The greatest number of syphilitic eruptions show themselves in the two first years which follow the infection.

<sup>5</sup> Nicolaus Minor Valentinus, mihi intimâ caritate conjunctus, ætatis xxiv annorum ferè, mediocris stature, atque habitudinis, complexionis sanguinæ, ad choleram tendentis, de mense Augusti habuit rem cum muliere, habende pudendam; quare eadem die ipse fuit eodem morbo infectus; quæ infectio, incepti apparere in virgâ, ut solet ut plurimum aliis evenire; nam sequenti die apparuit ulcus in virgâ cum quâdam duritie longâ tendente versus inguina ad modum radicum sorditæ et virulentæ. Post sex dies ulcere semicurato, arreptus fuit ab intensissimis doloribus capitis, colli, spatularum, brachiorum, tibiarum, et costarum, et præsertim in eorum musculis, cum maximis vigiliis, a quibus molestabatur, non nisi in nocte, post primum somnum. Elapsis postea X diebus, apparuerunt multæ pustulæ, in capite, facie, collo, etc. (Gasparis Torrellæ Consil. primum.—Aphrodisiacus, p. 546.)

<sup>6</sup> These febrile symptoms were remarked by Massa; "Et aliquando accidit febricula ante adventum cum aliquo dolore capitis vel frontis—fiunt pustulæ et cessant dolores, et aliquando non cessant si materia est plurima. (Massa. De morbo gallico, p. 45, cap. v.) Hecker and Morelli studied syphilitic fever; Carmichael has mentioned it in several cases, and I have myself often observed it.

<sup>7</sup> Attendendo colorem pustularum subalbidum, aliquando subnigram, aliquando aliquali subrubedine. (Aquilanus. (Seb.). De morbo gallico.—Aphrodisiacus p. 3.)

<sup>8</sup> Fuit etiam ab his pustulis et apostematibus, cum rumpuntur, ulcera diversorum generum. In quibus reperiuntur materiæ albæ viscosæ adherentes cum tenacitate. Quæ quidem materiæ in aliis ulceribus non reperiuntur. Et ulcera ista, cum pro-

861. Syphilitic eruptions are almost constantly accompanied with other symptoms of constitutional infection, such as pains in the bones, ulcers in the throat, &c., and they alternate sometimes with other symptoms of lues which cease on their appearance; farther, they are occasionally replaced by diseases of the bones, and different other grave affections; lastly, they now and then disappear for a time on the invasion or during the course of a serious disease, to recur for the most part with greater virulence on the establishment of convalescence.

862. It is difficult, if it be not perchance impossible, to fix the time at which the cure of a venereal eruption can be said to be accomplished: instances of relapse of these eruptions, and of the manifestation of other venereal symptoms are, therefore, of very frequent occurrence.<sup>1</sup> These relapses would be much rarer did not the patients of public hospitals so generally insist on their discharge before having had time to undergo a complete course of treatment, and did not patients in private life so commonly refuse to go on with the treatment prescribed for some time after they are apparently well, in the idle fear of having their constitutions impaired by the continued use of mercurial preparations.

863. The syphilitic *exanthematous* eruption<sup>2</sup> presents three appearances, distinguished from each other by their several colours, into the red, the yellow and the violet. The two first are frequently seen united in the same individual, and then the skin has a peculiar particoloured look, which has been compared to that presented by the surface of certain species of trout (J. L. Petit. Hennen).

The red syphilitic exanthema (*roseola syphilitica*) may be primary and acute, that is to say, it occasionally accompanies primary symptoms, for I have never known it to exist primarily and independently of other symptoms. It often precedes or accompanies other secondary symptoms;<sup>3</sup> but it does not often, as it has been said to do, accompany primary symptoms, and especially gonorrhœa; might I draw an inference from my own observations, I should say that it accompanied gonorrhœa very rarely. I have several times seen it coincide with a considerable eruption of flattish tubercles, this twofold eruption appearing several months after the cure of a chancre. The exanthema in question more rarely exists alone.

The eruption is characterized by spots of a *coppery red*, or of a tint very similar to that of measles. The spots, most generally dissemi-

nated over the trunk and extremities, are irregular, sometimes rounded, but much more commonly without any determinate figure, extremely superficial, not prominent, and disappearing completely under the pressure of the finger. Very conspicuous when patients have just taken active exercise, or when they come out of a vapour bath, they are scarcely visible when patients have been at rest for some hours and the temperature of the surface is low. To distinguish them readily, it is sometimes necessary to place the trunk and parts affected in such a manner as to make the light fall on them obliquely.

These patches very seldom coalesce, and the skin presenting its natural colour in the intervals between them, has a marbled appearance. When these spots are examined narrowly and with great attention, especially those developed upon the outer parts of the thighs, in those places where minute projections are observed at the roots of the hairs, each of them appears to be formed by the aggregation of four or five violet-red coloured points, slightly or not at all prominent, over which is spread a tint of less intensity that vanishes under pressure, exactly like a blotch of measles.

The spots of syphilitic exanthema are not generally attended either with heat or itchiness, although patients do occasionally complain of a slight degree of pruritus. Usually evolved without febrile symptoms, and unknown to patients, these spots often appear in the course of a few hours.

The red tint of the exanthema commonly disappears within a few days; the spots fade, become slightly yellowish,<sup>4</sup> like those of common measles, and remain in this state longer than these last. The desquamation that follows this eruption is extremely insignificant or altogether insensible; a few minute grayish or mealy-looking points are all that are ever seen on the surface of the skin.

864. This syphilitic exanthema is readily distinguished from the other syphilitic eruptions by its form, and from the exanthemata in general by the following character. From measles it differs in the absence of febrile and catarrhal symptoms, the duration of the eruption, etc. This duration of the eruption, and certain other concomitant syphilitic symptoms, also serve to distinguish syphilitic exanthema from roseola. Further, if roseola *vulgaris* and syphilitic roseola present nearly the same outward appearance at first, or during the few first days of their eruption, the red and slightly violet hue of the syphilitic efflorescence is more permanent than that of the common roseola, and is usually succeeded by a yellowish tint at a period when all traces of this less important malady have disappeared. It is still more easy to distinguish syphilitic exanthema from urticaria, in which the wheals are either paler or more rosy than the skin at large, are prominent and accompanied with pruritus of a very severe description, and often appear and disappear spontaneously once or oftener in the course of the four and twenty hours,—so many characters which are never presented by the syphilitic affection.

The small yellow irregular, flimsy and fleeting spots of syphilitic exanthema in its decline, are much slighter than the larger patches of chloasma; they are also in general disseminated over a much greater number of regions. The spots of measles as they are going off bear a pretty strong resemblance to those of the syphilitic exanthema become yellow; but in measles the symptoms which preceded the eruption, and in syphilitic exanthema the concomitant symptoms leave no room for uncertainty in regard to the diagnosis. I shall by and by specify the characters, by means of which syphilitic exanthemata may be distinguished from syphilitic spots or maculæ.

865. As to the *exanthematous* or *erythematous* inflammations of the throat, conjunctiva, prepuce, vagina, &c., of a syphilitic nature, their diagnosis would be attended with insuperable difficulties, were not these affections accompanied with other characteristic phenomena (squamæ, tubercula, ulcers, &c.), and were not their contagious nature unquestionable.

<sup>4</sup> Syphilitic exanthema has sometimes, from its commencement, the yellowish tint which is observed more frequently on the decline of the rosy exanthema. "We have also observed, during the treatment of phagedenic ulcers, an eruption of yellowish spots on the skin. They are neither pustules nor papulæ, since they do not rise above the level of the skin; nor are they coppery spots, having none of the general characters of these, nor are they of so long continuance; the spots of which we speak disappear at the end of ten or fifteen days." (H. M. J. Desruelles. Second mémoire inséré dans le recueil des mémoires de médecine, de chirurgie et de pharmacie militaires, t. xxvii. p. 177.)

longantur, fiunt profunda, virulenta, livida, corrosiva, sordida, cum duritie labiorum et carne ostracosa et aliquando fiunt ambulativa—et aliquando sunt perforata multis perforationibus. (N. Massa. De morbo gallico, cap. v.—Aphrodisiacus, p. 45, folio. Lugduni Batavorum, 1728.)

<sup>1</sup> Et sæpe post curationem hæc ægritudo recidivat et recidiva quandoque est eita et sæpe stat per annos, quæ in multis est deterior. (Massa. Op. cit. p. 45.)

<sup>2</sup> This eruption is described by Torrella, in his Consilium secundum: "Infecta autem virga, post xxx dies, post somnum prolixum horâ tertâ excitans se a somno, invenit totum corpus infectum maculis latis, rubeis, sine pustulis, etc. Fernelus has given its exact characters: (altera species) paulo deterior est quâ cutis universa crebris maculis minimè extuberantibus conspergitur, iisque parvis, lentiginis instar, ac modo rubris, modo flavis, quæ non antè deleri extinguere possunt, quam morbi radix sit evulsa...quam nulla graviora sequuntur incommoda." Fernel. De lue venérâ.—Aphrodisiacus, p. 613.) Hæfenreffer has given this description word for word. Hunter mentions exanthematous spots of a syphilitic nature. Willan, in his article on syphilitic psoriasis gyrata, mentions an exanthematous eruption of an annular form, which shows itself in patches upon the face, the extremities, and other parts of the body; this exanthematous eruption lasts several weeks, or even months, before any desquamation takes place; it is also accompanied with fever, pains in the head, limbs, &c. (Willan on cutaneous diseases. 4to. London, 1778—1814, p. 164.) There are some particular cases in different periodical publications: Syphilitic exanthemateuse guérie par les acides. (Journ. Hebdom. 1re série, t. i. p. 24.) I have seen a great many instances of this affection. Cullérier and his pupils speak of the syphilitic exanthematous eruption under the name of *pustules formées*.

<sup>3</sup> Syphilitic exanthema has often been seen with other secondary symptoms; in fifteen cases of eruptions, without other accompanying symptoms, mentioned by Dr. Hennen, and which made their appearance after Hunterian chancres, six were tubercular, five exanthematous, two pustular, one had something of a tubercular form, another was tubercular and vesicular. Of four cases of eruptions appearing after the same form of sore, and complicated ulcer of the throat, two were tubercular, one tubercular and squamous, and another tubercular and exanthematous. Of twelve eruptions appearing after ulcers, different from those described by Hunter, and without other symptoms, six were pustular, three were exanthematous, two were tubercular, and one tubercular and squamous. In six cases where the eruption was accompanied with ulcers of the throat, three were exanthematous, two tubercular, one papular, squamous and tubercular, and one pustular and tubercular.

Of three hundred cases of syphilitic eruption, after different primary symptoms, I have not observed the exanthematous eruption more than ten times! But this eruption may have been more frequent, as patients would scarcely present themselves at an hospital on account of so slight a symptom.

A *chronic exanthematous sorethroat*<sup>1</sup> is one of the most common of all the constitutional symptoms of syphilis. It differs in its appearance and in several other phenomena from simple or even phagedenic ulceration affecting the pharynx, which is for the most part attended with little difficulty in swallowing, whilst this symptom is always very decided in the syphilitic affection of the same parts. When the inside of the throat, and especially the posterior part of the pharynx and uvula are examined, these parts are generally observed to be red and swollen. The tonsils are occasionally a little enlarged, and the same may be said of the submaxillary glands. This tumefaction of the glands, which is in general accompanied with little pain, has been confounded with scrofulous swellings of these structures. Hunter is of opinion that this erythematous inflammation may be propagated along the œsophagus. The affection is analogous in its nature to chronic venereal ophthalmia.

The exanthematous is justly regarded as the least serious of all the forms of syphilitic eruption.

866. *Maculæ syphiliticæ*, *syphilitic spots*,<sup>2</sup> are occasionally observed on the trunk and extremities, but are much more commonly seen on the face, and especially on the forehead. These maculæ are rounded or oval in their figure, and vary in size, from that of a shilling or something less, to that of a half crown piece. They are of a very deep yellow coppery colour, their centres often darker than their circumferences, and disappear in some measure, but always imperfectly, under the pressure of the finger. They are occasionally accompanied with some pruritus. In general they are few in number; and they rarely become affected with evident desquamation. In the aged, and individuals of cachectic constitution, these maculæ are sometimes seen of a deep brown, and even of a blackish hue.

The duration of primary syphilitic maculæ, always less protracted than that of the stains which are consecutive to other elementary forms of eruption, especially when these have been followed by ulceration, is at all times difficult to calculate, and varies between one and several months. They generally get well from the circumference towards the centre, assuming the pale yellow colour of withered leaves.

867. These syphilitic maculæ are distinguished from chloasma by the small size and regular form of the spots, which in chloasma are always extensive and regular; the patches of chloasma further appear most commonly on the fore part of the breast and abdomen, and are never of a reddish-yellow or copper colour. They are also occasionally attended with a considerable degree of pruritus, and almost always affected with an evident furfuraceous desquamation. But it is much more difficult, especially in the absence of accurate information, to distinguish primary syphilitic maculæ from the spots or stains which syphilitic squamous patches and un ulcerated flat tubercles leave behind them after their disappearance. The yellow spots of the syphilitic exanthema are always evidently slighter, usually of smaller size, and less regularly circumscribed.

Syphilitic maculæ are almost always accompanied with other symptoms of venereal affection of the system.

868. Syphilitic eruptions are very rarely seen to affect the bullous form; I shall, however, by and by have occasion to describe an eruption which frequently accompanies the phlyzacious form of syphilide, and is characterized by large pustules, at the base of which a bullous areola is formed, and which at a later period becomes covered with a broad and prominent brownish scab, similar to that of rupia (§ 300.)

The following case induces me to imagine that syphilis may mani-

<sup>1</sup> This description of venereal exanthematous inflammation is more frequent than is generally believed. I have seen several examples even without eruption on the skin. Carmichael has described this exanthema very accurately; Hunter has also mentioned it.

<sup>2</sup> "Accidunt et maculæ corpora valde infestantes, quæ corpore purgato tolluntur, si fuerint rubæ, sanguisugæ applicentur, quæ materiam sugant; si nigræ, fortiter abstergentibus utendum est; si cum his fuerint tubercula, difficillius remouentur; si solæ, mirè iuvat amygdalinum oleum (Francisci Frizimelicæ. De morbo gallico tractatus. — Aphrodisiacus, p. 998).—Hinc, ergo cutis maculæ planæ, non extuberantes, ephelidibus similes, discretæ...latius expansæ si in pluribus locis continuis; livescentes, purpuræ, rosæ, flavæ, etc. (Astruc. De morbis venereis, 4to. Parisiis, 1738, p. 343.)

Secondary spots have been designated under other names (Defædationes, vestigia pustularum et aliorum ulcerum (Massa); Blotches (Hennen).

fest itself on the skin under a shape more completely bullous. A man, aged 58, of good constitution, came to consult me as an out-patient at the Hôpital de la Charité, on account of an eruption which two months before had made its appearance on the upper extremities, and within the last month had showed itself upon the buttocks. The appearance of this eruption was not in every place the same; where it seemed to be beginning, a small bleb was observed, transparent or nearly so, not very prominent, and of the size of a hemp-seed or small pea, standing in the middle of a spot slightly vinous in its colour, and as large as a sixpenny piece or a shilling, the part which was not raised by serum forming a broad areola around the bleb, well defined and not melting gradually into the surrounding skin. In other places these bullæ evolved on spots, which presented the same general tint, were succeeded by a small laminated, yellowish scab prominent in its centre, surrounded by a white rim not very distinct from the edge of the spot. On other spots, again, the scab which covered their centre was still smaller, and surrounded by a broader areola, of a yellow copper colour, separated from the healthy skin by an irregular rim; lastly, between these scabs and bullæ, the breadth and peculiar colour of whose areolæ distinguished them sufficiently from pemphigus, there existed many oval spots of a dirty yellow, and several others which were smooth and shining on the surface, and of a yellowish-red colour.

Several years before, this man had had three chancres on the corona of the glans, which had been treated and healed up under the influence of mercurial inunction continued for a month. A year before this he had also suffered from a gonorrhœa of which he got well after having taken the liquor of Van Swieten<sup>3</sup> for six weeks. Two years afterwards he contracted gonorrhœa, again; from this attack he also recovered, under the use of the same medicine continued for two months. From this time he has on several occasions laboured under excoriations on the penis, sores in the mouth, and spots upon his body. Very lately he has also suffered from pains in the joints and superficial bones.

I recommended him to make use of the tisan of Feltz<sup>4</sup> and the Sedillots pills.<sup>5</sup> I regret being unable to state the definitive issue of this treatment; the patient soon felt relieved, and then ceased his visits at the hospital.

869. There is another form of venereal eruption fully as rare as the preceding: this consists of a crop of vesicles analogous in form to those of eczema simplex, but a little less voluminous, and surrounded by a coppery and characteristic areola. I have taken notes of no other than the following case of this eruption; indeed I only remember to have met with the disease once besides, which was less distinctly marked and much more doubtful. A man of good constitution, and formerly a soldier, aged 35, had a gonorrhœa in his 20th year, (1819,) which was speedily and radically cured. A second clap, caught in the following year, did not last longer than a fortnight. Three years later, from a fresh infection, a chancre appeared upon the prepuce; this sore was dressed with mercurial ointment, and healed rapidly. A month after the chancre was whole, the patient began to feel pains during the night in the shoulders. The patient then took Van Swieten's liquor for a fortnight, and the pains left him. In 1827 nodes began to be formed on the left shin, and were treated with the tisan of Feltz. The pains of the bones which had attended them for three months ceased under the use of this medicine. The patient has long complained habitually of sore throat; but since October 1830, his distress from this cause has very much increased, and lately he has felt his food, in the act of swallowing, escape into the nasal fossæ. Night and day he suffers with violent pain in the head, and he once passed eight days without sleeping. For a year past he has followed the strictest regimen, eating little, abstaining from wine, and taking milk night and morning; this system did him no good; on the contrary, he lost flesh very much. More recently he has taken a tisan of the sudorific woods.

On the 18th of July, 1834, an eruption made its appearance on the hands and forearms, forehead and trunk, which, on the 2d of August, presented the following characters: On the forearms several irregular

<sup>3</sup> An alcoholic solution of corrosive sublimate.

<sup>4</sup> A compound decoction of sarsaparilla and sulphuret of antimony.

<sup>5</sup> The blue pill made with grease instead of syrup or confection of roses.—Tr.

clusters of minute reddish elevations, of the size of pins' heads, containing a turbid or opaque fluid. These vesicles were not itchy; they were more prominent and more globular than those of simple eczema, which they also exceeded somewhat in dimensions, but they were inferior in size, not so transparent, and disposed in clusters less regular than those of herpes; their reddish and rather livid tint distinguished them from the pustules of impetigo. In other situations the eruption formed small rings, analogous both in shape and size to those of measles. Many of the vesicles in several of the clusters had declined, and were succeeded by a slight exfoliation of the epidermis, presenting in some places a slender rim, which indicated exactly the former size of the vesicles. Wherever this exfoliation had taken place, the skin presented spots having precisely the same appearance as ordinary syphilitic maculæ. The eruption differed from syphilitic psudracia, the pustules of which are larger, more acuminated, and usually followed by scabs, and often by ulcers and cicatrices. A portion of the uvula and velum palati was destroyed; the posterior pillar of the left side and corresponding part of the velum palate had contracted adhesions with the opposite surface of the posterior parietes of the pharynx; a grayish ulcer, as large as a silver two-penny piece, was perceived on the right side of the palatine arch, near the median line and the commencement of the pendulous velum; the patient made no complaint of pain in the throat although he now no longer followed any system of regimen.

I recommended a course of the tisan of Feltz and pills of Sedillot, which the patient immediately entered upon and continued for some time with advantage. I saw him shortly afterwards; the vesicles had disappeared, but the spots still remained; I am not aware, however, whether the cure was complete, the patient having soon discontinued his visits at the hospital.

In another case of constitutional syphilis, I saw an eruption of small vesicles with violet-coloured bases in the hollow of the foot, which were probably of the same nature as those described in the preceding case.

870. The general character of this vesicular *syphilide* will only be accurately specified when a greater number of particular and more complete cases have been recorded. M. Gilbert<sup>1</sup> has published a case similar to the one I have detailed, and the Messrs. Cazenave and Schedel<sup>2</sup> have given another in which the eruption presented a different appearance.

871. In those who are labouring under syphilis, a number of *psudracious pustules*,<sup>3</sup> about the size of those of rosacea, are often observed. These small pustules may appear on any region of the body, but their most frequent seat is the forehead and the shoulders. The date at which this species of eruption makes its appearance, after that of the primary infection, is as uncertain as it is in regard to all the other syphilitic eruptions. I have occasionally observed it to supervene very shortly, sometimes only four or five weeks after this event. The eruption is sometimes *preceded* by fever, pains in the head,

shoulders, and larger articulations. After appearing on the shoulders, the eruption may spread to the extremities. The fever does not always cease on the evolution of a first eruption; it continues so long as fresh crops of pustules make their appearance. The articular pains are usually more severe during the night than the day.

872. The pustules are at one time extremely numerous and almost confluent on the face, back, and belly; at other times they are fewer in number, and disseminated over the whole surface of the body. They vary in colour from a pale to a deep crimson-red. They do not all make their appearance at once, and after a primary febrile paroxysm: they appear successively, so that in the same subject pustules in a nascent state, and in a state of maturity, are frequently to be seen at the same moment. The pustules individually are conoidal, of a dull red colour; their base is hard, surrounded by a coppery areola, their summit, slightly acuminated, is filled with serum or pus. In their decline the pustules are covered with a small scab, of a dirty yellowish-gray colour, under which there is found an ulcer, of such insignificant dimensions, that it might be covered with the head of a small pin. By and by, a small circular, brown, depressed cicatrice, which gradually acquires a dull white hue, succeeds the sore, around which a kind of tawny yellow areola is for a very long time perceived. After the fall of the scabs, however, it sometimes happens that nothing remains beyond small brownish spots or stains, without any appearance of ulceration or of cicatrice.

873. Syphilitic psudracious pustules are apt to be preceded, especially in individuals of bad constitution, by violet or nearly black stains, which only disappear very incompletely by pressure. These stains are occasionally very much crowded together, indeed, confluent, so as to form broad patches, as large as a five-shilling piece, and very commonly of an oval form. These spots become covered with a great number of small and slightly acuminated pustules, which for the most part fall into a state of irregular and generally superficial ulceration. After these get well, numbers of broad yellowish-brown patches remain on the skin, which are commonly beset with small, whitish, and depressed cicatrices.

874. When syphilitic psudracia have appeared as an abundant eruption upon the trunk and extremities, the *diagnosis* is seldom uncertain. The disease cannot be confounded with impetigo *sparsa*, the discharging pustules of which do not ulcerate, (§ 532,) nor with any form of accidental or artificial pustular eruption (§ 568). It is more difficult to distinguish the eruption of which we are treating, from that of acne and rosacea, when its principal seat is the back, and shoulders, and face. Yet as the pustules of acne rest on a red base, and those of rosacea are surrounded by a bright erythematous areola, whilst those of the syphilitic eruption stand in the midst of a copper-coloured injection; and, further, as rosacea does not ulcerate, and is not followed by the peculiar depressed cicatrices, observed after the greater number of syphilitic psudracia; and, lastly, as in acne, the skin generally looks shining and unctuous, and is often covered with spots and indurations, whilst in the syphilitic affection it is healthy, or rather dry, in the spaces between the pustules; there seems no great hazard of confounding one of these eruptions with the other. To conclude, these small syphilitic pustules are readily distinguished from venereal papulæ, when these several eruptions are at their height. The period at which the pustules dry up, differs also considerably from that at which the papulæ begin to shrink and desquamate.

875. Psudracious venereal eruptions are liable to be accompanied or followed by various other secondary symptoms.<sup>4</sup>

876. *Syphilitic phlyzacious pustules*.<sup>5</sup> An eruption of pustules, of

<sup>1</sup> "Un malade, offrant bien d'autres symptômes vénériens consécutifs, portait à la face externe et postérieure de l'avant-bras une large tache d'un rouge cuivré, obscur, semée de petites vésicules séreuses, passant à l'état de dessiccation, et assez analogues à celles de l'eczéma. La teinte cuivrée et livide de cette éruption, bien différente de la coloration rosée ou rouge de l'eczéma, l'aspect flétri des vésicules, l'absence des excoirations squameuses de la dartre squameuse humide, la marche de la maladie, les phénomènes concomitans, établissent des caractères distinctifs suffisans." (Gilbert. Manuel des maladies spéciales de la peau, 12mo. Paris, p. 203.)

<sup>2</sup> Cazenave and Schedel. Abrégé pratique des maladies de la peau, 8o. Paris, 1828, p. 419.

<sup>3</sup> Of one hundred and three cases of syphilide which I have seen, no more than six consisted of psudracious pustules. This form was pointed out long ago: "Est cum pustulis acutis, non latis, et festine, generatur in ea sanies quasi laudabilis." (G. Torrella. De pudendagrâ tractatus). The psudracious pustular syphilide is also vaguely indicated by J. Benedictus: "Pustulæ parvæ tendentes cum rubore ad citrinitatem, et velociter exeuntes, et ulcerantes, facientes in cute asperitatem et dolorem, etc. . . Si sunt, parvæ, duræ ad nigredinem tendentes cum privatione doloris," etc. (Joannes Benedictus. De morbo gallico libellus, cap. iii.—Aphrodisiacus, p. 171.) Hunter appears to have known this species of eruption. (Op. cit. p. 338.) M. Alibert has given a good representation of this eruption, under the name of syphilide pustuleuse lenticulaire, p. 43. Under the name of papular disease Carmichael has reunited the psudracious syphilitic eruption and the papular syphilitic eruption. He gives two cases of psudracious pustules: Case 1. Gonorrhœa, phymosis, inflammation of the glands, buboes, swelling of the scrotum; diminution of the symptoms; four months and a half after the attack, redness and excoriation of the throat; three days after, fever and eruption of psudracia; pains of the joints; small ulcers on the scrotum. Case 6. Superficial ulcer of the gland, buboes, fungous ulcer; eruption of psudracia.

<sup>4</sup> Dr. Carmichael assures us that in several hundred psudracious and papular eruptions which he has treated, he has never once met with exostosis at the same time. This complication is rare; nevertheless I have seen several cases of it.

<sup>5</sup> Torrella appears to have described this species of pustule: "Juvenis infectus pupendagrâ phlegmatica, cum pustulis grossis crustosis, ex quibus exibat sordities grossa ad alba fuscadinem tendens." (Gasparis Torrellæ. Consilium tertium.—Aphrodisiacus, p. 549.) Fallopius, in his description of crusted venereal pustules, appears to include phlyzacious pustules and syphilitic rupia: "Secundum genus pustularum est habentium crustam, et istæ rotundæ sunt, ut plurimum et crustas adeo crassas faciunt, et prominentes ut veluti cornuum principia videantur: isti cortices aliquando aridi, aliquando turgentis sanie sunt. Sanies aliquando lutea, veluti mel: aliquando alba, veluti pituita, aliquando subnigra, etc." (De morbo gallico tractatus.—Aphrodisiacus, p. 824.) Carmichael has lately described and represented syphilitic ethyma and rupia (pl. iii.), which he considers as eruptions peculiar

a larger size than those that have just been described, of a flattened form, not at all prominent, generally distinct, surrounded by a coppery base, containing, at their height, a yellowish fluid in their heads, which, by and by, dries into a blackish adhering scab, is frequently seen appearing upon the nape of the neck or shoulders, occasionally on the cheeks, or parts covered by the beard, more rarely on the extremities, and still more rarely on the other parts of the body, as a secondary symptom of syphilitic infection.

The eruption in this case may be scanty, the pustules appearing far apart and extensively disseminated, or, on the contrary, they may be rather crowded, regularly grouped, now in the shape of a kind of band passing from one cheek to the other across the chin, again in symmetrical lines upon the nucha, and down the shoulders on each side of the median line, so as to cover the region of the trapezius, or in directions which recall the course of the latissimi dorsi. Although I have occasionally met with this kind of symmetry in other cutaneous eruptions, I think I have seen it more frequently along with phlyzacious syphilidæ than any other form of disease. When the eruption appears occupying extensive regions, many pustules are commonly observed here and there in clusters, whilst others are scattered irregularly in the intervals between these.

This form of venereal eruption is rarely preceded by fever. It often shows itself after pains in the bones and joints have been complained of,—after ulcers have been seen in the pharynx, &c. Each pustule appears at first upon a reddish spot, the centre of which becomes purulent, whilst its base, as it extends, is surrounded with a slight areola of a deep or livid-coloured brown. Some of these pustules always remain of insignificant size, like those of ecthyma at their origin; the fluid they contain, as it dries, seems to become incorporated with the epidermis, and forms a small set scab, the centre of which is black, or nearly so, whilst the circumference is surrounded by the cuticle detached and dried. After the spontaneous fall of these scabs, the skin presents a spot of a coppery red, the centre of which is commonly occupied by a small depressed cicatrice. These consecutive spots or stains are much more conspicuous where the pustules are clustered.

The small phlyzacious venereal pustule differs from the psyracious pustule of the same description, in the circumference of the former being still somewhat the larger of the two, in its scab being also larger and more regularly set within a rim of cuticle, which membrane is also more extensively loosened around its circumference.

877. Phlyzacious syphilitic pustules approximate more closely in the particulars of form and size to the phlyzacious pustules of ecthyma and variola. Like these, for instance, they are almost always disseminated. The greater part of their surface, when they have attained their height, is of a yellowish-white, and the coppery circle which surrounds their base is broad and tinged. They begin to dry off in the centre, which presents a scab of a yellowish and brownish or olive green colour, of a flattened form, separated from their edge by a small circle, which is gradually effaced as the drying advances. When this process is completed, if the scab be detached, it is found to have penetrated the substance of the corion deeply, and to have concealed a little ulcer, which generally implicates the entire thickness of this membrane.

878. These consecutive ulcers are particularly remarkable among new-born infants after they have been several times immersed in the tepid bath, and the scabs by this means detached. They are also very apparent about the margin of the anus, on the upper and inner parts of the thighs, &c., situations in which the natural moist state of the skin prevents the formation of proper hard scabs. These ulcers, as I have said, are followed by depressed and very evident cicatrices. The form and dimensions of several of them seem occasionally to proclaim that they had succeeded ulceration of a serpiginous kind; but this is in appearance only, for instead of the cicatrized furrow succeeding this form of ulcer, the bands which here appear are found to be made up of a chain of *circular* cicatrices, touching each other by their edges.

The evolution of phlyzacious syphilida being successive, we may, in particular cases, often observe at the same time copper-coloured

to the phagedenic venereal disease. Cullérier designates them as scabby pustules; but he also applies this denomination to ulcerated tubercles, covered with scabs.

flattened pustules; pustules of the same general form and appearance, but of much larger dimensions; small laminated scabs, and others more prominent and more deeply set within the corion; livid and yellowish-coloured blotches; cicatrices of the same aspect, and when of an older date, depressed, and of a dull white; the sum of these appearances is very characteristic of the nature of the eruption.

879. It sometimes happens in a case of phlyzacious eruption, that a certain number of pustules, after attaining their height, increase in consequence of a considerable detachment of the cuticle effected by means of a deposit of purulent matter around their circumference. These pustules, the base of which becomes bullous, and which are subsequently covered with large and prominent incrustations, have been designated by reason of their appearance, under the title of *syphilitic rupia*. In this variety the scab is not only broader but more prominent, especially at its centre.<sup>1</sup> It cracks and becomes irregularly loosened around its circumference, and the skin in the latter situation is of a coppery hue, but is not ulcerated. After the central part of the scab is detached, a sore of greater or less extent is always exposed, which presents the general characters of syphilitic sores, and this latter circumstance is the one which distinguishes *syphilitic rupia* from *rupia simplex*, for both of them present central ulcers surrounded by a circular red surface and an epidermic border or rim.

880. When syphilitic rupia is left to itself, ulceration continues to go on under the scab, which becomes ever more and more prominent, and acquires the appearance of the non-venereal rupia *prominens* already described. When the scab is pressed upon, some purulent matter is made to exude from under it; its circumference also continues bathed in pus for a time. This secretion diminishes by slow degrees; the base of the incrustation then hardens; the cuticle loosens and cracks around its circumference; portions of the scab are next detached, so that it is lessened in thickness or diameter. The cicatrization of the sore goes on from its circumference towards its centre. When the whole of the scab is removed, and the ulcer completely healed, the cuticle which covers the cicatrix remains subject to repeated exfoliation for some time afterwards. The ulcer seldom exceeds in dimensions the size of the bleb which preceded it, unless it has been irritated by exercise when situated on one of the legs, or by stimulating applications, when any other part of the body is its seat.

881. I have seen syphilitic rupia presenting all the appearances of rupia *escharotica* in a woman who was labouring under a squamous syphilide. On the outer and lower part of this patient's right leg there was a gangrenous sore nearly as large as a crown piece, the surface of which was of a brownish black colour, spongy, covered with blackish or gray filaments, and which exhaled a gangrenous odour. A circular groove of considerable depth surrounded the eschar and separated it from the neighbouring skin, the cuticle of which was raised like a ring by the effusion under it of a quantity of purulent matter. After the detachment of the slough the ulcer presented the characters of syphilitic sores in general, and healed up as the other symptoms of the constitutional affection yielded under the influence of mercury.

882. Yellowish lenticular spots are occasionally observed on the palms of the hands and soles of the feet, of individuals labouring under syphilitic eruptions of different elementary forms. These are very similar in appearance to the pustules of small-pox, developed in the same situations in their stage of desiccation. If the cuticle covering these spots be removed with the point of a pin or a lancet, a small yellowish-coloured disc is discovered under it, which may be taken away, like that of small-pox, to which it bears the greatest resemblance. Through the cuticle these discs have a yellowish copper colour. When this eruption is not interfered with, the altered portion of cuticle and lenticular disc are detached. The palm and sole then look very much

<sup>1</sup> Here is a case of this rare variety. A man nearly thirty years of age had contracted the venereal disease four different times. The last infection was followed by gonorrhœa and ulcers on the corona glandis (treatment by mercurial friction, liquor of Van Swieten and tisan of Feltz). Shortly after he was seized with venereal pains, and after several vapour baths, an eruption of large pustules, similar to those of ecthyma, with coppery red edges, showed itself upon the breast, and successively on the trunk and limbs. The matter of these pustules, on drying, gave place to scabs of a dusky brown, most of them conical, similar to those of rupia *prominens*. In falling off, these scabs left bare ulcerations, which had the appearance of venereal ulcers. This serious disease was successively treated with subcarbonate of ammonia, muriate of gold, and nitric acid, and it was only after six months' care that the cure was accomplished. I have seen another case which also belonged to this variety.

as they do when they are affected with a squamous syphilitic eruption; but the presence of the disc under several spots, enables us to distinguish between these two forms of the disease. Further, in this eruption there is a less marked tendency to the reproduction of squamæ than in syphilitic psoriasis.

These venereal eruptions in the palm of the hand and sole of the foot, can never be mistaken for syphilitic rupia, the development of which, in these situations, is extremely rare, and which is, besides, sufficiently characterized by its central scab and the ulceration it occasions.

883. *Syphilitic papulæ*<sup>1</sup> are firm elevations, solid or containing no fluid, scarcely ever accompanied with pruritus, and generally ending in resolution and desquamation, but occasionally also in little depressions and small cicatrices.

This form of eruption may appear almost suddenly, or in a slow and successive manner.

884. When the eruption is rapidly evolved, it takes place within from twenty-four to forty-eight hours; it is sometimes preceded by general febrile symptoms, and with pains in the joints, symptoms which are especially relieved by blood-letting, when the state of the constitution does not contra-indicate the practice. The blood abstracted is almost uniformly buffy. The eruption shows itself most usually at once, or nearly at the same time over the whole body, but especially upon the back and the face. It is characterized by small solid elevations of a coppery red colour, slightly conical, but little prominent; and which only cause a trifling amount of pruritus, if perchance they occasion any. These papulæ are sometimes very closely crowded together, and almost confluent, so that the skin of the back and face presents a uniform reddish coppery colour. It very rarely happens that they are disseminated and isolated; often on the contrary they form small oval clusters, the size of a shilling or somewhat larger, separated from one another by spaces covered with thinly disseminated papulæ. Within a few days the eruption begins to fade; the papulæ shrink; may desquamate slightly; all leave small yellowish stains upon the skin which vanish very shortly.

885. Syphilitic papulæ are occasionally evolved in another manner, and present a different appearance. They make their appearance slowly and successively, commonly on the limbs and in the sense of extension, sometimes on the forehead and surface of the hairy scalp, larger than in the first instance, flattened, and of the size of small lentils, very regularly circumscribed and slightly raised above the general level; they are of a *yellowish copper colour*, not itchy, without any inflamed areolæ surrounding their bases, and separated by intervals in which the skin is healthy, or sallow and shriveled, an appearance which it is particularly apt to present in the aged, or individuals of indifferent constitution. The cuticle is detached from the summit of each of these papula, arrived at its height, in the form of a small dry and grayish-coloured pellicle, more strongly adhering at its centre than towards its circumference, and sometimes in the shape of a small disc. This desquamation is repeated from the surface of the papulæ until they have shrunk completely, and are replaced by little lenticular spots or stains of a grayish yellow, which continue visible for a very long time.

These broad yellow desquamating papulæ may be so much crowded over regions of such extent, as to simulate a squamous eruption,

especially if the neighbouring skin, dry and shriveled, is itself the seat of a desquamation at all considerable.

886. Syphilitic papulæ occur with a third appearance: they are of a brownish livid or violet colour, and are evolved slowly, and in succession like the yellow papulæ, the very considerable dimensions of which, however, they never attain. They are also less flattened, more prominent, and more constantly arranged in clusters; they continue long stationary at their height. Some of them, after the fall of the small epidermic disc that covers them, shrink away slowly, and the skin, in the corresponding points after their disappearance, presents a small wrinkled depression of a dirty brown colour, which might be covered with the head of a pin. Others ulcerate on their summits, and become covered with a small brown scab, similar in size to that which follows psyracious pustules. The ulceration does not extend to the whole surface of the papulæ; their base and their bodies shrink, and besides the small brownish depression in the point which they had occupied, the skin, at a later period, presents a little central point, of a bluish-white colour, which is occasioned by a true cicatrix.

After the shrinking of the clusters, they leave behind them oval spots or stains as large as a half crown, and even as a crown piece, of a yellowish brown, and occasionally of a livid colour, the surface of which is sprinkled over with small points of a deeper shade of the same tints. These little marks differ from those that succeed psyracious pustules in clusters, not only in the circumstance of their following papulæ, but in being commonly less crowded together, and more wrinkled than those that are the consequence of the pustular eruption in question.

887. The papular syphilitic eruption presents itself with yet a fourth appearance, and this is the last I shall mention; it occurs in the guise of large oval clusters, *pretty regularly circumscribed*, which, as in ordinary lichen *circumscriptus*, continue for some time to spread around their circumference, whilst they are getting well in their centre. The syphilitic may be distinguished from the simple eruption mentioned, by the greater size of the papulæ, and by their violet and coppery colour. In some cases, the centres of these circumscribed syphilitic lichenous eruptions ulcerate, sometimes to such an extent, as to leave broad cicatrices behind them. These are at first of a bluish colour, but at a later period, become of a dull white, and sometimes more than two inches in diameter.

This variety of the papular syphilitic eruption is extremely rebellious; it is of very rare occurrence.

888. *Syphilitic squamous eruptions*.<sup>1</sup>—These are characterized by *coppery patches* of a more or less regular round shape, smooth and shining, little or not at all affected with itchiness, the surface of which is the seat of an epidermic exfoliation.

889. These patches are generally met with on the face, forehead, surface of the scalp, and more rarely on the back of the body. In the majority of cases, the patches of these squamous eruptions are nearly of the same size as those of psoriasis *guttata*, *i. e.*, from six to eight lines in diameter. They generally appear six to eight weeks after the cure of primary syphilis: sometimes, however, they are much later of making their appearance.

They are most frequently *distinct*, slightly prominent, irregularly rounded, and covered with thin squamæ, which adhere pretty firmly. When these squamæ are detached, the skin beneath them is smooth, shining, of a coppery colour, and slightly raised and rounded. Each of the spots or patches is very regularly surrounded by a whitish rim or border, formed by the epidermis dried and detached or torn circularly. This edging of raised epidermis does not differ essentially from

<sup>1</sup> Syphilitic papulæ have been indistinctly described under the name of *pustulæ siccæ*, which the older writers have also made use of to designate tubercles and squamæ. Willan has very well described syphilitic, violet-coloured and ulcerating papulæ, and has distinguished them from lichen lividus. (Art. lichen lividus.) M. Alibert has given the principal characters of syphilitic papulæ, scattered or in groups, under the name of syphilide pustuleuse miliaire. A case is published under the erroneous name of *scabies venerea*.—(Journ. Gen. de Med., t. xli. p. 377.) Several pupils of the school of Cullérier (senior), describe them under the name of *miliary and itchy pustules* (Guérin Alex. *Diss. sur les pustules vénériennes*.—Thèse. 4to. Paris, 1813, p. 17). Carmichael has reported several cases: Case iii. Phymosis, discharge from the glans, pains of the joints, more violent during the night; five months' illness;—the sixth month, papular eruption, cure, relapse, tumours of the tibia.—Case iv. Superficial ulcer on the prepuce; a general papular eruption in clusters, and confluent; flat tubercles on the scrotum; pains in the joints.—Case v. Superficial ulcers; discharge from the glans and the urethra buboes; papulæ on the abdomen and breast.—Case vi. Discharge from the glans, superficial ulcer without induration; papular eruption; excoriation of the pharynx; pains in the joints: six months' illness. Case vii. Phymosis; discharge from the glans and urethra; excoriation of the throat; scattered yellow papulæ. Of one hundred and three cases of venereal eruption, I have only observed fifteen papular.

<sup>2</sup> Massa has particularized the appearance of certain syphilitic eruptions, § 891. Hunter has described the syphilitic squamous eruption, (especially of the hands and of the soles of the feet), and has remarked that the eruption was modified in its appearance, where two contiguous surfaces of the skin were in contact, as on the labia, about the circumference of the anus, &c.—(Op. cit., p. 339.) Willan has described *psoriasis* and syphilitic *lepra*, which he has distinguished, very properly, from *lepra nigricans*. Dr. Carmichael believes this form of venereal eruptions to be a consecutive symptom *peculiar* to the Hunterian chancre; and, as according to Dr. Carmichael, this ulcer is rare, he has been led to advance, that squamous syphilitic affections had been observed by him in a very small number of cases only, during the six or eight years which had preceded the publication of the second edition of his work; it is, notwithstanding, one of the most common forms of syphilitic eruption. In one hundred and three cases I have observed it eighteen times.

that which is observed to follow the desiccation of the small bullæ in some cases of pemphigus after the detachment of their laminated scabs; but the spots in the squamous syphilide surrounded by these cuticular rims, are raised and rounded in their centre, and of a reddish coppery hue, whilst the marks that remain after the detachment of the crusts of pemphigus are level, of a pale rose colour, and neither so smooth nor so shining. These remarks are also applicable to the red stains left by *rupia simplex*, after the complete or partial detachment of its scabs, which presents this peculiarity, that the epidermic edging around them is much broader and more irregular, and that the centres of the spots are often ulcerated and covered with scabs.

After the fall of the original discs or epidermic laminæ, which cover each syphilitic patch, the desquamation from their surface becomes much more trifling, and occasionally even insensible. If treated appropriately, the patches sink, become pale and disappear, without leaving cicatrices, after the lapse of one, two, or three months.

890. Syphilitic squamous eruptions occasionally present themselves in irregular groups, in which case their usual seat is the legs. The clusters blend by their adjacent edges; epidermic discs and laminæ are thrown off from several points of the surface of these broad irregular patches, which appear partly smooth, and partly covered with squamæ, and in other places of a coppery yellow colour. Besides these clusters isolated spots, covered or uncovered with squamæ, are almost always to be detected, existing on other regions at the same time.

891. Besides these two great divisions of the squamous syphilitic eruptions (*squamæ discretæ*; *squamæ confertæ*), they occur with a variety of particular appearances according to the regions of the body affected, which demand attention.

892. On the surface of the *scalp* the squamæ are always furfuraceous, and often of a yellowish, sometimes even of a slightly greenish tint. Here the spots when freed from squamæ, are not observed to be surrounded by the usual cuticular rim. The raised and rounded appearance of their surface is also less evident; yet the finger passed carefully over them distinguishes a slight degree of swelling, much less evident than that presented by the flat tubercular elevations which have been described, and which we shall immediately describe, under the name of *syphilitic lepra*.

893. In the *palms of the hands* and *soles of the feet*, syphilitic *psoriasis*<sup>1</sup> is almost uniformly *distinct*; it makes its appearance by a number of spots, of from three to four lines in diameter, but little or not at all prominent, or raised above the general level, and of a yellowish colour, very similar to that of the thick horny indurations of the cuticle often seen in the palms of the hands. If at this stage of the disease, a portion or the whole of the altered epidermis be removed from one of the spots, a thin layer of a yellowish substance will frequently be found deposited between the surface of the cutis and detached cuticle. Small lamellar scales of epidermis are very regularly thrown off from the palmar aspect of the hand, and sole of the foot, which almost always present a mixture of yellow, of red, of violet, and of copper-coloured spots or blotches, surrounded by an epidermic rim. The spots of syphilitic *psoriasis* are occasionally arranged in the form of a large ring on the palm of the hand; at other times they present the appearance of a kind of arc of a circle, something like *psoriasis gyrata*.

When the spots are evolved between the toes, they are first moist and whitish, then excoriated and red, and at length accompanied with rhagades or fissures.

When palmar or plantar syphilitic *psoriasis* is of considerable extent, and no means are taken to arrest its progress, the eruption is repeated several times in the course of a few months, and the skin cracks extensively in various directions. These rhagades are very much increased by using the hands in any way, especially by the constant motions required in handicrafts of all kinds, by the action of cold, the contact of acid baths, or alkaline leys, &c. When

squamous syphilitic eruptions occur by the edges of the nails, the parts around them are often very severely chapped, and true syphilitic onychia has occasionally been seen following this affection.

894. Those who are the subjects of syphilitic squamous eruptions of the nature of *psoriasis*, almost always exhibit about the axillæ, the inner and anterior parts of the thighs, the scrotum, labia majora, margin of the anus, commissures of the lips, &c., certain spots or patches which have many of the characters of flattened tubercles: this difference of appearance, however, in the squamous spots, seems to depend on difference of local situation. (a)

(a) Mr. Skey (*Lectures on the Venereal Disease*, in *Med. Gaz.*, 1839) has the following remarks on the principal syphilitic eruptions.—“The eruptive disease exhibits itself in one or more of three forms, of which the first and simplest is that which is called *mottling*; but it is important to observe that, although a frequent attendant on it, it is not peculiar to syphilitic disease.

“It consists in a patchy discoloration of the skin, varying in depth of colour from the lightest pink to a distinct red, abrupt in its margin, and slightly rough to the touch. Like a large variety of cutaneous eruptions, it fades on the approach of cold, appearing more distinct on the application of any forms of stimuli that tend to promote the cutaneous circulation. It appears most generally on the chest, front of the arms, and on the groin; it may also appear on the face or forehead. The patches are often very large, giving an altered tint to the surface, of some inches square.

“The two eruptions, however, that especially characterize syphilis, are *psoriasis* and *lepra*.

“Syphilitic *psoriasis* appears in the form of circular spots, about the size of a small finger-nail, generally round, or nearly so. These spots are based on disease, not of the cuticle, but of the skin, which is inflamed and thickened, giving to the spots a slight degree of elevation, perceptible to the touch on passing the finger over them. The base is red, or of a reddish brown, and from which the cuticle peels in dry scales or flakes, from the period of their first appearance; they are therefore characterized throughout by the scaly eruption. The process of desquamation occurs not in large, but often in minute and broken scales of morbid cuticle, and much less considerable than in some other forms of scaly disease; and this constitutes the prominent feature of the affection from the commencement, by which it is distinguished from the desquamation of pustular, vesicular, or papular eruptions, for in these the desquamation attends the latter stage only.

“The syphilitic *psoriasis* often makes its first appearance on the scalp and forehead, on the chin or upper lip, and back of the neck, and more frequently extends to the chest, abdomen, front or inner surfaces of the arms, chiefly about the elbow-joints, to the palms of the hands; also to the front and inner part of the thighs. Eruptions of all kinds are modified by the density of the surface they occupy; therefore we are not surprised to find syphilitic eruption of the palms somewhat peculiar. It forms what has been called a honeycomb eruption; the cuticle separates slowly in circular patches, and is imperfectly reproduced. Mr. Carnichael first remarked also the peculiar appearance of syphilitic eruption, when situated on commissures of skin, or where two cutaneous surfaces are in contact, as at the nates, or between the toes. Here there is no desquamation nor dryness, the eruption being more inflammatory and moist, like a soft and highly-organized wart. I am inclined to think, however, that this appearance is not peculiar to syphilitic disease, as I have seen it in phagedena, as well as in other eruptions, unequivocally not venereal. It is very rare that phagedenic eruption appears on the palms, but I have seen it distinctly marked in more than one instance.

“The third form of eruption is that of *lepra*, which is obviously pathologically identical with the last-described eruption, but appears in larger and deeper patches, surrounded by a narrow inflammatory ring, and based rather on the subcutaneous tissue than on the skin. These eruptions form incrustations of a brown colour, raised considerably above the surface, which separate as the substratum ulcerates. The crusts might be mistaken for the *rupia* of phagedenic disease, but they are slower in forming, and may be determined by the character of the eruption around. The eruption of syphilis—be it *psoriasis*

<sup>1</sup> *Psoriasis syphilitica palmaris et plantaris*, has been observed from the beginning of the epidemic of the middle ages. “Et cum ista aegritudo prolongatur, apparent in aliquibus fissuræ, et squamæ in volis manuum, et plantis pedum, et sunt albæ, duræ, sine humiditate, et aliquando invadunt alias partes corporis.”—(Massa. De morbo gallico, liber cap. v.—Aphrodisiacus, p. 45.) Astruc gives its characters under the name of *pelarelle*.—(De morb. Vener., lib. iv. cap. i.)

895. The coppery colour of the patches of the squamous syphilitic eruption, aids essentially in distinguishing it from simple psoriasis. In the syphilitic affection, too, the cuticle is detached from the skin; but there is not, as in ordinary psoriasis, an abundant production of squamæ.

896. The venereal disease may proclaim itself upon the skin in another form of squamous eruption, which has been described as venereal *lepra* (Willan).<sup>1</sup> This eruption, at its height, is characterized by rounded or oval-shaped patches, depressed in their centre, generally of a livid red colour, but occasionally almost black, from half to three-quarters of an inch in diameter, and covered on the surface with grayish epidermic lamellæ.

This eruption, which may be diffused over almost the whole body, is sometimes confined to a single region, as to the nucha and shoulders, to the hypogastrium and upper parts of the thighs, to the forehead and hairy scalp, &c. The patches severally commence as papular elevations of the livid or blackish colour mentioned, smooth on the surface, and not covered with squamæ. These elevations spread circularly until they are three or four lines in diameter, when their centres become depressed, whilst their edges, sharply defined, rise very distinctly above the level of the skin around them. The cuticle which covers them, now begins to assume a gray and somewhat yellowish tint, most conspicuous on those patches which are lightest in colour; and, by and by, it splits, and is cast off from different points of the surface, but especially from the centres of the patches. This desquamation is several times renewed, but it is never abundant as it is in *lepra vulgaris*, or in psoriasis. The cuticle, of no great thickness, smooth, shining and diaphanous, masks the violet tint of the corion, which it covers very imperfectly; it is, in fact, a simple desquamation of the cuticle that takes place upon these syphilitic spots, not an evolution of true squamæ. When the patches acquire a larger size, the desquamating process continues to go on from their margin, after it has ceased upon their centres, which are then smooth and shining, and of a yellowish coppery colour.

897. The advance of the syphilitic patches in question, towards recovery, is indicated by the sinking of their edges and their changing colour, passing from a livid or blackish red to a coppery yellow. The edges of the patches commonly sink in an irregular manner; they appear to break at intervals, and to change into flattened arcs of

riasis or *lepra*—is always characterized by desquamation of the morbid cuticle throughout its progress. The entire eruption appears dependent on one single cause, and *that* a general, and not merely a local one. If one part advances, the whole advances. We need not expose the entire person of a patient, with the view to ascertain the condition of the eruption on a remote part of the body, as is required in the case of phagedenic disease, in which we find the actions of health and of disease variously intermingled—some spots desquamating in the last stage, while new ulcers or rupial crusts are forming elsewhere; but, as in the exanthemata, the whole surface appears obedient to one common influence. Syphilis, unless in a very advanced form, rarely affects the whole surface; those parts I have already mentioned being most obnoxious to it; whereas phagedena is less discriminate in the surfaces it involves. As a general rule, subject, however, to exceptions, the front surface is the seat of early syphilitic eruption, the back in a greater degree that of phagedena.”

<sup>1</sup> *Syphilitic lepra* is only mentioned in an extremely vague and uncertain manner by the modern writers, before Willan, who has described it under the name of venereal *lepra*, and has well distinguished it from the *lepra vulgaris* and the *lepra nigricans*. Venereal *lepra*, says he, differs from *lepra vulgaris* and *lepra nigricans*, by the absence of a hard scaly edge to the circumference of the patches, which are never covered with thick squamæ. Besides, the venereal patches are soft and supple, not dry and rough, and they sometimes ulcerate, which the patches of ordinary *lepra* never do. Carmichael mentions syphilitic *lepra*, following Willan particularly in his description. M. Alibert has given a case of it under the name of *pustular syphilide*.—These spots, of a dusky red, do not at first rise above the level of the integuments, but they soon begin to do so, especially around the edges, which gradually become more elevated than the centre, and are at the same time covered with small white squamæ. These patches had hard, *ruised*, circular edges; the centre was paler than the circumference; in the centre, slight asperities were observed, which were covered with epidermic squamæ; their coppery colour proclaimed their syphilitic nature. (Precis. Theor. et Prt. des Mal. de la Peau, t. ii. p. 227.) I have myself seen several cases of this kind. The Messrs. Cazenave and Schedel have detailed a case in which the patches were extremely dark in colour.

circles, showing a greater intensity of colour than the areas they embrace. It sometimes happens that the whole of the patches begin to fade at the same time, and nearly in an equal degree, over every part of the individual patches: the raised edges which distinguished them then disappear, and the skin presents mere rounded copper-coloured spots, that scarcely desquamate, similar to primary syphilitic maculæ. For several weeks after every trace of elevation has vanished from the margin, the spots continue in the guise of blotches, of an earthy yellow colour, which retain the form, and very nearly the dimensions, of the patches.

898. The colour of these squamous patches, and the appearance of their surface, may be modified by various topical applications—by baths, washes, &c. Under the influence of the vapour bath, I have seen their colour gradually deepen until it became nearly black, and their surface, freed from squamæ, only become covered again after an interval of several weeks. The dark colour disappeared to a certain extent, but still very imperfectly, under the pressure of the finger. In this state it might be found very difficult to distinguish these syphilitic patches from certain forms of *lepra* (*lepra livida*), the spots of which had also been freed from squamæ. The spots of simple *lepra*, however, it may here be observed, are generally larger and rounder than those of syphilitic origin, which are far more frequently oval than circular in their outline, and much more rarely confluent, and united into broad bands and patches, than those of *lepra*.

899. Another circumstance further contributes very commonly to distinguish these eruptions,—it is this: in the centre of one or more of the large patches of the squamous syphilide (*lepra syphilitica*), a purulent point makes its appearance; or, otherwise, their circumference is in parts traversed by irregular sero-purulent looking bands. Small scabs, the form of which is in accordance with that of the purulent deposit beneath the epidermis, to which they are due, then cover a portion of the surface of the patches, which continue squamous over the rest of their extent. After the detachment of these incrustations, and of the altered epidermis, slight excoriations are perceived, which, in their turn, are succeeded by superficial cicatrices. Nothing of this kind is observed to happen in connection with patches of common *lepra*. Indeed the squamous syphilide itself, unless when thus complicated with accidental pustules, is never followed by excoriations or cicatrices.

900. When the squamous syphilide appears between the buttocks, on the scrotum, about the navel, and over the upper parts of the thighs, where two contiguous surfaces of integuments are in contact, the patches present a very different appearance; their surface is then soft, moist, covered with a whitish unctuous and fetid matter, and the cuticle, instead of desquamating, is continuous, smooth, and of a dull white or grayish colour.

901. Of all the forms under which syphilis shows itself upon the skin, the *tubercular* is the most frequent.<sup>2</sup> Syphilitic tubercles are of a livid or coppery red colour, *smooth*, or covered with *squamæ*, *flat* or *prominent*, *dry* or *moist* on the surface, sometimes supporting *fungous growths*, frequently occupied by *circumscribed ulcerations*, and covered with thick scabs, or degenerating into *extensive sores* of a phagedenic or serpiginous character, hidden under rugous and broad incrustations.

Syphilitic tubercles appear *scattered* or *clustered*, or arranged in circular bands, which circumscribe, more or less completely, spaces of the skin, which is indifferently healthy, or altered in a greater or less degree.

902. We occasionally observe on the face, especially on the cheeks and *alæ nasi*, a number of oval or pyriform tubercles, very prominent, of various sizes, from that of a pea to that of a small olive, either *clustered* together, or irregularly disseminated over a surface of variable extent. Smooth and shining on their surface, they do not show

<sup>2</sup> Massa certainly points out tubercles as a species of pustulæ.—“*Demonstrativa (signa morbi gallici) sunt pustulæ cum quadam duritie, aut eminentia, et malo colore in capite toto, vel fronte circa originem capillorum, vel in aliis corporis partibus, et maxime in angulis oris, et hoc sæpe in infantibus accidit, et in adultis quandoque, quæ sunt eminentes humidæ.*” (Aphrodisiacus, p. 46.) The word *pustule* has likewise been employed as a generic term, to indicate several different alterations of the skin, such as squamæ, pustulæ, tubercula, &c., by almost all the writers who described the epidemic syphilis of the fifteenth century, as well as by those who have followed them. Leoncini, however, has made use of the word *tuberculum*. (Aphrodisiacus, p. 38.)

any thing like desquamation; neither do they occasion pain; and they may continue for months, and even for years, without undergoing any change. They seldom or almost never ulcerate; but, in the course of time, the cuticle upon their surface ends by exfoliating. This is the rarest of all the tubercular syphilitic eruptions. It is not uncommon, however, amid the more ordinary forms of the tubercular syphilitic eruption, to distinguish a certain number of tubercles which continue stationary, whilst those in their vicinity are desquamating, or falling into a state of ulceration, and becoming covered with scabs.

903. Instead of being even, smooth, and shining, like the tubercles that have now been described, syphilitic tubercles are occasionally affected with a true desquamation of the cuticle covering their surfaces (*squamous tubercles*).<sup>1</sup> A single tubercle of this description is occasionally observed to be developed on the upper lip, along with other symptoms of syphilitic infection. Or, a number of smaller tubercles, but little larger than papulæ, are often seen clustered upon one of the alæ of the nose, a situation in which, if the disease be left to itself, rhagades and fissures are formed at a later period. These squamous tubercles are often disposed like a wreath, or in the form of a ring, upon the forehead and neck. A series of round tubercles, as large as peas, and of a coppery colour, are frequently seen, accurately arranged side by side, and forming complete circles of varying diameter. From the summits of these, and occasionally even from almost their entire surface, a small, dry, hard, and grayish-coloured disc is detached. This desquamation does not take place from the whole of the tubercles at the same time, and every trace of it may disappear after the use of the tepid and vapour baths. The tubercles then look smooth, like those of a stationary nature, but they are never so prominent as these last. The skin of the interior of the rings is generally healthy. When the constitutional disease is yielding to appropriate treatment, the tubercles shrink; they approach more and more nearly to the level of the skin; the exfoliation becomes less and less conspicuous, and before long, nothing more remains than a reddish or yellowish stain, which, in its turn, vanishes likewise.

904. A particular variety of tubercle, the flattened form of which distinguishes it from all the others, is frequently spoken of under the name of the *flat tubercle*. This variety is most usually developed on the genito-anal region, and is always moist and often excoriated. Upon the scrotum, on the penis, on the pubes, on the anterior and inner parts of the thighs, the round or oval-shaped tubercles of this description occasionally attain a size little less than that of a shilling. They are sometimes several lines in thickness, and stand out in very prominent relief upon the integument of the verge of the anus, of the labia majora, &c. Their surface swells, becomes wrinkled, often presents linear excoriations, and secretes a dirty white, and faint and sickly smelling matter. These tubercles are sometimes clustered around the anus, so as to form a large ring, flattened, but still pretty prominent, whose sanious surface is traversed by numerous chaps and crevices, the deepest of which sometimes penetrate even into the cavity of the rectum. It more frequently happens, however, that these tubercles are evolved at some distance from the edge of the anus, and this is one among several other circumstances, which serves to distinguish them from hemorrhoids.

When these tubercles are neglected or improperly treated, when the fetid discharge they pour out is left bathing their surface, the wrinkles they present are not only transformed into deep chaps, but into ragged ulcers, the appearance of which is grayish, eroded, and granular, like that of several other syphilitic sores. The edges of the tubercles swell, and become more prominent, whilst their centres appear depressed. Under the influence of appropriate treatment, on the contrary, these tubercles shrink, the fluid they secrete diminishes in fœtor and in quantity, and ceasing at length to discharge, a slight exfoliation of the epidermis takes place from their surface, which goes on during a certain time.

The *scrotum* is occasionally covered with these tubercles. They are in general isolated, of an exact round figure, extremely prominent,

and furrowed or wrinkled on the surface by the natural inequalities of the part.

On the glans penis, the inner surface of the prepuce, of the labia majora, and minora, on the commissures of the lips, in the inside of the mouth, &c., these tubercles, instead of the deep red colour which they present on the inner and upper aspects of the thighs, on the body of the penis, and other regions, have a bluish-gray tint, owing to a thickening of the epithelium covering these parts. Between the toes too, this flat description of tubercle appears under the form of small whitish or grayish, and prominent patches, often excoriated in the centre, and accompanied with rhagades between the digits. These patches differ from the corns that are sometimes developed between the toes,<sup>2</sup> by being attended with a greater degree of puffing of the corion at their base.

About the commissures of the lips, this same description of tubercle does not commonly exceed the size of a large lentil, divided across its middle by a furrow which frequently changes into a chap. The nipples of woman who have become infected by suckling a syphilitic infant, are sometimes covered with flat-shaped tubercles, which the continued suction of the child causes to chap, to become excoriated, and to inflame in a very painful manner. These tubercles in some cases even ulcerate to a greater extent than they are ever observed to do in any other part of the body. Upon the navel, and within the meatus auditorius externus, these tubercles have nearly the same smooth and reddish appearance which they present on the inner and upper parts of the thighs.

905. The flattened tubercles of the scrotum and vulva are occasionally mixed with other forms of tubercles, which are covered with true *fungous growths* (*vegetations*).<sup>3</sup> These excrescences never attain such magnitude as those which are designated by the titles of *cauliflowers* and *cock's combs* (*choux-fleurs* et *cretes de coq*.)

906. On the hairy scalp, the flattened syphilitic tubercle appears under the form of spots of a reddish-yellow colour, nearly of the size of a silver three-pence, and covered with minute yellowish, and occasionally greenish squamæ. On applying the finger to the surface of these patches, it will be discovered that they are produced like those of syphilitic lepra, by a positive increase in the thickness of the skin; but their centres are not always depressed. These flat-shaped tubercles often form a band on the upper part of the forehead, and towards the roots of the hair, which spreads regularly over the temples; they are apt to ulcerate and become covered with thick scabs.

907. Other tubercles are of a nature essentially disposed to ulcerate, and form a very remarkable group, to which several varieties belong (§§ 908, 909, 910, 911, and 912.)

908. Upon the forehead and those parts of the cheeks which, in men, are covered with the beard, are sometimes seen a number of olive-shaped and very indolent tubercles, of a coppery hue, the surface of which is traversed by a small sinuous and irregular furrow that appears perforated and worm-eaten in parts. Upon these sinuous furrows and within these small holes, little greenish scabs are formed of a very adhering nature. The particular character of these small ulcers, is their linear disposition and the little tendency they show to unite, even when they are contiguous. After the shrinking and healing of these tubercles, the surfaces which they have covered appear stained, and covered with cicatrices, like those of serpiginous syphilis in miniature.

909. We sometimes see developed on the skin of the elbow, upon that which covers the head of the fibula, on the ridge of the nose, &c., circular or semi-circular clusters of tubercles, three or four lines in diameter, slightly elevated in the centre, and of a very deep livid or violet hue. Inflammatory action is before long set up in the tubercles, in the middle of these groups, or in those at the greatest distance from the edge of the clusters, as a consequence of which a purulent point is formed on their summits, that afterwards dries up into a black or brown-coloured scab. These tubercles shrink and leave violet-coloured blotches covered with minute cicatrices, surrounded by a raised and

<sup>1</sup> These are apparently the tubercles which Fallopius has indicated in the following passage:—At major pars (pustularum) nihil sub se continent, et præcipue quæ nascuntur in capite, rotundæ sunt, crustamque habent tenuem; quoties ego video pustulas in capite aut rhagades in manibus, indicium certum profero Gallici; cætera signa fallunt nos, hæc certissima sunt. (Aphrodisiacus, p. 824.)

<sup>2</sup> "Si vero in dictis ulceribus superficialibus, et præsertim pedum, essent aliquæ materiæ induratae ad modum clavorum," etc.—(Torrella. De ulceribus in pudendagra, tractatus. Aphrodisiacus, p. 540.)

<sup>3</sup> These fungoid tubercles are mentioned by De Vigo: "Pustulæ crustosæ et interdum cum carnositate elevata ad modum verrucæ super frontem, caput, collum, et faciem, brachia, et tibias et fere per totum corpus diffusæ."—(Aphrodisiacus, p. 449.—Devergie, op. cit. pl. 17.)

very well-defined tuberculous circle or arch, which is extended and increased by the addition of new tubercles, in the manner of eccentric eruptions generally. If the disease is allowed to run its own course, the middle tubercles of these clusters ulcerate more and more, and after a certain lapse of time, when the healing of the ulcers has taken place, the skin presents livid cicatrices of a circular or semi-circular shape, traversed by whitish bands, surrounded by a circle of tubercles, or edged with a tubercular arch, on which are often seen small angular ulcers, sometimes covered with scabs, the shrinking and healing of which do not take place till a much later period.

910. Broad syphilitic ulcers<sup>1</sup> which have entirely destroyed the skin and subjacent parts, are sometimes seen at the angles of the mouth, about the *alæ nasi*, or on the cheeks, and more rarely on other parts of the body. Similar ulcers sometimes begin, as I have ascertained in several cases, by broad tubercles which ulcerate at the top after having remained stationary for a considerable time. Several of these tubercles, three, four, or a still greater number, often appear almost at the same time on one of the places which I have just mentioned; their bases soon join, they suppurate at the top, and the various small ulcers thus produced, by uniting, give place to a sore whose edges, hard, livid, raised, and tubercular in some parts, jagged and angular in others, are deeply cut as if with pinking irons. The surface of this ulcer, of a yellowish-gray colour, and bathed in a sanious pus of a bad description, is uneven and beset with reddish points, but not very painful. If an ulcer of this description is left exposed to the air, it becomes covered with a yellowish brown-coloured incrustation, which is deeply set within the rim of the sore. When this scab is pressed, a sanious fluid often exudes from some point in the circumference of the sore, where the ulcerative inflammation appears most active. These sores generally show a disposition to destroy parts both superficially and more deeply; they are succeeded by irregular cicatrices, and often by considerable deformity.

Tubercles of the description that engage us are often evolved on the *alæ* of the nose, and end in phagedenic ulcers, which occasionally destroy no more than the skin; these sores are followed by deeply depressed cicatrices. When both of the *alæ nasi* are implicated at once, or when an erysipelatous inflammation of bad character takes possession of these parts, they are apt to be completely destroyed by the ulcerative processes, the energy and rapidity of which can then only be compared to what is observed in certain cases of lupus. Lastly, cases occur in which the syphilitic inflammation is propagated, even into the nasal fossæ, causing ulceration of the pituitary membrane, the destruction of the cartilages, necrosis of the *ossa nasi*, turbinated bones, &c., and occasioning a characteristic deformity of the most hideous description.

911. The title of the *serpiginous syphilide*<sup>2</sup> has been given to the secondary venereal ulcers which appear most commonly on the back, and pursue their course superficially in lines or in spirals in different directions. Ulcers of this description are also observed on the extremities and in the neighbourhood of the great joints. These ulcerations usually commence with a tubercle, of a ruddy violet or livid colour, oval and deep, which, after remaining stationary for a considerable time, inflames and suppurates, and is replaced by a deep ulcer, the dimensions of which do not exceed that of the tubercle. But this ulcer shortly spreads either at one end or the other: it forms a deep furrow, often the width of the little finger, which extends further and further, sometimes forming a complete circle, which circumscribes a larger or smaller surface of healthy skin; at other times taking the form of the letter C. or E., as in psoriasis gyrata, or irregularly circumscribing almost all the skin of the back, or of the interior parietes of the abdomen. It is worthy of notice, that whilst these serpiginous ulcers are making their way on the skin, by spreading in this manner from one end, they cicatrize at the other, even when no treatment has been had recourse to to stop their progress. These ulcers that appear in grooves or furrows, independently of this particular form, have other

special characters; they are attended with little or no pain; inflammation extends very little way beyond their edges; and they are sharply and deeply cut.

The discharge in which these large ulcerated grooves are bathed, dries in yellowish or light brown scabs, upon exposure to the air. These scabs are interrupted here and there along the furrows, by ulcerated surfaces, bathed in pus. When these serpiginous ulcers are seen on the back, on the belly, or the legs, arranged in large rings, the diseased skin almost always presents a mass of ulcerated circles covered with brown scabs, furrows whose edges are bathed in pus, and deep cicatrices in narrow stripes of a bluish or whitish hue, according as they are of more ancient or more recent date. This variety of syphilis is very rebellious.

912. Serpiginous ulcers are sometimes seen in arcs or circles, which, while their internal edge cicatrizes, spread in an eccentric manner from their external edge, so as always to preserve the form of a furrow in attacking the surrounding parts.

Lastly, consecutive ulcers are sometimes developed on the trunk, and more frequently on the face, which, in their progress, partake, at the same time, of the character of the eating ulcer of the angles of the mouth and of that of the serpiginous ulcer; this description of ulcer has been designated, under the name of the phagedenic consecutive ulcer.<sup>3</sup>

It is seldom observed at its commencement. When it is developed on the face, a swelling of a tubercular nature sometimes appears on one of the cheeks, followed by erysipelatous tumefaction; the skin becomes of a ruddy violet colour and shining; the little hard and circumscribed point which appeared primarily, suppurates and ulcerates; small analogous ulcerations often form in the same manner not far from each other; some become covered with a yellowish-brown scab, which adheres pretty firmly, and continues long attached to them; upon other ulcers in the neighbourhood of the angles of the mouth, the secretion of pus is too active and abundant to allow any scabs to form, or the natural motion of the parts tends constantly to detach them. These ulcers increase in the same manner as the phagedenic ulcers of the angles of the mouth. Others, arising near the zygomatic arch, extend towards the lower edge of the jaw and follow its contour; a thick matter of a yellowish-white colour, formed by mortified cellular tissue, sticks to their bottoms; their hard edges differ from those of ordinary serpiginous ulcers, in the skin that surrounds them almost always undergoing change, and becoming covered with squamæ and scabs, or being traversed by bands, and marked with cicatrices. When the face has been thus scarred by several phagedenic ulcers, it frequently becomes the seat of an erysipelatous swelling, sometimes preceded by pretty severe febrile symptoms, after which the disease is improved or aggravated according to the state of the constitution. When the cure of this frightful malady has been effected by methodical treatment, the face does not present, as after serpiginous syphilis, regular cicatrices in the form of bands; it is seamed rather, traversed with cords, as after burns or the lupus exedens, which destroys the skin superficially.

913. Small tumours are often developed in the subcutaneous cellular tissue, particularly in that of the limbs, about the size of a pea, movable, not painful, and not causing the skin to change colour, (*subcutaneous syphilitic tubercles*). They subsequently increase in size, inflame, contract adhesions with the skin which covers them, and become red. These tubercles then soften and perforate the skin; the result of this is the formation of small ulcers, whose edges are loosened, and whose openings are narrower than their bottoms, which are of a yellowish or dirty white.<sup>4</sup> This appearance is the effect of a sort of slough, formed of mortified cellular tissue, which sooner or later is detached, and leaves bare a red unequal surface, that continues

<sup>3</sup> This is the *ulcus manducativum* of Torrella; several ancient writers, and of late Carmichael, have designated it under the name of the phagedenic ulcer.

<sup>4</sup> Ego sæpe studiosâ aperui pustulas morbi gallici, et quamvis extra apparebant rubicundæ, vel alterius coloris, apertis tamen, in basi et in profundo erat quædam materia alba, densa, viscosa, . . . hanc eandem materiam videmus quotidie in apostematibus duris, quæ vulgares gummata appellant. (Nicolaus Massa. *De morbo gallico*, cap. iv. Aphrodisiacus, p. 43.)—Filius-familias cladem gallicam patiebatur. . . . sed de repente centum pene locis tubercula apparuerunt atheromatibus similli, et parvarum lupinarum instar. Ballonii. *Paradigmata* 20. Oper. Omn. Ed. J. Stewart, 4to., Geneva, 1762, t. ii. p. 527.)—Cullérier. *Art. Gomme syphilitique*. (Dict. de méd. et de chir. pratiques.)—Bacot. (Lond. Med. Gazette, vol. iii., p. 149, 1829.)

<sup>1</sup> Rubræ aut flavæ pustulæ, primùm quidem circâ frontem ac tempora, poneque aures, dein in capite atque etiam in reliquo corpore, erumpunt et extuberant rotundo schemate, siccæ, sine pure, quæ dein sicca crusta obducuntur: atque si negligantur, serpunt in ambitum, excavantque cutem, dum ex pustula verum ulcus fiat.—(Fernelii *Universa medicina*. Coloniae Allobrogum, in-fol., 1670, p. 585.)

<sup>2</sup> Massa, Torrella, &c., have spoken of this species of ulcer under the names of *ulcus ambulativum*, and *ulcus esthiomenum*.

to be bathed in pus of a bad description. These ulcers may assume a better appearance, but the redness of the granulations is generally hidden beneath a layer of whitish matter, as if their surface had been touched with a weak solution of nitrate of silver. These ulcers left to themselves extend slowly, and almost always by the destruction of their loosened, livid, or violet-coloured edges. When an ulcer of this kind remains exposed to the open air, it becomes covered with a brownish-yellow scab, deeply set within its edges; it may become sanious and bleeding from walking, if seated on the lower limbs. When these tubercles are thus ulcerated, and when the disease has lasted for a month or longer, other subcutaneous tubercles in different stages, and a number of cicatrices are always met with scattered over the limbs.

914. After the development of one subcutaneous tubercle, more frequently after it has become softened, and ulceration has taken place, several others appear in its neighbourhood, which in their turn soften and burst the skin. When similar groups of subcutaneous tubercles form on the legs, the skin becomes of a very deep violet-red colour, in the spaces between them, and the perforations which they make are often so near to each other, as to give the skin the appearance of a sieve.<sup>1</sup> Two or three of these ulcers sometimes terminate by uniting, and giving place to larger and more irregular ulcerations. Between the ulcers, the subcutaneous cellular tissue often swells unequally, and forms hard and prominent ridges, of a still deeper tint than that of the surrounding skin, which stretch away from the clusters. When the cure is completed, the skin of the legs remains marked with large yellowish or violet-coloured blotches, intersected with circular-shaped depressed cicatrices, and only recovers its natural colour and former pliancy very slowly, and after a long interval has elapsed.

915. Besides the sores which follow pustules, tubercles, &c., there are other cutaneous ulcers which succeed gummy tumours (*tumeurs gommeuses*), thickenings of the periosteum, caries of the bones, inflammations of the lymphatic glands, &c. Thus the tumours with soft centres and hard edges, which are evolved upon the superficial bones, more especially on the os frontis, having been preceded and accompanied by nocturnal pains, are followed by perforations of the skin, the edges of which are extensively detached, whilst the bottoms of the sores look grayish or white, and are often occupied by the bone naked and in a state of caries. These ulcers are never healed but very slowly and with extreme difficulty.

916. Chronic syphilitic inflammation of the lymphatic glands of the neck and axilla, is not only followed by considerable enlargement of these glands, but in many cases by *fistulous ulcers*, the edges of which are hard and livid, and the bottoms grayish. Sores of this description are also very rebellious, although less serious in their nature than those last mentioned.

The fistulous ulcers that follow venereal enlargement of the testis rarely become extensive.

917. I must here also give an account of the appearances presented by ulcers of venereal origin, developed on the external organs of generation. After the consolidation of chancres, we frequently see the cicatrices giving way, and the ulcers now formed more frequently assuming the aspect of secondary than of primary syphilitic sores. Secondary sores may also be, and indeed frequently are evolved on the penis and pudenda, in consequence of venereal eruption upon these parts with an ulcerating tendency. These sores are generally circumscribed with tubercular bases; sometimes, however, they have the characters of *serpiginous* ulcers, which traverse the skin of the penis and scrotum in circles, and zigzag lines; and in a few rare cases they show the *phagedenic* tendency, when they destroy, both superficially and in depth, a greater or less extent of the organs of generation.

918. In those who are labouring under constitutional syphilis, *leech bites* are occasionally known to be followed by sores, which acquire all the characters of secondary syphilitic ulcers, and become covered with scabs, very similar to those of the ulcerated phlyzacious syphilide. The bites of leeches, applied in the vicinity of the genital

organs, in the treatment of primary venereal sores and buboes, are also occasionally observed to degenerate into ulcers of a venereal aspect; and it is a very remarkable fact that, in the same individuals, or in different circumstances, the bites of leeches rarely change into venereal sores, when the animals have been applied to parts remote from the genital organs: this remark has already been made by M. Desmellés.

919. When secondary syphilitic ulcers are long kept in an irritable state, by means of stimulating applications, or indulgence in wine, rich food, &c., in individuals disposed to cancerous affections, the diseased parts harden, become covered with yellowish excrescences, and are attacked with acute lancinating pains (*degenerated venereal ulcers*).

920. Secondary venereal ulcers have also been frequently observed on different mucous membranes. Those of the velum palati, of the uvula, of the posterior surface of the pharynx, of the tonsils, &c., are by much the most frequent of any; but they are also encountered on the gums, on the inner aspects of the cheeks, in the vagina, &c. Like secondary venereal ulcers in general, those of the throat are not painful, and patients are frequently only admonished of their existence by the difficulty they experience in speaking or in the act of swallowing. The bottom of these ulcers at their outset, is of a grayish-white, like that of primary venereal sores. The colour is due to the presence of a layer of solid matter, proceeding from a kind of mortification of the tissues. This kind of eschar is very superficial at first, and resembles a strongly adhering false membrane; by and by it is detached, and leaves exposed a deep and well-defined ulcer produced by this loss of substance. This chancre-like inflammation frequently occasions the destruction of the uvula and velum palati.

In other cases these pharyngeal ulcers are preceded by flat tubercles; their progress is then less rapid. After the cure of venereal ulcers of the pharynx, cicatrices of a bluish tint, but which become white in the course of time, are observed on the surfaces they occupied. In some cases, moreover, considerable deformity of the pillars of the velum palati are observed to ensue. These parts are very apt to contract adhesions with the posterior parietes of the pharynx.

On the inner aspect of the cheeks, along the edges of the gums, and on the palatine arch, venereal ulcers frequently present the serpiginous character; their edges, which are irregularly jagged, and their surface, almost always present a bluish-white cast of colour, very distinct from the usual colour of venereal ulcers of the throat. The serpiginous venereal ulcer of the inner surface of the cheeks, like that of the skin, frequently heals up at one end whilst it is advancing by the other. When completely whole, the cicatrice is often torn by the motions of the parts occasioned in speaking and mastication.

Ulcers and their cicatrices are occasionally seen in the vagina, and even in the œsophagus and larynx. Ulcers of the nasal fossæ coincide for the most part with affections of the bones of these parts or of the arch of the palate.<sup>2</sup>

<sup>2</sup> Some cases go to prove that syphilitic ulcers may be evolved in other parts of the internal mucous membranes. Joubert tells us that he had observed them in the trachea; and ulcers of the large intestines have been discovered in the bodies of those who either died whilst labouring under constitutional syphilis, or who had, at some former period of their lives, suffered from this cause, which bore a great resemblance to syphilitic serpiginous ulcers of the skin. Although the following case may not be held conclusive, I am tempted to state it briefly: A man about thirty years of age, and of fair constitution, was recommended to my care at the Hôpital de la Charité, on account of a disease of the great intestine, which was accompanied with the excretion of a certain quantity of pus, which was at one time passed along with the feces, and at another came away pure or mixed with blood. The finger, passed up the rectum, detected neither stricture nor swelling. M. Costellat, by means of his improved bougie (*porte meche*), showed us that the ulcer was situated at the upper part of the rectum. The patient's appetite was good, and there was no visible derangement in any other part of the intestinal canal, nor in any other apparatus of the system. The patient had not observed that his evacuations were purulent for more than seven or eight months; he made no complaint of pain in the abdomen, and very strong pressure was required over the recognized seat of the disease to cause any even there. The absence of acute pain, and of all the other general symptoms proper to cancerous affections, did not allow me to entertain the idea that the ulcer was of this nature; but it was in vain that I persevered during the course of two months in the use of every means I thought likely to bring about the cicatrization of the sore—no progress seemed to have been made in the cure. The patient having at a former period laboured under a venereal affection, although there was now no evident symptom of the disease, I determined on trying the effect of the pills of mercurial ointment, (three of Sedillot's pills daily,) and in the course of a fortnight, under the influence of this remedy, the purulent discharge began to diminish, and at the end of two months ceased entirely, when the cure appeared to be complete.

<sup>1</sup> Massa speaks of ulcers which unite the principal characters of consecutive ulcers with those of subcutaneous tubercles: "Ulcera perforata multis perforationibus."—(Aphrodisiacus, p. 45.)

921. Although the appearance of secondary syphilitic ulcers is very nearly the same as that of primary sores, many, since the publication of Mr. Hunter's experiments, have imagined that the nature of these two species of ulcer was not identical; that primary sores were contagious, for example, and that secondary ones were not. Still, the greater number of observers admit, with Hunter, that both of these varieties of ulcer, especially the latter, are advantageously treated by the exhibition of mercury. This circumstance has been held by other practitioners as a sufficient proof of identity in the nature of these ulcers, and they have admitted all indiscriminately as contagious. (a)

922. On the mucous membrane of the genital organs, around the anus, more rarely on the common integument of the body, and on the mucous membranes of the nipples, of the mouth, pharynx, &c., we frequently observe excrescences evolved in the form of warts, cocks'-combs, cauliflowers, &c. These are due to morbid thickening of the corion, vascular rete and epidermic lamellæ, and to increase of size in the papillæ of the skin.

These excrescences are of two descriptions: syphilitic and non-syphilitic. To distinguish them, attention must be paid to the situation in which they are evolved, to the previous state of the surface upon which they have appeared, to their progress, and to the coincidence or otherwise of syphilitic symptoms generally, rather than to the physical characters of the growths themselves, which generally bear the greatest resemblance to each other, whether they be specific or not. Hunter<sup>1</sup> and several other writers have denied the existence of any excrescence *truly syphilitic* in its nature. They regard the whole of these growths as the consequence of simple inflammation, and rest this opinion mainly or altogether on the fact of the little influence possessed by mercury in their treatment. But if the inflammation of chancre has the power of causing what may be called primary excrescences, numerous cases leave no doubt of the fact, that certain excrescences are owing to the *syphilitic cachexia*, and that they sprout without evident inflammation.

(a) "The general proposition, that secondary syphilis in all its stages is incommunicable, is liable to some exceptions. A mother labouring under syphilis may communicate it to her child *in utero*, and the child may be infected after birth by a nurse who has at the time syphilitic ulceration of the nipples, or by its mother under the same circumstances, if the disease of the nipple have been derived from a strange child; but we are told, curiously enough, that no instance is known of a child, diseased in the manner just specified, infecting its own mother, although it will readily transmit the syphilitic disorder to a strange nurse. A woman thus affected, and in whom, together with ulceration of the throat and cutaneous eruptions, there are moist excrescences about the pudenda, may transmit the disease to the husband. Dr. Colles believes that the secondary form of syphilis may be farther imparted to other members of the family, by contact, use of the same utensils, &c. He asserts that its contagious property, but not its virulence, increases in proportion as it extends farther from its source."—*Bell & Stokes's Lectures, &c.*, pp. 565-6, vol. ii., 3d ed.

As regards the order of causation in syphilida generally, there is no little difference of opinion. M. Cazenave asserts, that they may appear simultaneously with the primary disease, chancre, gonorrhœa, &c., and hence be themselves primitive, as well as, a more common case, occur after a longer period from the first infection, being then secondary or consecutive syphilida; or, finally, be congenital, constituting hereditary syphilida. This author, like Carmichael, contends that syphilitic eruptions may ensue on simple gonorrhœa, and even, as it would seem from some estimates, more frequently after this disease than chancre. The period of incubation, or that between the primary infection and the appearance of the syphilida, has been stated in the text (§ 856 and note). M. Cazenave makes the average about five years; and their early development most probable after chancre complicated with bubo. The papular and exanthematous syphilida appear in the shortest, and the tuberculous in the longest period after the primary disease.

Excrescences of the description under review have been met with in many parts—about the verge of the anus, on the navel, on the wrists, near the angles of the mouth, around the neck, &c.

About the *verge of the anus*,<sup>2</sup> they have always a broad base, and generally extend in the form of broken arcs of circles or imperfect rings; they are flattened, nearly of the same colour as the skin, often moist on the surface, and the neighbouring integument is occasionally red and slightly excoriated. When one of these warty bands is put upon the stretch by drawing the skin opposite ways, especially in the direction of its breadth, the surface is made to exhibit a great number of clefts, some of which, deeper than the rest, show themselves as true rhagades. Those excrescences, the surface of which looks flattened, are occasionally formed by a succession of foliaceous prolongations applied one over the other. When they are removed with a knife, they are found to be formed by an hypertrophy of the corion, the development of which has not been equal at every point. Under the magnifying glass, this inequality of development is very apparent; the vessels which shoot into the different points of excrescence, are, however, generally obvious even to the naked eye. The cuticle which covers them is frequently softened.

The excrescences with broad bases are very distinct from those fungous tubercles upon which excrescences are only evolved after they have fallen into a state of ulceration.

In the *perineum*, excrescences occur more rarely than they do about the margin of the anus. They are oftenest seen extending along each side of the raphe, and have all the characters of those of the fundamen-

I have met with syphilitic excrescences surrounding the *wrist*,<sup>3</sup> in the shape of a broad band, and forming a kind of warty nap or pile, by the assemblage of an infinity of minute papillary prolongations, several lines in length, redder than the surrounding skin, and in several places covered with a cuticle of considerable thickness. The excrescences that are occasionally observed about the *alæ* of the nose, on the eyelids, or in the meatus auditorius externus, approach in their general appearance to those of the wrist and perineum.

Cutaneous excrescences may show themselves, especially on the neck, under another guise, that namely of small flattened tumours the size of a lentil, of a yellowish or brownish colour, soft to the touch, not cleft on the surface, and in which the morbid growth of the corion appears to have taken place evenly and in circumscribed points.

923. Excrescences of the *mucous membranes of the genital organs*<sup>4</sup> appear most frequently among men, in the depression which separates the corona glandis from the prepuce, sometimes on the prepuce itself, more rarely on the glans itself, or about the orifice of the urethra.

<sup>2</sup> The excrescences, with broad bases which are evolved in the neighbourhood of the rectum, were known to, and have been more or less accurately described by, the ancient authors, under the name of *thymi* and *condylomata*. (Celsus, *de re medicâ*, lib. v., sec. 18, 8. Lib. vii., sec. 30.—C. Plinii. *Sec. Historiæ mundi*, lib. xxx. c. 8. fol. Lugduni, 1587.) Galeni Opera, fol. Bâsil, 1562. CI. iii. p. 170, et chap. v. p. 411. Cælius Aurelianus, *de morbis acutis et chronicis*, J. Conrado, edente, &c. Amstelodami, 4to. 1549, p. 393.—Ætius, *Tetrabiblos*, editio Cornarii: Bâsil, 4to. 1749, de affectionibus sedis, p. 739.—Paul Æginetæ. *Opus de re medica*, lib. vi. cap. 80, Parisiis, 1532. Ætius has given a good description of the other species of excrescences which appear round the anus, under the name of *thymi* and *sycois*.

"*Thymi* enim in corpore tuberculosæ sunt eminentiæ, asperæ, subrubræ, oblongæ, præter naturam auctæ, sanguinem effundentes dum auferuntur amplius quàm pro apparente magnitudine. Abundat autem hæc affectio circa sedem et pudenda ac media femora. Quandoque etiam in facie constitit. Et quidam sane parvi sunt et vocantur thymi: aliqui vero magnitudine excedunt, et appellantur ficus. Mansueti igitur thymi, carunculæ sunt parvæ quidem, verum inæquales, obscuris eminentiis exasperatæ, albicantis coloris, aut subrubræ et doloris expertis... Medicamenta quæ consumunt ac resiccant thymos, sunt ea quæ communiter curant etiam reliquas verrucas." (Op. cit. p. 741.) These excrescences appear even to have been known to the Roman poets: "Sed podici lævi cœduntur tumidæ medico ridente marescunt" (Juvenalis. *Satyr* iii.) Celsus seems to regard them as the consequences of inflammation.

<sup>3</sup> An old man, who had had a dozen different attacks of venereal disease, came under my charge at La Charité, as affected with rheumatism. On the palmar aspect of the wrist, he had a large reddish spot, in shape something like a horse-shoe, the surface of which was beset with papillary warts covered with thick cuticle, which could be detached by the use of warm fomentations. They then appeared under the guise of a kind of *turf* or *nap*, very similar to those syphilitic excrescences which occur at the root of the glans. Were these excrescences syphilitic or not? They were certainly in a situation where such growths are rarely seen, and had all appeared in the course of the last five or six years.

<sup>4</sup> Excrescences of the penis appear to have been mentioned by Celsus: "Occalescit etiam in cole interdum aliquid, idque omni penè sensu caret quod ipsum quoque excidi debet." Ætius describes them more clearly: "De thymis in sede diximus,

<sup>1</sup> Hunter (J.) on the Venereal Disease, 4to. London, 1786. Part iv., chap. 5, sect. 4.—Cooper (S.) Dictionary of Practical Surgery, 6th edition, 8vo. London, 1830, Art. Wart.

Among women they occur most frequently on the inner surface of the labia majora, or at the junction on the labia minora. Different titles, such as *cock's-comb*, *cauliflower*, and *raspberry* excrescence, have been given according to the general forms and appearances of these growths, which often occur severally, but frequently also blended together in particular cases.

By *cauliflower* venereal excrescences are understood small reddish or whitish tumours, single or manifold, which arise from the membrane upon which they are developed, by means of a kind of peduncle or foot-stalk, and expand into a voluminous granular head, occasionally bleeding or covered with a puriform secretion. These excrescences, by their numbers or their size, impede in a greater or less degree the functions of the parts upon which they sprout. Thus, when they are evolved about the extremity of the prepuce in individuals labouring under phymosis, or when they nearly close up the meatus urinarius, they render the excretion of urine difficult. They have been seen evolved beneath the prepuce as large as a walnut, projecting in very strong relief externally, and accompanied with a fetid discharge. In some cases, too, in which the prepuce has chanced to be perforated by a syphilitic ulcer, venereal excrescences have been observed evolved near the corona glandis, which penetrating and passing through this opening, expanded greatly externally. In females, an extensive crop of these excrescences has been seen, obstructing the orifice of the vagina, and proving an obstacle to sexual intercourse and parturition, until removed by an operation.

924. On the surface of the tongue and in the throat, excrescences have frequently been known to exist, the nature of which was never ascertained. Excrescences of the cauliflower kind, have been known to occur in the pharynx,<sup>1</sup> and to attain such dimensions, that after having altered the voice, and impeded respiration more and more, they finally caused death by suffocation.

Cases in which excrescences of a venereal aspect were evolved on the inner membrane of the heart,<sup>2</sup> and great vessels, have been recorded. If, in some instances, there be a show of probability in considering such excrescences as syphilitic, there is not one on record in which they have been proved irrefragably to have been so; and on the other hand, it is undoubted that they have been met with in individuals who had never in their lives suffered from syphilis.

925. *Syphilitic alopecia or baldness, (Pelarola, Brassavolus),*<sup>3</sup> which sunt autem et hic thymi aut in sola glande, aut in cole, aut in præputio. Antea vero dictum est quod mansueti facile curantur, maligni difficiliter et per affectu partis ablationem sanantur."—(Opus cit. de thymis in pudendis, p. 748.) The historians of the syphilitic epidemic of the middle ages seem to have paid little attention to these excrescences of the genital organs and verge of the anus. Yet Fallopius describes them with care, and speaks of their proper treatment. He observes that they are consequent on ulcers: "Ultimo sanatur caries in pudendo, et solet semper loco cicatrices subescere quædam verruca, veluti caruncula," etc.—He distinguishes them into syphilitic and non-syphilitic.—"Harum (op. cit. p. 817), duplex est genus, aliud gallicum, aliud non gallicum, major pars non est gallica." He remarks, however, that excrescences not syphilitic may become contagious through negligence of proper cleanliness. (Of late M. Desruelles has given a very particular account of these excrescences in his *Second Mémoire*, inserted in the *Mém. de Méd. &c. Militaire*, vol. xxviii. p. 337.)

<sup>1</sup> Marcellus Donatus has given a case which is quoted by Schenckius (lib. i. de faucibus, obs. ii.). "Civis habitu corporis melancholico præditus verrucis quampluribus gutture, faucibus et radicem lingue occupantibus diu vexatus fuit."—Albucasis (Chirurg., lib. ii. cap. 36), relates the case of a woman, in whom excrescences in the interior of the throat impeded respiration and deglutition. Andral has given a case of growth within the larynx (Precis d'Anatomie Pathol., t. 2ème partie, p. 472). M. Ferrus showed a preparation very nearly similar to that described by Andral, at one of the meetings of the Acad. Royale de Médecine. I met with a third instance of the same kind at the Hôpital de la Charité, in the body of a woman, aged about fifty. The tumour was attached near the upper edge of the left ventricle of the larynx, and expanded above its upper orifice. M. Roux had already discovered this portion of the tumour with his finger; and its presence was farther proclaimed by a distressing dyspnoea, and a peculiar whistling of the air, especially as it entered the larynx in inspiration. Had not symptoms of inflammation of the lungs been detected, and led me to augur unfavourably of the result of an operation, M. Roux would have performed tracheotomy; and possibly this might have been done with success.

<sup>2</sup> Corvisart gives two cases of excrescences of a venereal appearance existing on the mitral valves of individuals who had been formerly affected with venereal diseases.—(Essai sur les Maladies, &c., du Cœur, 8vo. Paris, p. 217.) Lennec has described two species of excrescence of the lining membrane of the heart.—1st. *Végétations verruqueuses*; 2d. *Végétations globuleuses*; but he thinks we have no adequate grounds for speaking of them as syphilitic in their origin.—(Traité de l'Auscultation médiate, t. ii. p. 618, 2ème ed. Paris, 1826.) Messrs. Bertin and Bouillad believe that the influence of syphilis, in the production of these excrescences, has at all events been greatly exaggerated.—(Traité des Mal. du Cœur, 8vo. Paris, 1824, p. 232.)

<sup>3</sup> H. Fracastorius speaks of the loss of the hair and beard, as one of the frequently

was a frequent symptom of constitutional infection, during the latter half of the sixteenth and beginning of the seventeenth century, is at the present day one of the rarest phenomena of the disease. For more than twenty-five years, says Cullérier, during which I have seen from two to three thousand venereal cases annually, I have not met with more than three or four instances of general alopecia, and fifty or sixty of the partial affection.<sup>1</sup>

I have myself noted no more than a single case of general baldness from a venereal cause; but I have repeatedly seen the hair partially lost, among individuals who exhibited the characteristic symptoms of constitutional syphilis.

Syphilitic alopecia cannot be distinguished from the other varieties of the same affection, save by the nature of the symptoms which accompany or precede it; one of its most striking characters is its accompaniment by nocturnal pains in the bones.

926. The nails as well as the hair undergo several changes in consequence of venereal infection. We have to specify, 1st. Inflammation of their matrices, generally known under the name of syphilitic onychia; 2d. Certain changes of structure in the nails; 3d. Loss of the nails (*syphilitic ungueal alopecia*).

*Syphilitic onychia*<sup>2</sup> is observed to occur more frequently in the toes than in the fingers. Several toes are usually affected at the same time; and it is not uncommon to see the whole of them either simultaneously or in succession attacked with this kind of inflammation, which is almost invariably accompanied with unequivocal symptoms of general venereal infection; in some rare instances, the disease is seen expending its virulence almost exclusively on the matrices of the nails.

In the greater number of cases, the border which externally marks the root of the nail and extends along its sides, swells in one or more places without any great amount of pain. The swollen parts have a violet or livid red colour; after the lapse of several days, their surface becomes excoriated. It frequently happens, too, that a sero-purulent exudation takes place between the root of the nail, and the swollen roll of skin which covers it; ulcerative inflammation then commences, and destroys this fold of integument to a greater or less extent, and exposes almost the whole of the root of the nail. If the disease be left to itself, the neighbouring integuments swell, the edge of the ulcer becomes painful, and has a grayish colour; a sanious discharge lodging between the nail and its matrix, loosens it partially at first, and ultimately brings about its complete detachment. The matrix of the nail thus exposed, has the look of a sanious ulcer, surrounded by a red and swollen marginal roll, which, in one or several places, is the seat of ulcers often characteristic in their appearance. If no steps be taken to check the progress of the disease, the edges of the sore become fungous; shapeless horny productions are thrown out from the surface of the matrix on those places that have escaped ulceration; and in this state the mischief is always remedied with extreme difficulty; the

occurring symptoms of syphilis: "Et quod mirum omnibus visum est, capillorum, et reliquorum pilorum casus homines ferè ridiculos facit, aliis sine barba, aliis sine superciliis, aliis glabro capite in conspectum venientibus: quod infortunium prius putabatur ex medicaminibus evenire, præsertim ex argento vivo: mox certiores facti omnes, sciunt ex ipso morbo immutato procedere, quin immo (et quod pejus est) jam nunc multis videntur labefactari dentes, quibusdam etiam cadere (Opera omnia, 4to. Venetiis, 15-84. De morbis contagiosis, cap. ii.; de syphilide, p. 91). This symptom, which has been ascribed to the action of mercury, was consequently observed among individuals who had undergone no kind of treatment. Vide Forestus (De lue venerea, lib. xxxii. obs. 25), and the passage of Fracast. as quoted. Massa also speaks of the loss of the hair in syphilis: "Et quoniam inter quamplurima morbi gallici accidentia depilationes capillorum, barbæ, aliarum partium corporis," etc. (Aphrodisiacus, p. 103.) Ferri (De morbo gallico.—Aphrod., p. 438), J. B. Montanus (De morbo gallico.—Aphrod., p. 584), B. Victorius (De morbo gallico.—Aphrod., p. 645), G. Fallopius (De morbo gallico.—Aphrod., 822), L. Botallus (Luis vener. curandi ratio.—Aphrod., p. 875), D. Leonus (De morbo gallico.—Aphrod., p. 906), F. Frizimelia (De morbo gallico tract.—Aphrod., p. 998), and a great number of other authors speak of the phenomenon, with more or less ample details. On this the reader may farther consult Fernelius (De lue venerea.—Aphrod., p. 613), A. M. Brassavolus, (De morbo gallico.—Aphrod., p. 650), who make a distinct species of syphilis of it.

<sup>1</sup> Dict. des Sciences Méd. Art. Alopecie Vénéérienne.  
<sup>2</sup> In the *Aphrodisiacus*, several passages having reference to the loss of the nails may be found; but inflammation of their matrices is nowhere clearly mentioned. In latter times, Astruc, and several other authors have spoken of it, or have given cases: Delpech (Chirurg. clinique, 4to. Paris, 1833, t. i. p. 364: ulcération du contour des ongles).—Léclut (Etudes anatomico-pathologiques sur l'onglade).—Devergie (Clinique de la maladie syphilitique, 4to., t. ii. pp. 221, 403, Art. Onglade).—Récamiér (Revue Médicale, mars 1830).—Ratier (Journal Hebdomadaire, 2ème série, t. viii. p. 48).—Rynd. On onychia. (The Dublin Hospital Reports, t. v. p. 274.)

affection of the ungueal matrix has then gone to such lengths, that the production of a well-formed nail becomes impossible in future.

927. By contrasting these characters with those of scrofulous onychia, (§ 739,) little difficulty is usually experienced in distinguishing the two diseases from one another. With regard to primary syphilitic sores which have been occasionally seen evolved on the fingers, the venereal poison having been inoculated by means of a scratch or an abraded surface, they differ essentially in their progress from the chronic inflammation of the ungueal matrix, known under the name of onychia.

Syphilitic onychia does not always appear with characters so destructive as those which have been indicated: after the ulceration of the fold of skin which covers the root of the nail, this last is thrown off without the matrix itself becoming ulcerated; a new nail is ere long produced, the inflammation abates, and the disease goes on to recovery; but this amendment frequently proves no more than temporary, and the disease makes its attacks upon one or several others of the digits.

The distinguishing feature of this species of onychia is its occurrence independently of all appreciable outward cause. It is also very constantly distinguished in one case, by the grayish and eroded appearance of the sores; in another, by the other general syphilitic symptoms with which it is accompanied; in a great number of cases, however, the influence of mercurial preparations in its cure, is the final and irrefragable criterion of its actual nature.

928. According to Astruc,<sup>1</sup> the inflammation and suppuration of the ungueal matrices which constitute syphilitic onychia, may be preceded by an alteration of the nails themselves, which become hard, brittle, and similar to those we shall have occasion to describe in the following paragraph: this must be a very rare occurrence, however, for I have never met with it myself, and in all the writers I have consulted on the subject, I have observed no mention of a similar case.

929. Under the influence of an inveterate syphilitic infection, the nails occasionally undergo a remarkable change in their appearance and in their structure.<sup>2</sup> From their extremities, and to a certain distance upwards, they become thicker, drier, more brittle, and more opaque than usual; they are frequently of a yellowish-white colour, and exfoliate or throw off pieces from their surface, which then appears rugous, cracked, and uneven. The extent of this alteration is accurately shown on the nail by the change of colour in the part affected. I have had patients under my care, who, though they had repeatedly taken away with a file or pen-knife, almost the whole of the nails thus affected, assured me that the nails were constantly reproduced with the same alteration of structure, and the same general appearance. The act of cutting these thickened nails is almost always painful, on account of concussion given or traction exercised during the process being communicated to the root of the ungueal matrix.

This alteration of the nails is sometimes observed in different degrees, on those both of the fingers and toes at the same time. It

<sup>1</sup> Demum unguis, qui extremæ cutis appendices sunt, inæquales, crassi, rugosi, scabri fiunt, et obortus ad radices reduvius, panaritio, inflammatione, ulcere sponte decidunt: unde l'onglade.—(Astruc de Morbis veneris, 4to., lib. iv. cap. i. p. 333.)

<sup>2</sup> Contingit et in hoc gallico affectu unguium casus, quem ungiarolam vulgus vocat: affectus potius fœdus, quam dolorosus: nam decidunt unguis et capilli, ut dentes faciunt, et hic affectus nonnunquam capillorum casum sequitur, nonnunquam antecedit, tamen semper illum præcedunt, aut bubo, aut penis exulceratio, aut oris exulceratio, etc. (Ant. Musæ Brasavoli de radicis Chinæ usu tractatus.—Aphrodisiacus, p. 727.) Consult, in addition, Augerii Ferrerii de pudendagra, liber secundus.—Aphrod., p. 925; J. Hunter, Traité des maladies vénériennes, trad. de l'anglais, p. 340; Cullérier, Dictionnaire des sciences, med., Art. syphilis.

"Si quis unguis veluti leprosus habeat, hoc morbo gallico referat acceptum. Hæc autem affectio vulgo ab unguebus (onglade) vocatur."—(G. Rondolet. De morbo gallico.—Aphrodis., p. 939.) I was lately consulted by a man of vigorous constitution, aged fifty-four, who, when only eighteen years old, had contracted bubo and several chancres, which had got well under the use of mercurial inunctions and fifty-four days confinement. At the age of thirty-five, he contracted gonorrhœa, which, treated at first by emollients, and afterwards by the balsam of copaiva, was followed by pains in the joints. These went off, and he continued well till the age of forty-seven, when the nails of the feet began to change without pain: a yellowish dry matter was first deposited between the inferior surface of the nail and the corion; the nails themselves became in part yellow and brittle. Shortly afterwards the nails of both hands became affected in the same manner. These the patient filed away to near their roots, in the hope of seeing them reproduced of natural appearance. The alteration of the nails was speedily followed by plantar pains of such severity as to prevent the patient from sleeping. I prescribed a course of blue pill and tisan of Feltz; after three weeks the pains in the soles had almost ceased, and the nails were shooting forth much less altered in their appearance: every thing promises a speedy and complete recovery.

is frequently accompanied with considerable pain, which is complained of, especially during the night, and about daybreak, in the soles of the feet. I have observed this alteration of the nails in individuals who had formerly suffered under syphilis, and occasionally when no other trace of the disease remained. In these cases, I was only led to look on the alteration of the nails as engendered by a syphilitic cause, from finding that the pains which accompanied it, disappeared under the influence of the administration of mercury, and that the diseased nails were, after the course was completed, replaced by others of normal appearance.

This affection of the nails is extremely rare, and must not be confounded with that which occasionally occurs in the course of inveterate lepra, psoriasis, and pityriasis, and as a consequence of chronic eczema of the fingers.

Several authors mention a syphilitic alopecia, (*unguiarola* Brassavolus,) or loss of the nails without previous syphilitic local symptoms, in individuals labouring under constitutional syphilis.

930. Several writers mention the alteration and loss of the teeth,<sup>3</sup> (*Dentarola*, Brassavolus,) analogous to those of the nails, in consequence of a syphilitic taint of the constitution. Were I to decide according to my individual experience, I should say that such affections of the teeth were extremely rare at the present day; perhaps I have not investigated the point with all the attention necessary.

931. The whole tribe of syphilitic eruptions are frequently complicated with one another: it is common enough at the same time, and in the same individual, to meet with tubercles, squamous patches, papular eruptions, maculæ, &c. And these simple or complicated tegumentary affections, are almost always preceded and accompanied with a variety of other symptoms proper to constitutional syphilis.

932. Articular pains,<sup>4</sup> and pains in the bones, are the most frequent of all the symptoms of constitutional syphilis. Their distinguishing peculiarity is their greater severity during the night than during the day, and the readiness with which they yield to the administration of mercury. The more superficial bones, the tibiæ, the humeri, the cranium, the clavicles, &c., are the most frequent seats of these syphilitic nocturnal pains.

933. Syphilitic periostosis, exostosis, caries, and necrosis,<sup>5</sup> occasionally follow the cutaneous eruptions which are due to the same cause; always more obstinate than these last, they often continue

<sup>3</sup> These affections of the teeth, as symptoms of syphilis, are mentioned by the older writers: "Addit (de signis morbi gallici) corruptionem palati et dentium." G. Fallopii de morbo gallico tract.—Aphrod., p. 781.—Aug. Ferrerii, de pudendagra, lib. secundus, cap. ix. Ad commotos et infectos dentes.—Aphrod., p. 926. Itaque, si una cum pilorum defluvio, dentes unguisve decidunt... citra tamen unguentum ex hydrargyro, et suffumetum ex cinnabari utendum. (Alex. Sra. Petronii. De morbo gallico. Aphrod., p. 1336.) Others have spoken of the loss of the teeth; but it appears probable, from their mode of expressing themselves, that they intended to signify the loosening and loss of the teeth consequent on the destruction of the gums by venereal ulcers. "Et corrosione gingivarum et casus dentium causat." (A. Massa. De morbo gallico.—Aphrod., p. 103.)

<sup>4</sup> These pains, which, by some pathologists, have been attributed to the action of mercury, were frequently complained of on the first appearance of the epidemic syphilis, in the middle ages, shortly after the invasion of the disease, and before any kind of treatment had been tried: "Nicolaus minor Valentinus, mihi intimâ caritate conjunctus, ætatis xxiv., annorum fere, mediocris stature, atque habitudinis, de mense Augusti habuit rem cum muliere, habente pudendagram; quare eadem die ipse fuit eodem morbo infectus, quæ infectio incepit apparere in virgâ, ut solet ut plurimum aliis evenire. Nam sequenti die apparuit ulcus in virgâ cum quadam duritie longâ, tendente versus inguinâ ad modum radii cum sorditie et virulentia. Post sex dies, ulcere semicurato, arreptus fuit ab intensissimis doloribus capitis, colli, spatularum, brachiorum, tibiarum, et costarum, et præsertim sic eorum musculis cum maximis vigiliis a quibus molestabatur non nisi in nocte post primum somnum" (Gasparis Torrellæ. Consilia adversus pudendagram.—Aphrodisiacus, p. 548.) Invenit ei dormiendo in eodem lecto cum fratre suo infecto, et incipit a doloribus, tandem post duos menses, facto totâ die laborioso exercitio, in nocte, horâ quâ molestabatur a doloribus, a capite usque ad pedes correptus fuit a pustulis grossis, crustosis cinericeis, et postea non fuit molestatus a doloribus. (Ibid., p. 550.)

I have myself known pains of this description to occur in consequence of gonorrhœa, and other primary symptoms, which had been treated without mercury.

<sup>5</sup> "Corrosio mala ossis... fit que durities juncturarem cum tumore in morbo inveterato" (N. Massa. De morbo gallico.—Aphrodisiacus, p. 46.) Fallopius gives a more ample description, and appears to have been the first who broached the opinion, adopted by so many of the recent writers, relative to the influence which the use, and especially the abuse of mercury, has on the production of these affections of the bones. "Sæva valde est in morbo gallico ossium corruptio... ita ut totum viderim cranium exesum: ego habeo infinita exempla; sed aliquando etiam corruptuntur ossa palati, ut totum palati os recedat, et non solum palati ossa id patiuntur, sed etiam narium: et sciat, quod non in omni inveterato gallico hoc fit, sed tantum in illis, in quibus inunctio facta est cum hydrargyro." (Fallopii. De morbo gallico tractatus. Aphrod., p. 827.)

after the disappearance of the cutaneous affections, and then require particular modes of treatment for their cure.

934. The *gummy tumours*, (*gummata*, *atheromata*,<sup>1</sup>) situated more deeply than syphilitic subcutaneous tubercles, and very frequently developed over bones, are frequently followed by ulcers in the form of *excavations* or *holes*; they are very rarely met with accompanying a first attack of syphilitic eruption.

935. Under the title of *cachexia syphilitica*, medical writers have described a profound and serious implication of the general system, which cannot usually be satisfactorily explained from any great severity in the evident symptoms of a syphilitic taint, nor from the extent of the lesions which have preceded it, nor from the influence of any measures of cure which may have been employed in previous stages of the complaint. We do occasionally, in fact, meet with adults, and men still in the vigour of life, who, having contracted syphilis, appear to sink prematurely into old age; their skin sallow, loose, and earthy to the touch, seems more than adequate to surround their shrunken extremities. With this cachexy of adults, we must assimilate that under which those unfortunate children almost always labour, whose parents are affected with constitutional syphilis: these infants have the look of diminutive old men.

936. *Phagedenic ulcers* of the amygdalæ, velum palati, and pharynx,<sup>1</sup> are very frequently encountered at the same time as venereal eruptions. Serpiginous ulcers of the gums, of the tongue, and inner aspects of the cheeks, are much less commonly met with.

937. *Purulent syphilitic ophthalmia* is often associated with venereal eruptions among newborn infants; and ophthalmia without purulent discharge and unaccompanied with pain, but frequently followed by small ulcers, spots, and partial opacities of the transparent cornea, is often observed along with syphilitic eruptions in adults. Iritis is found to occur along with various forms of syphilide, but more frequently with the papular than any other. I have several times seen the affection supervene after the apparent cure of this eruption, and without the recurrence of any other form of syphilide.

938. Several diseases of the *nervous system*, amaurosis, deafness from paralysis of the auditory nerve, paralysis of the limbs, neuralgia, &c., and different internal inflammatory affections, as of the œsophagus, larynx, trachea, and even of the bronchi and intestinal canal, observed in individuals suffering under cutaneous eruptions and various other serious symptoms of constitutional syphilis, are phenomena which have been called in question on account of their extreme rarity, but of which the reality can be proved by incontestable facts. The venereal nature of such accidental and grave diseases is rendered still more probable by the circumstance of their yielding readily to mercury.

939. To conclude, almost the whole of the simple inflammatory affections of the skin, such as scabies, eczema, prurigo, &c., &c., may be accidentally associated with an eruption of a truly syphilitic nature: in the public prisons it is by no means uncommon to find scabies complicated with constitutional syphilis. (a)

If the diagnosis of these complex cases require much discrimination on the part of the physician, there are other complications, the treatment of which is surrounded with peculiar difficulties: such are those in which constitutional syphilis is associated with scrofula, with scorbutus, or chronic inflammation of the cœcum and colon.

940. *Diagnosis*.—I have already made known the distinguishing characters of the different varieties of syphilitic eruption, from those

(a) A good description of venereal eruptions will be found in Mr. Babington's Notes on Hunter (*on the Venereal Disease*.—Am. Ed., p. 242-4), and a yet fuller one in M. Cazenave's *Traité des Syphilides*.

<sup>1</sup> "Præterea sunt *apostemata dura*, adhærentia paniculis et ossibus ut sunt ossæ foreulæ pectoris, crurum, et frontis quæ a vulgaribus gummata appellantur... hanc eandem materiam videmus quotidie in apostematibus duris quæ vulgares gummata appellant. Nam quando inciduntur, aut ex se rumpuntur, sunt plena materiæ *albæ, viscosæ*, et aliquando cum lividitate, quandoque vero cum rubedine aliquâ secundum diversam admisionem." Massa (*Aphrodisiacus*, p. 46—43). G. Fallopius (*De gummatis gallici*.—*Aphrod.*, p. 826), distinguishes *gummata gallica* into *tophaceous* or *hard*, which appear to have been nodes and thickenings of the periosteum, and *soft*, which included three varieties; one, of the consistence of lard; another, pulaceous (*Atheroma gallicum*); and a third, soft like honey (*Meliceris gallica*).

<sup>2</sup> "A principio apparent in gutture mollificatio uvæ et apostemata, sclerotica mala quæ non maturantur nisi raro, et ulcerantur ulceratione maligna, quæ apostemata in recidivâ sæpè apparent," etc. (N. Massa. *De morbo gallico*.—*Aphrodisiacus*, p. 46).

unspecific eruptions, of like elementary forms, or which bear any resemblance to the syphilides in outward appearance, or any analogy with them in their progress. (§§ 863—914.) I have also given the proper and distinguishing symptoms and characters of primary and secondary ulcers. To complete the diagnosis, I have only farther to exhibit the characters which distinguish syphilis from some other diseases, to which it bears a certain resemblance.

941. Hunter, Abernethy, and several others, have spoken of certain eruptions having the appearance of true syphilides, and requiring to be distinguished from these, as differing from them essentially in their nature (*pseudo-syphilis*; *syphiloid diseases*, Abernethy).

I shall, by and by, examine (*vide Vocab.*), with reference to their similarity to syphilis, the affections entitled *schervivio*, *sibbens*, *rade-syge*, *yaws*, *maladie de la baie de Saint-Paul*, *morbus Bruno-gallicus*, &c., which have been considered by some pathologists as distinct diseases, and by others, and more frequently, as peculiar or still undescribed forms of syphilis. Mean time the works of Hunter and Abernethy may be consulted for information in regard to the diseases which have been entitled pseudo-syphilitic.<sup>2</sup>

<sup>2</sup> Hunter (on the venereal, pt. vii. chap. ii, on the diseases which resemble syphilis), has endeavoured to show the analogy which scorbutic spots may in some cases present to venereal eruptions, of syphilitic to rheumatic pains, and of venereal tumefaction of the bones and periosteum, to that which is sometimes occasioned by scrofula and rheumatism. Hunter asserts, moreover, that there are certain affections which resemble the venereal disease, not only in appearance, but in their mode of contagion; that they give rise immediately to analogous effects, and produce consecutive symptoms resembling those of syphilis. In support of this opinion, he quotes the case of a surgeon, who, on opening an abscess in the shoulder of a negress labouring under yaws, accidentally inoculated one of his fingers, which was slightly excoriated, with the matter, and was attacked with tumours, that were unsuccessfully combated by mercury, with nocturnal pains of the tibia and fibula, afterwards with a scabby eruption on different parts of the body, and at a still later date with a discharge of viscid mucus from the throat and nostrils.

To this case, which Hunter thinks ought to be distinguished, both from the venereal disease and the yaws, he adds two others: one is that of a man who, after being cured of a chancre, had, about six weeks after another sexual intercourse, an excoriation of the prepuce, which became very deep and painful; the woman was attacked with a swelling in the groin, which suppurated, and was cured at the end of six weeks; but during that time the skin became covered with crusted pustules, some occurring on the face and thighs, though the hands and feet were more particularly the seat of the eruption, and there the epidermis was detached in scales. The whole of these eruptions got better without mercury. The second case is that of a man of debauched habits, who had a painful ulcer on the glans penis, which was made worse by the use of mercurial preparations; a considerable tumour existed on the right side of the frontal, and on the left parietal bone, together with spots on the inner part of the left tibia; these two symptoms disappeared; but some months afterwards, the tumour of the cranium reappeared; several abscesses formed; the bones of the skull became carious, and several ulcers were the consequence.

A nurse gave the right breast to her own child, and the left to a child of a neighbour; about six weeks afterwards, several ulcers formed round the left breast, the glands of the axilla swelled, the ulcers spread, and the nipple was destroyed; cicatrization took place at the end of three months; the child had aphthæ in the mouth, and ulcers on different parts of the body. This woman subsequently suffered from pains in the bones and joints, and these were succeeded by an eruption on the arms and thighs, which terminated in ulceration; she was unable to take mercury on account of its always producing fever; she afterwards became pregnant, and was delivered of a diseased child, whose body was covered with a scabby eruption, and which lived about nine weeks. The child, for some time before its death, had been entrusted to the care of a wet nurse; before long, the nurse was attacked with pain in the head, sore throat, and an ulcer on the breast; the bones of the nose and palate also exfoliated. The mother of the child again became pregnant, and was delivered of a sickly infant, which died at the end of a month. About a year afterwards, this woman's ulcers broke out afresh, and although they were treated with mercurial dressings, and mercury was also administered internally, it was not till the end of the year that they began to cicatrize.

The first of these cases quoted by Hunter, will be particularly examined when we treat of yaws; the remainder do not appear to me to differ from ordinary cases of venereal infection, excepting as regards the inefficacy of the mercurial treatment, which, as is well known, is not applicable in all forms or at all periods of syphilitic disease. With regard to the cure of ulcers on the genital organs without mercury, we are no longer at liberty to conclude any thing from that against their venereal nature, since it is now an ascertained fact, that every form of ulcer of the genital organs is capable of being healed without the exhibition of this mineral.

M. Abernethy (*Surgical Observations*, 8vo., London, 1804: on diseases resembling syphilis). "A gentleman thought he had infected a slight cut on his hand (which was situated in front and just below the little finger) with the discharge from a bubo in the groin, which he had opened. The wound fretted out into a sore, which he showed me, about the size of a sixpence, and which I affirmed had not the thickened edge and base, and other characters of a venereal chancre. I therefore recommended him to try the effect of local means and not to use mercury. In about a month the ulcer contracted in its dimensions, and assumed a healing appearance. A considerable tumour arose over the absorbing vessels which proceed along the inner edge of the biceps muscle. The tumour was discussed, and the sore healed without mercury. Three weeks afterwards, in each tonsil, there was an ulcer deeply excavated, with irregular edges, and with a surface covered by adhering matter; ulcers in short, which every surgeon who depends on his sight as his guide, would have pronounced

Whilst the epidemic elephantiasis of the Greeks, (the leprosy of the middle ages,) was still frequently observed in Europe, and when syphilis prevailed extensively at the same time, it became of importance to point out the distinctive characteristics of these two diseases, both of which were looked upon as contagious, and both of which deeply deranged the constitution, produced spots, tubercles, and ulcers on the skin, caused the hair, eyebrows, and beard, to fall off; occasioned ulcerations in the mouth, nose, nasal cavities, and larynx.

In the present day, well-determined differences in their appearance, progress, and above all, in the mode of development of their primary symptoms, would no longer leave any uncertainty as to the diagnosis of these two diseases, even if elephantiasis had not ceased to exist among us.

Scorbutus can never be confounded with the cachectic state which is sometimes observed in constitutional syphilis, or after the abuse of mercurial preparations.<sup>1</sup>

With regard to scrofula, the glandular enlargements, the ulcers, caries and fistulæ, which it produces, and the cicatrices which these leave behind them after cure, the inflammation of the eyes, the affections of the throat, and enlargements of the tonsils, the discharge and ulcers of the nose, the swellings about the joints, and other diseases of the articulations which it occasions, have likewise peculiar appearances which, in almost all cases, prevent their being confounded with affections of a syphilitic nature exhibited in the same parts. But a degree of real uncertainty is sometimes experienced when we find a person of scrofulous habit attacked by secondary syphilis, and presenting disorders of the nose and eyes, the appearance of which is neither decidedly scrofulous nor decidedly syphilitic, and endeavour to distinguish the influence of the constitutional peculiarity from that of the venereal virus, on the development of these disorders, with a view to determine their treatment. These difficult cases, which are unfortunately of too frequent occurrence, are always very troublesome.<sup>2</sup>

942. It is a very general opinion that syphilitic eruptions, left to

to be syphilitic. Shortly after, also, some copper-coloured eruptions appeared on his face and breast, which were declared to be syphilitic by several surgeons. A circumscribed thickening and elevation of the pericranium covering the frontal bone appeared at the same time. "The young man went into the country, and the symptoms disappeared in a fortnight without the use of mercury." This last circumstance confirmed Mr. Abernethy in the opinion he had formed, that the disease was not venereal; persuaded as he felt, that a disease which got well spontaneously and without mercury, could not be syphilitic; an opinion which a multitude of well-authenticated facts contradict sufficiently now-a-days, to justify me in considering as really venereal the disease under which this young gentleman laboured.

Carmichael, in his "Essay on Venereal Diseases," chap. v., when speaking of diseases most likely to be confounded with those of venereal origin, details several cases, the venereal nature of which appears to me to be very probable, and which cannot with propriety be separated from the history of syphilis; he makes mention, however, of a case of phagedenic ulcer of the throat, which made its appearance without previous syphilitic infection either of recent or older date, according to the testimony of the patient.

<sup>1</sup> Sebastianus Aquilanus (De morbo gallico.—Aphrodisiacus, p. 5) maintains the identity of elephantiasis and the morbus gallicus. P. Maynard (De morbo gallico tractatus.—Aphrod., p. 389), and several others, are of the same opinion. Other writers have thought with reason, that syphilis was a distinct disease; among those of this opinion, I may particularly mention N. Leonicens (De epidemia, &c. Aphrod., p. 17); G. Fallopius (De morbo gallico tractatus.—Aphrod., p. 763); H. Fracastorius (De syphilide seu morbo gallico lucubratio.—Aphrod., p. 203, &c.).

<sup>2</sup> The abuse of mercurial preparations has long been held the cause of very serious injury to many individuals attacked with syphilis. This opinion has lately obtained extensive credit in England, France, and Germany; and the physiological school has contributed powerfully to its propagation. See on the ill effects of mercury, Fallopius (De morbo gallico tractatus.—Aphrod., p. 809).—Sintelaer. "The Scourge of Venus and Mercury, &c., with the true way of curing the mercurial pox, found to be more dangerous than the pox itself."—London, 1737. Ludolf. "Demonstratio, quod atrocissima luis venerea symptomata non sicut affectus morbi, sed curæ mercurialis institutæ." Erford, 1747. Consult also Hunter on the danger of giving mercury when the disease is not venereal, that is to say, when the symptoms are not such as those which he considers exclusively venereal.—(Traité des maladies Vénériennes, Paris, 1787, p. 407), and even in the diseases which he believed to be syphilitic, (idem, p. 361). For my own part, my conviction as to the specific and curative action of mercury in the treatment of venereal diseases is now stronger than ever; and I do not recollect a single case in which I have had reason to regret having employed it. This leads me to conclude, that there is much exaggeration in what has been said in regard to the ill effects of mercury, always admitting that salivation, hydrargyria, and mercurial fever are serious evils, the occurrence of which cannot always be effectually guarded against, even by administering this medicine in doses calculated with the utmost care. But these accidents rarely supervene when mercury is cautiously exhibited, and though they did happen much more frequently than they do, they are slight evils to place in opposition to a curative influence, which has never been approached in power by any other mode of treatment devised.

themselves, are not susceptible of *spontaneous* cure:<sup>3</sup> nevertheless, we do occasionally find venereal eruptions, and other secondary symptoms of syphilis disappearing of their own accord for a time; but they almost always reappear afterwards, either in the same form or under some different aspect. (a)

(a) See note in a subsequent page, in which Mr. Mayo's observations on this point are stated.

In summing up the characteristic features of syphilitic eruptions, with a view to diagnosis, we may lay down the following propositions.

The colour of syphilida depends on a morbid secretion of the corion, constituting the pigment, or, as it is now called, the chromatogenous apparatus; and, in this respect, their study might come under the head of disorders of this apparatus. Swediaur was the first to designate the hue of syphilitic eruptions by the term red copper-colour, which sometimes passes into a yellowish-blue, as we see after a bruise. M. Cazenave (*Traité des Syphilides*) says, that the colour varies from a coppery-red to a brownish-gray; and he regards it as diagnostic. It is met with in the papulæ and tubercles, and at the base of the pustules and vesicles; it constantly accompanies the squamous elevations, sometimes the squamæ themselves. It is but partially removed by pressure of the finger; and constitutes sometimes the entire disease. It is of a more lively hue at the beginning of the eruption, and becomes more and more gray as it is about to disappear. This colour will sometimes remain after the eruption itself has disappeared, and particularly so, if the latter has left behind it any cicatrix.

Another peculiarity of syphilida is the great tendency to assume a circular form. This is manifest, not only in separate patches, limited to a small surface, but it is also seen when the eruption is disseminated over a large space, in which we can still detect a circular arrangement or segments of circles. This latter trait is chiefly noticed in serpiginous syphilida. We cannot, however, claim for this circular arrangement a diagnostic value in the syphilida generally, since in some of them it is not seen, and in other cutaneous eruptions, not of a syphilitic nature, it is met with, as in simple herpes, lepra vulgaris and some varieties of lichen, &c. Besides, it is worthy of remembrance, that in syphilitic eruptions of other orders, as in the tuberculous, for example, there is a constant tendency to this circular arrangement. This feature has been noticed by authors, who describe a venereal eruption, particularly when affecting the face, by the term *corona veneris*.

Another feature in syphilitic eruptions is their chronic duration. Even when the premonitory symptoms seem to announce an acute disease, the eruption itself is slow in its progressive changes. If it be a pustular syphilide, we often see it with a large indurated base, terminating in a minute point of suppuration. If vesicular, the vesicle, though voluminous, remains unchanged, without rupture or loss of transparency, during a period of four, five, six and even eight days, surrounded by a red areola. The progress of the eruption is always slow, suppuration difficult, and cicatrization still more so—a chronicity this, which it is important to remember, in forming our diagnosis of syphilida.

As regards the secondary lesions, we find the squamæ to be thinner and drier than in simple squamous affections; and they are not so large, as they never entirely cover the eruption or pustule, around which they form a whitish band. Bielt laid considerable stress on this appearance. The squamæ are formed again very slowly; and hence we so often find the papular elevations in syphilitic psoriasis and lepra deprived of their squamæ.

The scabs are commonly thick, greenish, sometimes bluish, hard, furrowed as it were, and very adherent. It may be that they cover an ulceration, and then they are softer, larger at their base, and in a measure surrounded by a soft coppery circle which overlaps them a little; or, again, they may rest on a cicatrized point, and they are then retracted, horny at their base, which is unequal, and which, by successive separations, displays gradually a cicatrix into which it is seemingly implanted by mammillated terminations that are surmounted by a small, dry and whitish desquamation.

<sup>3</sup> Wilson.—Observations on the Natural or Spontaneous cure of Syphilis. (Transactions of the Edinburgh Medico-Chirurgical Society, vol. iii. p. 1.)

943. *Prognosis.*—In general a venereal eruption, considered in itself, is the more serious in proportion to its tendency to terminate in ulceration. There are, besides, certain kinds of ulcers, (the *serpiginous* and *phagedenic*,) which have a greater tendency than others to spread superficially, or to penetrate in depth. The prognosis is also more or less unfavourable, according to the seat of the ulcers, and the importance of the parts which are implicated, and which are liable to be disorganized or destroyed by them; it is almost superfluous to add, that syphilitic exanthemata, vesiculæ, acute papulæ, squamæ, and non-ulcerating tubercles, are not otherwise serious than as evidences of the cause which has produced and continues to maintain them.

Nevertheless, several of these superficial lesions must be considered as the more serious, on account of certain disorders which usually follow them, or habitually supervene during their existence. Thus phagedenic ulcers of the velum palati, more frequently accompany the squamous syphilide than any other form of venereal eruption; iritis is oftener associated with papulæ, &c. The prognosis may be rendered still more unfavourable by the long standing of the disease, by the effects of ineffectual modes of treatment, and by the multiplicity or serious nature of concomitant symptoms, for example, of diseases of the bones. Independently of these considerations, the coincidence of scrofula, the decay of the constitution under the influence of the syphilitic virus, or of a chronic affection of one or more of the viscera, and frequently also the mode of affection, for the disease is always more malignant if received by hereditary descent, by nursing or inoculation, than when caught by sexual intercourse, are circumstances which render the prognosis particularly unfavourable. Farther, there are many circumstances which oppose themselves to the successful treatment of the disease—such as the necessity of residing in cold and damp situations, fatigue, and even active bodily exercise, improper diet, excesses of every kind, &c., which all tend to render the prognosis more or less unfavourable.<sup>1</sup> (a)

944. *Treatment.* The treatment of the syphilitic eruptions, like

These observations suggest the further remark, that in all the syphilida, if we except the exanthematous and squamous, there is a great tendency to destruction of tissue, as we see in the indelible cicatrix, whether it be preceded by ulceration or not.

The circular form of syphilitic ulcers is a constant feature and is especially observable in those following ecthyma. As just intimated, there may be loss of parts without ulceration. These singular results obtain in the papular and tubercular syphilida, without there having been any wound or the slightest ulceration. The ulceration succeeding to a tubercle or pustule, is very minute; and if, sometimes we see a shoulder or half of the arm covered with a large cicatrix: this last will be found to be the effect of an union of several tubercles and ulcerations which have successively run into one another. This circumstance will, also, serve to explain the apparent irregularity of the rounded form of the eruptions and ulcerations.

If to these different characters of syphilida be added the little, even local excitement or reaction, the absence of heat, acute pain, and above all, of pruritus, even in forms which, generally, in the simple state, are accompanied by extreme itching, we shall have a picture of the symptoms common to syphilitic eruptions, and which, when present, constitute the main outline of their diagnosis. For farther details on this head, including a minute description of the particular symptoms of the syphilida, etc., I refer the reader to Cazenave's work, already quoted.

(a) Vesicular syphilide may sometimes become a grave disease by its obstinacy and the pains that accompany it, as well as by the irregular and deforming cicatrices left after it. These remarks apply, however, only to a rare variety, the syphilitic eczema impetiginodes.

Bullous syphilide is always of grave import, whether it shows itself under the form of the pemphigus of children newly born, a disease which M. P. Dubois has always found to be fatal, or appears under the form of rupia, an affection which commonly indicates

that of almost all chronic diseases of the skin, imperatively requires that regard should be had, not only to the form, extent, and duration of the eruption, but also to the age and constitution of the patient.

Under the title of *preparatory treatment* are included those dietetic and general measures,—change of regimen, rest in bed, and those preliminary steps, which have for their object to bring the constitution into the most favourable state for the administration of curative and specific means. In my opinion, this preparatory treatment, too often neglected, is of the utmost importance.

945. Persons of sanguine or plethoric temperament ought to be bled once or twice during the first fortnight of treatment: they ought to continue in a state of constant repose in bed, and be kept upon very low diet of a cooling kind;<sup>2</sup> and in cases complicated with fever, phagedenic ulcers of the throat, and inflammations of the conjunctiva, or of the iris, the blood-letting, both local and general, ought to be repeated at intervals less remote: in short, in this first stage, and under such circumstances as we have described, it is of advantage, even after all symptoms of febrile excitement have ceased, that the patient should remain for several days in bed, and not swerve from the regimen prescribed.

Persons of a dry and irritable temperament, and habitually subject to obstinate constipation, should undergo, for eight days or so, a preparatory course of tepid baths and gentle aperients. We should aim, on the contrary, by means of nutritious diet and the moderate use of good wine, at fortifying the lax constitution of persons of a lymphatic or scrofulous temperament; by the same means we should also endeavour

a broken-down constitution, and which leaves behind it deep, and deforming scars.

But of all syphilitic eruptions, the most alarming, under every aspect, is unquestionably the tuberculous form, which is usually an evidence both of a secondary syphilis and of deep contamination. From its habitual seat in the face and sometimes scalp, the deep and extensive destruction of parts, and the often frightful cicatrices which it causes, tuberculous syphilide, and especially the perforating and serpiginous variety, combines, in itself, all the conditions which constitute both the absolute and relative gravity in the prognosis of syphilis.

In conclusion, as M. Cazenave (*op. cit.*) has well remarked, the syphilida in themselves alone, may give rise to serious disorders, followed possibly by frightful deformities; but they cannot be said to be the cause of death. When the patient sinks under the disease, happily a rare case, it is owing to deeper seated lesions—laryngeal phthisis, or more frequently ulcerous enteritis. This result may also be owing to a cachectic habit of body, and to a union of concomitant symptoms which attack all the tissues, and which are manifested in hectic fever, diarrhœa, hemorrhages, fetid sweats and finally death.

<sup>2</sup> Already, in the time of Massa, several physicians attributed the cure of syphilis, not to medicine, or to decoction of guaiacum, but to regimen: "Multi, qui ad pauca respiciunt, auri sunt dicere, quod sanitas quæ sequitur per potionem dictam, non est ab ipsa virtute ligni, sed a tenuitate dietæ, qui etsi sine ratione et experimento, hoc dicant," &c. (Massa, *ibid.*, p. 65.)—"Si multa quantitas cibi cum dictâ decoctione admisceretur, extingueretur ejus vis, et sic, aut multum debilitetur operaretur, aut nihil. (Massa. De morbo gallico, cap. vii.—Aphrod., p. 65.) He proves the necessity of abstinence upon physiological grounds, and the case of a man who had made use of the wonted remedies without obtaining a cure, in consequence of having failed to observe any regular regimen, and neglected the use of purgative medicines; the patient having afterwards submitted to the same plan of treatment, with restricted diet and the use of aperients, the pains, swellings and ulcers were cured in the space of twenty days.

Massa, Ulrich Von Hütten, and almost all the practitioners of their times, have insisted on the necessity of observing a strict regimen, and for food have prescribed white meats, fresh eggs, &c. The diet recommended by Massa is as similar as possible to the *cura famis* of the moderns—"et ejus prandium sunt uncie quatuor panis bene fermentati non saliti et uncie tres carnis vitulinæ vel hœdinæ, sive pullorum galinarum parvorum, etc.... et sint conditæ istæ carnes sine sale, etc.... et sic facere oportet usque ad vigesimum diem et plus si virtus ægri toleraverit." (Massa. De morbo gallico.—Aphrod., p. 63.) At the same time the patients were kept quiet, and took warm decoction of guaiacum, in order to promote perspiration. The food was afterwards gradually increased in quantity. During the *cura famis* or dietetic mode of treatment practised in the hospital for venereal subjects at Stockholm, the patient is confined to his room for about six weeks, and receives no more than about four ounces of roast beef, and five ounces of the best wheat bread, daily; his beverage is a decoction of simlac china. If this regimen is found considerably to reduce the strength of the patient, which seldom happens, the quantity of food is increased. All the symptoms have generally disappeared in the space of three or four weeks; and at the end of six, the treatment is suspended for three weeks, and then resumed for three weeks more.—(Bulletin des sc. méd. de Férussac, t. xiii. p. 152.)

<sup>1</sup> Preterea gulosi, bibuli et multum coeuntes, et sine regula omnia comedentes, et male se habentes in regimine reliquarum rerum non naturalium, non sanantur nisi raro. (M. Massa. De morbo gallico.—Aphrodisiacus, p. 47.)

vour to recruit a constitution which is enfeebled by age, or which has suffered by privation. I have found that, in women attacked with chlorosis, dysmenorrhœa, and amenorrhœa, the cure of venereal eruptions was facilitated by modifying the constitution at the same time by means of chalybeate preparations and bark.

The patient ought carefully to guard against exposure to cold or damp, and should sedulously abide by the regimen proper to his state and constitution.

The duration of the preparatory treatment may be diminished or increased according as the syphilitic symptoms appear to require prompt measures for their relief, or as the absence of severity in these allows more active treatment to be deferred.

946. Of all the therapeutic means we possess of combating a general or constitutional venereal taint, there are none more certain in their effects than the *preparations of mercury*; but experience has shown that these ought not to be administered during the existence of febrile symptoms, or of any very decided signs of local irritation. Under such circumstances, they not only do not act favourably, but are often positively prejudicial; whereas the *antiphlogistic regimen*<sup>1</sup> always moderates the symptoms, and not unfrequently causes them to disappear entirely, at least for a time. It frequently happens that it is only after this preparatory treatment that mercury can be made to act beneficially.

947. For several years past, I have adopted, as the ordinary method of treating syphilitic eruptions, the use of mercurial ointment, made into pills, internally;<sup>2</sup> and every day's experience satisfies me of the superiority of this method above all others. It has the advantage over the administration of mercurial ointment by friction, of being more certain in its curative effects, and of being exempt from the filthiness and destruction of linen which the other necessarily entails. Many comparative experiments have satisfied me that the absorption of mercury, administered internally, is more certain and regular than when employed by way of inunction; the quantity actually taken into

<sup>1</sup> For the last thirty or forty years, several practitioners of great merit, among whom may be reckoned Thomson, Hennen, Ferguson, Guthrie, Rose, and others in England, and Desruelles, Devergie, &c., in France, rejecting, in a great degree, the idea of the specific action of mercury in this disease, have agreed to meet it on the general principles pursued in the treatment of inflammatory diseases. (a) Some of the disciples of the physiological school, still more strongly imbued with the doctrine of simple irritation, deny altogether the *specific character and virulent nature* of the disease itself; and treat its primary, and even its secondary symptoms, which they look upon as sympathetic, by simple antiphlogistics.

Militaires*, 8vo., Paris, &c.—Devergie. *Clinique de la maladie syphilitique*, 4to. Paris, pl. L. F. R. S. Richond de Brus. *De la non-existence du virus vénérien*. Paris, 8vo. 1826.

<sup>2</sup> F. Fritze (*Handbuch über die venerischen Krankheiten*, Berlin, 1790, 8vo.), Terras (*Remarques et observations sur l'usage et les bons effets de l'onguent mercuriel*, administré à l'intérieur, sous la forme de pilules, pour la guérison des maladies vénériennes. *Journ. général de méd.* t. xxi. p. 33), Sédillot (*Remarques sur un savon mercuriel*. *Journ. général de méd.* t. xvi. p. 37), have dwelt on the advantages of this method of administering mercury; and the reason of its not having been more generally appreciated is probably to be ascribed to the dose having been recommended to be carried as far as twelve pills a day, a quantity which inevitably produces salivation. I have adopted the formula of Sédillot, in the preparation of the pill of mercurial ointment, viz.: mercurial ointment, one drachm; Spanish soap, two scruples; powder of althea root, a scruple; mixed well together, and made into pills of the weight of four grains each, and prescribed in doses of two or three, very rarely of four, a day, for a month or six weeks.

Plenck (Jos. Jac.) (*Methodus nova et facilis argentum vivum agris labe infectis exhibendi*, Vindob., 1776), also employed mercury internally with very great success: the pills and mercurial mixture of Plenck, the pastils of M. Lagneau, blue pills, &c., are preparations whose action is similar to that of the pills of Sédillot. Schlesinger recommends a *mercurial mixture*, analogous to the mixture of Plenck, which he used with much success for children. Finally, Chaumette (Aut) (*De morbo gallico*, chap. 7, *curatio per pilulas mercuriales*. Aphrod., p. 555), gives a formula which may be considered as the origin of all the preceding compounds.

(a) To these we may add the names of Wallace, Ballingall, Carmichael and Ricord, and in our own country Dr. Thomas Harris, who has promulgated his opinions on the subject. As regards practice, I have for a number of years treated syphilis in all its stages without mercury, except as an occasional alterative, used after the same indications as in a great number of other diseases.

the system then depending on the greater or less degree of diligence used in rubbing in the ointment, and on the aptitude or disposition of the skin to absorb the mineral, which is known to vary in every individual. Since I have depended on this method of administering mercury, and I have long employed it with a degree of success truly remarkable, I have not had, either in my private practice, or in the course of my duty at the Hospital of La Charité and its dispensary, a single bad case of salivation or mercurial inflammation of the mouth or throat. Whenever the action of the mercury showed itself upon the gums, I have always succeeded in obviating the mischief which was impending, either by diminishing the dose of mercurial ointment, or by suspending the use of this remedy for some days. To adults and persons of mature age, I have prescribed two, and sometimes three, of the pills of Sédillot,<sup>3</sup> to be taken fasting, every morning, for a month or six weeks—seldom for a longer period. If the affection is of long standing, I almost always prescribe at the same time, a pint of the *tisane de Feltz*<sup>4</sup> daily, and the tepid bath two or three times a week; and where the eruption is accompanied by pains in the superficial bones or joints, I recommend a grain or a grain and a half of the gummy extract of opium at night.

Under the influence of this treatment, it is not unusual to observe a marked change in the state of syphilitic eruptions, ulcers, tubercles, &c., by the twelfth or fifteenth day from its commencement, and sometimes even sooner; and I have not met with any case of syphilitic eruption in persons of unbroken constitution, which a month or six weeks of this treatment has not made to disappear. In those cases in which the syphilitic virus has extended its action to the osseous system in any remarkable degree, and those in which numerous ulcers had formed upon the extremities, in consequence of the softening and suppuration of subcutaneous tubercles, or in persons who exhibited other symptoms of syphilis of long standing, I have sometimes administered considerably larger doses of mercurial ointment than those mentioned, prescribing every day, for a fortnight towards the close of the treatment, from four to five of the pills of Sédillot. But the cases in which this more active mode of prescribing mercury (which is liable to be followed by salivation) is necessary, are very rare; and I never have recourse to it except when I conceive that the inconvenience of salivation will be more than compensated by the cessation of rebellious symptoms, and the more rapid progress of the disease towards a cure. Finally, I ought to add, that the mercurial ointment, thus administered, never produces any marked derangement in the functions of digestion; the patient in general experiences no other sensible effects from its use than the progressive diminution of his venereal symptoms, followed by a complete and permanent cure. In this latter respect the preparation of mercury now recommended, has incontestable advantages over the corrosive sublimate exhibited internally.

948. Although the external application of mercurial ointment,<sup>5</sup> either by friction or otherwise, is less certain in its effects on the constitution in the majority of cases, it nevertheless presents certain advantages under particular circumstances. For instance, when a syphilitic eruption is accompanied by a chronic enlargement of the testicles without pain, when buboes of the groin exist at the same time, mercurial inunction practised upon the lower extremities is always of advantage. The same mode of administering mercury by rubbing in on the forearm and arm, ought also to be recommended in those cases in which the syphilitic poison has been accidentally inoculated by punctures or excoriations of the finger, and has been followed by enlargement of the axillary glands, and cutaneous eruptions.

<sup>3</sup> Vide Formulæ at the end.

<sup>4</sup> Ibid.

<sup>5</sup> Several ointments containing mercury and litharge, originally employed by the Arabians in chronic diseases of the skin, and subsequently by Theodoric, Guy de Chauliac, Arnaldus de Villanova, &c., were afterwards used by Massa and his contemporaries, in the treatment of the venereal disease. After having been prepared by a course of baths and purgatives, the patients usually rubbed in a dose of the *Saracen ointment*, as it was called, before the fire, every evening on going to bed. In some serious cases accompanied with *cachexia*, Massa, after having tried mercurial inunction and cinnabar fumigation in the ordinary manner without effect, sometimes suspended the treatment on the twelfth day, for ten, fifteen, or twenty days, and even a longer period, during which time, wine and generous diet were ordered for the patient, who was again subjected several times in succession to this double influence of mercury, and an analeptic or nutritious regimen till the cure was accomplished. This method appears to me to be applicable to several analogous cases.

Moreover, mercurial ointment applied by way of friction, and directly as a dressing to syphilitic eruptions, to tubercles, and, above all, to the moist tubercles of the margin of the anus and genital organs, and to ulcers, exercises, independently of its specific and general action on the constitution, a topical influence which expedites the cure of the local affections.

After taking several baths for the purpose of cleansing the surface of the skin, and shaving the hair from the legs, the patient generally rubs in for the space of fifteen or twenty minutes daily, from the ankle to the knee, half a drachm of the strong mercurial ointment. The following day, the inunction is applied to the thigh of the same limb; and the day after that, the patient takes a bath and recommences rubbing in, in like manner, on the opposite extremity: the patient should wear stockings and drawers by night as well as through the day, in order to avoid staining his bed and body linen with the ointment, which leaves marks that are very difficult to be effaced. The dose of mercurial ointment may be increased to two scruples or a drachm daily, when, after the twentieth friction with the smaller quantity, the disease continues stationary, or but little modified in its appearance, and when there are at the same time no symptoms of swelling of the gums, or other phenomena indicative of a mercurial affection of the system. I may add that, in very long standing and inveterate cases of syphilis, which have resisted the more ordinary modes of treatment, I have seen the inunction of large doses of mercurial ointment, cause all symptoms to disappear, after having produced a violent attack of fever and *copious salivation*.<sup>1</sup> When recourse is had to this method of treatment by salivation, it is necessary to examine the posterior fauces very carefully, and to attend to the state of the respiration, in order to meet at once any symptom of œdematous inflammation of the glottis or base of the larynx, should this appear.

In ordinary cases, from forty to fifty frictions, administered in combination with a decoction or infusion of the sudorific woods, generally suffice, in adults, to complete the cure.

The activity of the function of absorption in children and its inactivity in aged persons, require that the dose of ointment, and number of frictions, should be materially diminished for the former, and that the time of inunction especially should be prolonged for the latter.

949. The *bichloride of mercury* (corrosive sublimate),<sup>2</sup> adminis-

<sup>1</sup> Similar cases, and the additional fact, confirmed as it is by daily observation, that mercury is in general the more efficacious in proportion as its peculiar effects are more easily excited in the system, and as the gums are more readily affected during its administration, undoubtedly gave rise to the opinion formerly universally entertained, that salivation was necessary to accomplish the cure of the venereal disease. (Système de M. Boerhaave sur les maladies vénériennes, trad. en Français par M. de la Métrie, Paris, 12mo., 1735.)

<sup>2</sup> Strongly recommended by Blancard, and Frick, and its effects better studied by Hoffman and Boerhaave, the use of corrosive sublimate internally has become general in Europe since the numerous experiments made by Locher, a pupil of Van Swieten, were made known, who, with this preparation, treated four thousand eight hundred and eighty venereal patients successfully. (Obs. Tract. circa luum venereum, etc. Vienna, 1762, 8vo.) In France, J. J. Gardanne, (Recherches pratiques sur les différentes Manières de traiter les Maladies Vénériennes, 8vo. Paris, 1770.) Cullerier, and several of his pupils, have highly eulogized this remedy, which continues to be much employed at the present day, but which was not a favourite with Astruc and Swediaur. It has been charged with producing hæmoptysis, phthisis, with causing abortion, &c. Gardanne frequently administered the sublimate conjointly or alternately with mercurial inunction, a method approved by Dehorne. (Exposition raisonnée des différentes méthodes d'administrer le mercure, etc., 8vo. Paris, 1774.) Pibrac has exaggerated the ill effects of the sublimate, but has made some useful remarks on the inconveniences attending its internal administration, and particularly on the danger of its application to ulcers, &c. (Mém. sur l'usage du sublimé corrosif. Mém. de l'Acad. de Chirurg., t. iv. p. 153, 4to.)

Dzondi has proposed to administer sublimate in somewhat large and constantly increasing doses. He makes use of the following pills:—R. Hydrargyri sublimati corros., gr. 12; Solv. in aq. distill. q. s.; add. micæ pains albi, sacchari albi a q. s. ut f. pilul. gr. j, No. 240; and observes,—1stly. The pills must only be taken every other day. 2dly. They are not to be taken oftener than once in the day, and that immediately after dinner, a little water being drunk after them. 3dly. The patient commences by taking four pills, and increases the dose by two each time, so as to take thirty on the last day of treatment, which makes a grain and a half of sublimate at a time. 4thly. The large doses may be divided into fractions of five, six, and eight pills, swallowed one after the other. 5thly. If the pills are rejected by vomiting, an equal number is given a short time afterwards with two, three, or four drops of tincture of opium. 6thly. If colicky pains of the abdomen are complained of, three, four, or five hours after the dose is swallowed, from two to six drops of tincture of opium may be administered. 7thly. The treatment is continued during three times nine days, and no ordinary circumstances must be allowed to interfere with its full enforcement in all its points if we would be certain of a radical cure, though all the symptoms should have disappeared during the first half of the course. 8thly. Should

tered in doses of a quarter, a third, and sometimes of a half a grain a day for one or two months, is also a very efficacious remedy in venereal eruptions, and other symptoms of constitutional syphilis; but it is, in my opinion, a remedy which ought not to be employed until after mercurial ointment has been already repeatedly but ineffectually administered, and the necessity is felt for having recourse to some other preparation. The sublimate occasions salivation more rarely than friction with mercurial ointment; it is easily administered, not expensive, and it causes certain symptoms, and in particular, nocturnal pains in the bones, to disappear rapidly. But it has often, and justly, been charged with deranging the stomach, and, in some cases, with determining gastro-intestinal and pulmonary inflammations.

950. In the hope of obviating at least some of the bad effects of this remedy, without depriving it of its advantages, it has been proposed to dissolve it in water, and administer it in baths, hand and foot-baths, in lavements, and in gargles, or to employ it by way of inunction in combination with grease.

I have made many trials of the sublimate bath;<sup>3</sup> and in some cases, this mode of using the preparation has appeared to me to be of real efficacy; I have, for example, found it particularly useful among children, females, and persons whose skin was delicate. But I should never recommend the sublimate bath to be ventured on where the surface of the body was covered with numerous or extensive ulcers. Gargles of a weak solution of the sublimate, have appeared to me of service in ulcerated states of the throat, accompanied with little inflammation.

I have sometimes had recourse to mercurial *foot-baths*<sup>4</sup> in cases of syphilitic ophthalmia, in conjunction with mercury administered at the same time in other modes, which were, however, as I apprehended, incapable of acting in the same precise manner as the pediluvia.

I have never put mercurial *lotions*<sup>5</sup> or *lavements*<sup>6</sup> to the test of experiment.

I have tried frictions on the soles of the feet, with Crillo's *sublimated ointment*, the efficacy of which appeared to me very inferior to that of the common mercurial ointment.

The iodides of mercury,<sup>7</sup> combined with lard, and employed with so much success in friction against tubercular eruptions, are of peculiar

any especial cause, salivation for instance, render it imperative to suspend the treatment for some days, as soon as the reason for pausing is removed, the pills must be resumed at the number at which they were left off, so as to fulfil the whole period of four weeks. 9thly. Besides the pills, decoction of sarsaparilla must be given daily, and drank at intervals, particularly in the afternoon, either hot or cold. 10thly. The patient ought to be made to perspire slightly during the whole time of treatment, even on these days when the pills are not taken; he ought not to leave his room in winter, and only at noon in summer; he should be warmly clothed, and avoid exposure to damp and currents of air, not going near the windows; in short, he should take every precaution against getting chilled or catching cold, for a week or a fortnight after the cure is completed. 11thly. The patient should confine himself to half his ordinary quantity of food if he be a moderate eater, and to the third or fourth only when he is in the habit of eating much. He should take but little fluid, and not exceed a small roll morning and evening. 12thly. He may eat or drink what he pleases, with the exception of pork, goose, duck, game, cheese, acids and milk, and must be moderate in the use of spirituous liquors. 13thly. No local means should be resorted to for the purpose of accelerating the cure, farther than preserving the parts affected from the impression of cold air, and procuring a free outlet for any matter that may be formed.

<sup>3</sup> Sublimate baths, introduced by Baumé, and extolled by Caffé, (Avantages des bains mercuriels dans le traitement des maladies cutanées et vénériennes, 4to., Paris, 1815,) and by Wedekind, (Arch. gén. de méd., t. xxiii. p. 275,) have also been recommended in inveterate venereal cases, four drachms of corrosive sublimate, and the same quantity of muriate of ammonia, previously dissolved in water, being added to an ordinary tepid bath. F. M. B. Bonnardel has made use of this remedy in syphilitic and other arthritic complaints. (Gazette Médicale, t. ii. p. 418, 1834.)

<sup>4</sup> F. Tambone asserts, that by means of *mercurial pediluvia*, he cured twelve patients labouring under inveterate syphilis (Bulletin des Sciences Médicales de Ferrussac, t. xxii. p. 407). Verducci states, that he has employed mercurial pediluvia successfully in cases of chronic ophthalmia and ulcers of the throat. (Archives gén. de Méd. t. xxvii. p. 281.)

<sup>5</sup> Mattioli was the first who substituted *fomentation* with a solution of sublimate, for mercurial inunction. (De morbo gallico. Aphrod.)

<sup>6</sup> Royer. Diss. sur une nouvelle méthode de guérir les maladies vénériennes par les lavemens, Paris, 1764. Ferrand. Obs. sur les différentes méthodes de traiter les maladies vénér. avec par les lavemens Mercuriels. Narbonne, 1770, 4to.

<sup>7</sup> M. Bielt was the first, I believe, who employed the iodurets of mercury in the treatment of syphilitic eruptions. I have also prescribed these preparations in the same circumstances for several years, at the Hospitals of Saint Antoine and La Charité. I now make use, almost exclusively, of the dento-ioduret; the usual dose, internally, is the twelfth of a grain; externally, I employ it in proportions of one-twentieth or one-twenty-fourth in the composition of ointments.

utility in subduing induration of the spermatic cord, and certain glandular enlargements, which, in their appearance and progress, seem to partake at once of a venereal and a strumous character. In such circumstances, and where venereal eruptions exist at the same time, they may generally be employed in preference to any other preparation of mercury: their activity requires that their effects should be attentively watched. I frequently employ the deuto-iodide internally, and generally in doses of one-twelfth of a grain. I have several times observed transient inflammation of the *large* intestines supervene during its administration, but this always promptly disappeared by the suspension of the remedy, the use of which I did not resume till after an interval of several days. (a)

951. There are various other preparations of mercury, which have been employed with success in the treatment of the syphilides. I have myself made trial of several of these but a very few times, and of some of them I have never studied the action at all. Thus, calomel has been recommended<sup>1</sup> in its simple form, or combined with hemlock and aconite, with dulcamara, or antimonial preparations. But calomel so often produces salivation, even when combined with gentle aperients, that after having employed it in the papular syphilide complicated with iritis, I was induced to abandon its use, and substitute for it pills of mercurial ointment, or corrosive sublimate. Calomel blown upon ulcers of the cornea, in quantities of a grain daily, has often appeared to me to be of very great utility; I have ordered it to be drawn up the nostril with less evident advantage, in cases of ozæna. Some practitioners have recommended its being taken in this manner into the nostrils when not ulcerated, with a view to obtain the effects of its absorption; others have proposed to rub the gums and inner surface of the cheeks with calomel.

952. The bromide of mercury,<sup>2</sup> the cyanide of mercury,<sup>3</sup> and Hahnemann's soluble mercury,<sup>4</sup> appear to be remedies of undoubted power, and might very properly be substituted for the preparations which I have first and most particularly recommended, should the effects of these be found to be trifling, or not at all apparent; in my own prac-

(a) The iodides of mercury were introduced into therapeutical use by Bielt, and have since then been largely employed in the treatment of secondary syphilis. Of all the preparations of mercury, of all the means lauded in the treatment of secondary syphilis and especially syphilida, there are none, says M. Cazenave, that can compare with the iodides of mercury.

The entire value of this eulogy will be better understood by collating it with what the same author says of iodide of potassium. This salt, he tells us, acts sometimes with a promptitude which can only be compared with the effects of the proto-iodide of mercury. He has employed them both of late years, and with nearly equal success. My own experience with the iodide of potassium in tuberculous syphilide and ulcerated sore throat, induces me to place the utmost reliance on its rapidly curative powers in the diseases in question. M. Cazenave tells us, that his observation confirms the remark of Bielt, that opium combined with the proto-iodide of mercury neutralizes, in a measure, the effects of the latter; and hence he forbids the union under these circumstances. See next note.

<sup>1</sup> P. Clare ("A new method of curing Lues Venerea by the introduction of Mercury through the orifices of the absorbent vessels on the inside of the mouth," 3d edition, London, 1780), was in the habit of using calomel, in doses of half a grain, or a grain rubbed upon the mucous membrane of the mouth; this application ought to be repeated several times a day, and it is necessary to avoid drinking or spitting out the saliva.

Calomel, gum guaiacum, and black sulphuret of antimony, enter into the composition of Plummer's pills, which have been, and still are much in use.

<sup>2</sup> According to Werneck, the proto-bromate of mercury acts in the manner of calomel, and the deuto-bromate has medicinal properties analogous to those of corrosive sublimate. The first dose, ought not to exceed the twenty-fifth part of a grain, but should be augmented by two-twenty-fifth's every second day. (*Journal für chir. Augenheilkunde*, t. xiv., p. 215. Extrait dans le *Bulletin des sc. méd. de Ferrussac*, t. xxiv., p. 206.)

<sup>3</sup> The cyanuret of mercury, first employed by Chaussier, has been specially studied by M. Parent (*Note sur l'emploi du cyanure de mercure dans le traitement de la syphilis*. Gazette méd. in 4to. Paris, 1832, t. iii., p. 386). The dose is, in the first instance, the sixteenth part of a grain, and is gradually increased to half a grain. (*Ibid.*, p. 810.)

<sup>4</sup> Hahnemann's soluble mercury (the ammoniacal sub-proto-nitrate of mercury), has been employed in doses of from half a grain to a grain, generally combined with opium.

tice, however, I must say, that I have never had occasion to go beyond the preparations in general use. (a)

953. Experience having shown that, in very inveterate venereal cases, considerable advantage is often derived from combining the action of mercurial preparations with those of the sudorific woods, with purgatives, as well as with the preparations of antimony and arsenic, the result of this observation has been the introduction and very general use of several kinds of tisans, of several compound reme-

(a) "In the first stage or secondary form of constitutional syphilis, that in which the mucous membranes and skin are more especially affected, mercury finds its most numerous and rational advocates; nor does scrofulous complication prevent its use by some of the most experienced of these. In English and American practice, inunction and the blue pill, or calomel and opium, are more commonly directed. In France and on the continent generally, a marked preference is given to corrosive sublimate, combined with opium or aconite. I ought, however, to except M. Ricord and a few others who recommend at this time the proto-iodide of mercury. He begins with one grain for a dose, combined with opium or extract. cicut., the latter in quantity from three to five grains, and he carries the iodide as far as six grains in the day, but does not exceed this. Where there are much restlessness and irritability, no uncommon associates of constitutional syphilis, opium, extolled almost as a specific in the early times of the venereal disease in Europe, has been of late more appreciated for its curative virtues, in addition to its purely anodyne properties. As an adjuvant to mercury and iodine, it is worthy of all notice. I shall not pretend to deny the utility of the mercurial practice in secondary syphilis, but I can speak confidently after positive experience of the success attending the use of iodine in tincture, and of the iodide of potassium, with the compound syrup and decoction of sarsaparilla in cases of venereal disease, both of the tonsils and mouth, and in tubercular ulcerations—after mercury had been prescribed by those who preceded me in vain."—*Bell & Stokes's Lectures on the Practice of Physic*, vol. ii., p. 567.

To these remarks of mine I may add, that, they who are constitutionally lymphatic and anemic, or who, from long dissipation and destitution, are thrown into a cachectic condition, will be materially benefited by tonics, both medicinal and nutritive. Of the former, the iodide of iron will do double service, both by giving tone and removing, in a degree at least, the syphilitic disorder.

In syphilitic psoriasis and lichen, and in ulcerative psoriasis, lepra, tubercle, ecthyma and rupia, the iodide of potassium is both the safest and most efficient remedy. M. Herbert Mayo (*loc. cit.*), recommends it to be administered in doses of a scruple three times a day (for ulcerative syphilida of the skin); but it is proper to begin with small doses, giving at first five or seven grains only, and gradually increasing the quantity, which may thus be raised to half a drachm, with half a grain to a grain of iodine in combination. "Sometimes it will appear prudent to continue the use of the iodide in scruple doses three times a day for two or three months at a time; when it happens, that, although fresh ulcers are continually breaking out, while the first are healing, yet on the whole the patient's strength and general condition are progressively improving under the treatment. In other cases the influence of the iodide is temporary only, and to reacquire efficiency, it must be disused for a fortnight or longer, and this frequently." Opium is beneficial: first, by calming pain and giving sleep; secondly, by preventing the iodide of potassium from disordering the system. Similarly strong testimony to the curative powers of the iodide of potassium in secondary syphilis, including tubercular and other cutaneous eruptions, is borne by MM. Cullerier, Ricord, Cazenave, and Dr. Wallace. M. Ricord sometimes begins with the use of the iodide of mercury, as already described, but rarely for a long period; and he continues the iodide of potassium in gradually increasing doses. Very commonly he makes use of the latter alone, and relies on it, even after the tubercles have become ulcerated.

Mr. Mayo advocates the propriety of letting some cases of syphilitic psoriasis wear themselves out; and he intimates that when the disease is suspended by treatment, it returns after an interval, and its duration may thus be lengthened.

dies,<sup>1</sup> of many empirical formulæ, and of different plans of treatment generally, in some instances too highly extolled, in others too much depreciated.

954. The expense and want of cleanliness inseparable from the practice of mercurial inunction, independent of the salivation which this mode of administering mercury frequently occasions, the various bad effects attributed to the prolonged use of corrosive sublimate, and the less certain action of the other mercurial preparations, and a kind of prejudice against mercury in any shape, have combined to stimulate practitioners to look around them for other anti-venereal remedies. Of these the nitric acid, the subcarbonate of ammonia, certain preparations of gold, of antimony, and of arsenic, and several articles of vegetable origin, have been proved to be the most generally useful.

955. The *nitric*<sup>2</sup> and nitro-muriatic acids have been repeatedly recommended as anti-syphilitic in their action on the economy, and I have several times seen papular syphilitic eruptions disappear completely during the use of a nitric acid sherbet; but, as outpatients do not always present themselves at the hospital when they suffer a relapse, the trials I have made of this acid are too few to enable me of my own knowledge to assert, that it is adequate to accomplish a complete and permanent cure.

956. It has also been proposed to substitute *ammonia* and *subcarbonate of ammonia*,<sup>3</sup> for mercurial preparations in the treatment of syphilis; I have had considerable opportunities of trying the effects of these medicines, and although I have known some complete cures to result from their employment, I am inclined to regard them as less efficacious than mercury.

957. The preparations of gold<sup>4</sup> were also from a very early period recommended in the treatment of the venereal disease, but had fallen into almost entire disuse, when M. Chrestien, in 1810, again directed attention to their efficacy in certain cases.

958. I have seldom combatted venereal eruptions, or other syphilitic symptoms exclusively, by means of arsenical preparations;<sup>5</sup> but

<sup>1</sup> See, in the list of formulæ: *Arts*. Tisanes de Feltz, Tisane d'Arnould; Tisane Royale, &c.; decoction de Zittman, &c.

<sup>3</sup> Peyrilhe, "Remède nouveau contre les maladies vénériennes, etc.; ou essai sur la vertu anti-vénérienne des alcalis volatils," in 8vo. Paris, 1774. After a preparatory course of purgatives, baths and diluents, Peyrilhe prescribed a sudorific alkaline infusion, prepared by infusing for an hour, by gentle heat in a covered vessel, half an ounce of senna leaves, and four ounces of the leaves of the melissa officinalis in two pints of water. To twelve ounces of this infusion, four ounces of sugar, and a drachm or a drachm and a half of subcarbonate of ammonia were added. This dose was divided into four portions, of which the patient took one in the morning fasting, and one in the evening, four or five hours after dinner. This treatment was continued without interruption for eight days; the patient then paused for eight or ten days; during which time he confined himself to his ordinary beverage (a weak infusion of melissa); he then took an aperient, and recommenced the alkaline infusion. The treatment was then suspended and resumed two or three times. According to Peyrilhe, eighteen days continuance of the ammoniacal beverage suffice, in the greater number of cases, and thirty in those of a more inveterate description, to complete the cure. The dose of subcarbonate requires to be increased or diminished according to its effects upon the different systems of organs.

<sup>4</sup> Lecoq, so early as 1540, makes mention of preparations of gold. Horat speaks in high commendation of his "diaphoretic gold," a mixture of calomel, chlorate of gold, and a little gold in its metallic state. On the method of administering the preparations of gold, consult J. A. Chrestien. <sup>5</sup> Gmelin asserts, that arsenic is used in syphilitic cases by the inhabitants of Siberia. Zugenböhler (Hufeland and Himly, Journal des Prakt. Arzneykunde, 1809, fasc. 5).—Girdlestone (Lond. Med. and Physic. Journ. Feb., 1806).—Adair (Medical Commentaries of Edinb., t. ix. p. 35).—Kupperman, (Diss. de medicamentorum ex auripigmentis preparatorum prestantissimo usu medico, presses Bruchner, 1758, 4to.), have also mentioned the efficacy of arsenical preparations in venereal diseases.—See also Edinb. Med. and Surg. Journal, vol. vi. p. 56.

one of the remedies which I most frequently employ, the *tisane de Feltz*, contains a very small yet sensible quantity of arsenious acid in its composition, and I have become satisfied that this acid is not without its share in the general efficacy of the medicine. Fowler's solution and other arsenical preparations have also been satisfactorily proved to have been useful in certain cases of inveterate syphilis, after the disease had resisted the power of mercury.

I ought, however, to add, that I invariably prescribe the pills of mercurial ointment internally, at the same time with the arseniated decoction of sarsaparilla, or tisane of Feltz. This method of treatment, by which the effects of mercury and arsenic are combined, succeeds so perfectly in almost every instance, that it is, according to my experience, more efficacious than any other.

959. Several vegetable preparations have long possessed, and still enjoy an extensive reputation for their influence in subduing venereal symptoms. In the first rank of this class of remedies must be placed, the diet drinks, entitled *sudorific*, the active principles of which are extracted from sarsaparilla, sassafras, guaiacum, and smilax china; and next to them the decoctions of daphne mezereum, lobelia syphilitica, and arctium lappa.

960. The efficacy of the *guaiacum officinale*,<sup>6</sup> has been very unnecessarily called in question of late; a decoction of this substance, in large doses, is often indisputably useful, and has the advantage of being much less costly than that of sarsaparilla.

The employment of sarsaparilla<sup>7</sup> in venereal diseases, is also of very ancient date. The best mode of preparing the decoction, is to put two ounces of the root, without being split or washed, to steep for four and twenty hours in a pint of water; this quantity is then to be reduced one half by gentle boiling. The patient, being in bed, should take the half pint of decoction lukewarm, and sweetened with syrup of sarsaparilla, in three different doses in the morning fasting.

This root is the basis of the *tisane de Feltz*, and enters into the composition of almost all the compound vegetable drinks and decoctions, which have been found really useful in the venereal disease.

The decoction of the *smilax china*<sup>8</sup> is looked upon as less efficacious in general than those of guaiacum and sarsaparilla. I have myself used it but very little.

The infusion of the wood of the *laurus sassafras*,<sup>9</sup> combined with an equal quantity of the decoction of guaiacum, or of sarsaparilla, is

<sup>6</sup> It being generally the custom in France, to employ a combination of all the sudorific woods in the preparation of anti-venereal tisans, or decoctions, and as their action is almost always associated with that of mercury, it is necessary to turn to the writings of those authors who were in the habit of employing one or other of these kinds of wood exclusively, to obtain convincing proofs of their utility.

In this respect the observations of Oviedo, in Spain, of Poll, in Germany, and of Massa, in Italy, are perfectly conclusive. Poll asserts, that nearly three thousand persons, who had been reduced to the most deplorable condition, owed their cure to guaiacum. (De cura morbi gallici per lignum guaiacum.—Aphrodisiacus, p. 241.) Massa has described with much precision and detail, in his valuable work, the preparation of the decoction of guaiacum which was prescribed in large doses, as well as the strict regimen which the patient was required to observe during the use of this remedy, to which he attributes very great efficacy—an opinion which he supports by very full and conclusive cases (De morbo gallico.—Aphrod., p. 65). Ulrich von Hutten has also treated, with much attention and ample details, the manner of administering guaiacum, and dwells strongly on the necessity of following a very strict regimen during its use. His plan is, in fact, a *cura famis* (De morbi gallici curatione per administrationem ligni guaiaci. Aphrod., p. 275). Hunter considered this wood to possess great efficacy in syphilitic cases.

<sup>7</sup> Massa (De morbo gallico, cap. x., de radice salsæperillæ, etc.—Aphrod., p. 81), has described with much care the method of using it. From his time to the present, it has been customary to make infusions or long macerations of this root, which are afterwards concentrated and given as tisans. It is in this manner that the syrups of sarsaparilla and of Cuisinier, as well as the tisane de Feltz, rob de Laffecteur, etc., are prepared.

Mr. Richard Battley (Edinb. Med. and Surg. Journal, vol. xvi., p. 473), is of opinion, that the most active principles of this root reside in the cortical part, and that these are completely extracted by cold infusion. M. Hancock, a Brazilian physician, also satisfied himself, that a protracted process of boiling was very destructive of the medicinal effects of this substance.—(Journal de Pharm., t. xvi. p. 31.)

<sup>8</sup> N. Massa (De morbo gallico, cap. xii. in quo de radice Chinæ disseritur.—Aphrod. p. 95). Andrea Vesalius (De radice Chinæ epistolæ.—Aphrod., p. 585), A. Brassavola (Tractatus de radicis Chinæ usu.—Aphrod., p. 711), have all studied the action of this root very particularly.

<sup>9</sup> Before their conquest by the Spanish arms, the natives of Florida employed sassafras against syphilis. The Spaniards transmitted the knowledge they acquired of the properties of this plant to Europe in 1555 (Voyage de Francois Coreal aux Indes Occidentales, trad. de l'Espagnol, Amsterdam, 3 vols. 12mo., 1722). But it has not been made the subject of so many experiments as guaiacum, sarsaparilla and smilax china. A. Monavius has published a treatise on this subject (De ligno fœniculato sive sassafras, 1582). Joannes Varandæus (Tractatus de elephantiasi seu lepra, de

often more readily borne by the stomach than either of these preparations singly, and in this point of view may be considered as of real utility; but sassafras is in general considered as a less efficacious medicine in venereal eruptions, than guaiacum and sarsaparilla.

961. Opium<sup>1</sup> has never appeared to me to possess any curative influence on venereal eruptions, when administered internally; but when applied externally to certain ulcers, and particularly to those with sprouting surfaces, it expedites their cure in a remarkable manner. Farther, in allaying the pains of the bones and joints which frequently accompany venereal eruptions, and in procuring sleep to patients exhausted by long and incessant suffering, opium contributes powerfully to aid the action of the general curative means employed. Indeed I rarely think of treating constitutional venereal symptoms, without administering opium at the same time. In fine, when patients have suffered from the use of mercurial medicines, and symptoms of nervous or gastro-intestinal irritation intervene, the employment of opium will be found beneficial during the whole of the interval in which the mercurial treatment is suspended.

962. The anxiety to find substitutes among our European vegetables for the exotic woods and roots, particularly sarsaparilla, the expense of which is so great as to place it beyond the reach of the poorer classes, the popular notions of the virtues of several of the more common herbs in some districts, and the adoption of these notions by practitioners, have led to numerous experiments, the results of which, however, are not thoroughly determined.

Among the vegetable substances thus examined, the following have been the subjects of most frequent experiment, viz.:—*aconitum napellus*;<sup>2</sup> *anemone pratensis*;<sup>3</sup> *astragalus exscapus*;<sup>4</sup> *arctium lappa*;<sup>5</sup> *buxus sempervirens*;<sup>6</sup> *lobelia syphilitica*;<sup>7</sup> *conium maculatum*;<sup>8</sup> *climatis recta*;<sup>9</sup> *juniperus sabina*;<sup>10</sup> *daphne mezereum*;<sup>11</sup> *gratiola officinalis*;<sup>12</sup> *carex arenaria*;<sup>13</sup> *saponaria officinalis*;<sup>14</sup> &c. But the well established sufficiency of mercurial preparations in combination with the use of the sudorific woods, in subduing every variety of venereal symptom, has left me no inducement to make trial of the above-named articles of the materia medica, always excepting hemlock, which has appeared to me to be of evident service in cases of syphilitic eruption accompanied with pain or ill-conditioned ulcers, and the mezereum bark, the very active decoction of which is of unquestionable use in the squamous syphilides, complicated with pains of the bones.

lue venerea et hepatis, Genevæ, 1640, 8vo.), remarks, with truth, that sassafras is especially serviceable in cases of syphilitic cachexia.

<sup>1</sup> Schoepff (Schreiben von der Wirkung des Mohnsafts in der Lustseuche, Erlangen, 1781, 8vo.), made known the excellent effects obtained by Nooth, by prescribing opium in syphilis; they have since been studied by Carminati, (Opuscul. Therapeut., vol. i. p. 6,) by Pasta, (Della facoltà dell' opio nelle Malattie Veneree, Bergamo, 1788,) and Rudolph, (Diss. opii in luis venereæ sanatione efficacia, Erlang., 1792.)

<sup>10</sup> Quarin. Animadv. Pract. cap. xvi. de morbis venereis, p. 190 (combined with antimony, formula 43).—The bark and wood of the box-tree were anciently recommended by Leo Africanus, Brassavola, and Auger Ferrerius.

<sup>11</sup> Russel has very strongly recommended the daphne mezereum against exostosis and periostosis, (Méd. obs. and inquiries, vol. iii. p. 189,) and Cullerier has found it efficacious in certain venereal eruptions.

<sup>12</sup> J. Kostrzewski, (Diss. de gratiola, Vieuna, 1775, 4to., fig.), says that the internal use of this plant cures venereal ulcers of the nose and throat, nodes of the bones, &c. Dehaen, in venereal complaints of long standing and bad character, used a mixture consisting of three grains of sublimate, six ounces of elder rob, two drachms of the extract of gratiola, and one drachm of extract of aconite. The dose was a teaspoonful two or three times a day, and the patient was made at the same time to take an infusion of althea root, and veal broth.

<sup>13</sup> Gleditsch, Murray and Reuss propose to substitute the roots of the *carex arenaria* for those of sarsaparilla, in consequence of the moderate price they bear, and even their greater efficacy.

963. *External treatment*.—Independently of the means calculated to subdue the general venereal infection of the system, there are others which are especially applicable to divers kinds of eruptions, ulcers, concomitant symptoms, &c.; these are almost always external or topical applications, which are generally limited in their operation to effects of a merely local nature, but which, nevertheless, do occasionally extend their influence to the constitution at large.

964. *Syphilitic exanthema*, the *vesicular psyracious*, the *pustular* and the *simple papular* forms of syphilitic eruption, always disappear under the influence of general treatment, with which simple or vapour baths may be occasionally associated.

965. The *phlyzacious pustular syphilide* and *syphilitic rupia* require particular local treatment in addition to the general measures prescribed. When the pustules are very much crowded, and the skin in the intervals between them is inflamed, emollient tepid baths, soothing cataplasms, and the application of pieces of perforated linen rag spread with some mild mercurial cerate, check the progress of inflammation, and prevent the formation of larger ulcers if the principal seat of the disease be the inferior extremities, the shoulders, &c.

966. The resolution and cure of *moist* and *flattened tubercles* developed in the neighbourhood of the genital organs, or on the margin of the anus, are singularly expedited by covering them with dressings of soft linen, spread with a mild mercurial cerate.

Gentle frictions, with an unguent of the *proto-iodide* and *deuto-iodide of mercury*, or of the *iodide of sulphur* over the large non-ulcerating tubercles which sometimes occur on the scrotum, the superior and internal surface of the thighs, under the armpits, on the face, &c., almost always and very speedily succeed in discussing them. These large tubercles are also occasionally very promptly made to disappear by the aid of fumigations of cinnabar,<sup>15</sup> which have also been used in other forms of venereal affection.

The local treatment of ulcerating tubercles is very similar to that proper for syphilitic ulcers.

967. With regard to syphilitic *maculae*, whether primary, or secondary to other forms of venereal eruption, they may be quickly made to fade and gradually to disappear, by being anointed with weak mercurial ointment, or the use of a liniment of muriatic acid.

968. The *squamous* syphilitic affections are advantageously modified by fumigations of cinnabar, used alternately with vapour baths; but they almost always get well without any kind of specific local treatment, by merely cleansing the surface of the skin by the use of the tepid bath from time to time.

969. The treatment of *ulcers* of syphilitic origin is much more complicated, and requires to be modified according to their state, their standing, and the various circumstances which may have accidentally contributed to ameliorate or to subdue the inflammatory actions of which they are the seat. Emollients and bleeding are only indicated in those cases where, after walking or other exciting causes, venereal ulcers of the inferior extremities have become painful, and their bases the seat of a tumefaction, which extends in a greater or less degree beyond their circumference. In those individuals whose general constitution did not appear to have suffered, I have repeatedly practised bleeding in cases where the skin around the trochanters, and the external parts of the shoulder, was thickly beset with small round ulcers, intermixed with numbers of subcuta-

<sup>15</sup> Si unctiones non sanant, fortissimum medicamen est *suffimigium* (Massa. De morbo gallico.—Aphrodisiacus, p. 101). Massa used half an ounce of cinnabar, and two drachms of oil of turpentine, which were placed on a pan over hot coals, in a kind of tent (*tentorium*), in which the patient remained for a period short or long in proportion to his strength. Mattioli, Lobera, Fallopius, Rondeletius, etc., have also recommended fumigations of cinnabar, a subject on which Lalouette (Anc. Journ. de Méd., t. xlv. p. 195), and Werneck (Bull. des sc. Méd. de Férussac, t. xxii. p. 406), have published some interesting observations. When the fumigation is *general*, the cinnabar is placed on a porcelain or earthenware tile, exposed to the flame of a spirit lamp, and the vapour is confined under a cloak of oil-cloth which envelops the patient. Each fumigation, performed at night, in a room at 18° of Reaumur, lasts for a quarter of an hour, after which the patient is put to bed. Eighteen or twenty fumigations, of from twenty to forty grains (Werneck) suffice for a cure. I generally employ a much larger quantity of cinnabar at the hospital of La Charité; half an ounce of cinnabar is thrown upon a hot plate, and the vapour rises into the fumigating box in which the patient is enclosed. Massa projected the cinnabar on hot coals; I have employed the cinnabar successfully in this manner, in *local* fumigations directed to the nose or face; but in this case the sulphuret of mercury is in great part decomposed, and the fumigation contains mercury in a state of vapour and sulphurous acid gas.

neous tubercles, and these regions were the seat of pretty severe local pain and puffing of the cellular membrane; I have almost always found the blood let, in such circumstances, buffy. I have also on several occasions had recourse to bleeding and emollient applications in cases where similar subcutaneous tubercles, developed in groups on the calf of the leg, formed hard irregular masses under the skin, from whence knotty cords extended in different directions into the cellular substance around. When there are many small ulcers very much crowded together, on the top of the shoulder, for example, and the skin is detached to a considerable extent after the expulsion of the sloughs at their bottom, it is scarcely ever either necessary or proper to divide the kind of bridges of integument which separate the different ulcerated orifices from one another; I have often been struck by the rapidity with which these parts become reunited, and cicatrize under the influence of mercurial treatment. It is therefore sufficient in the greater number of cases to dress the ulcers with pledgets of perforated linen, spread with mercurial cerate, and to apply plenty of soft lint over all. When the eruption occurs on the lower extremities, slight compression with a roller is an after means that contributes powerfully to the recovery of the parts affected.

It is generally considered sufficient to dress the slight superficial ulcers of the flattened species of tubercles with mercurial cerate; this dressing is also mostly applicable to simple and circumscribed secondary venereal ulcers, which show no tendency to spread rapidly either in breadth or in depth. When fungous granulations arise on the surface of these sores, it is advisable to touch them lightly with nitrate of silver, or they may be sprinkled with calomel, and the cure is then usually accomplished without any other local attention. Phagedenic ulcers imperiously require that their condition should be modified by topical applications of greater energy. Frequent experience has demonstrated that the greatest advantage is often derived from touching the surface of these ulcers with a hair pencil or dossil of lint dipped in the solution of the *acid nitrate of mercury*.<sup>1</sup> In some cases it is necessary to repeat this caustic application once or oftener, if not to the whole extent of the ulcer, at least to several points of its surface. *Nitric acid*, a strong solution of nitrate of silver, and other caustics, have also been employed in similar circumstances; but they are less frequently used in the present day than the acid nitrate of mercury, with which cauterization, either deep, or superficial, may be made, and apparently with better effect than with any other species of escharotic.

When ulcers of this kind occur on the face, and erysipelas supervenes, whether in consequence of the use of escharotic remedies, or spontaneously, the inflammation, if it be not accompanied with general symptoms of a very serious nature, must be left to itself; for it has frequently been noticed that after the subsidence of the erysipelas, these ulcers advanced more rapidly towards cicatrization, and that tubercles, when any existed in the neighbourhood of the region affected, afterwards disappeared with great celerity.

The ulcers of syphilitic rupia and those that succeed the large tubercles which become perforated in their centres like boils, are generally found covered with prominent crusts, adhering more or less firmly, which it is advisable to detach by means of cataplasms and warm baths, in order that the ulcers they conceal may be properly dressed; but it is in vain attempting to obtain the cicatrization of these by the use of escharotics, unless the constitutional disease, of which they form but one of the symptoms, has been previously subdued by appropriate medication.

Serpiginous ulcers require general measures for their cure, much more than any form of topical application, however energetic. It is familiarly known, indeed, that they constantly cicatrize spontaneously at one extremity whilst they continue to make progress at the other; and in several attempts which I have made by cauterizing deeply the edges of the ulcerating extremity, and even interesting the healthy

skin, with a view to check the morbid processes, I have had the mortification to see the parts go on ulcerating beneath the eschar, and the evil continue to spread and furrow the skin till its progress was arrested by a recurrence to general constitutional treatment.

970. When *excrescences* can be conveniently attacked with cutting instruments, it is advisable, in the majority of cases, to remove them with flat curved scissors, and immediately to cauterize the small wound which results from this trifling operation with nitrate of silver. This excision ought in general only to be practised after the constitutional affection has been subdued, and when there is no longer reason to fear that the excrescences may be reproduced by the cause which gave them birth in the first instance. When these excrescences are only slightly elevated above the level of the skin, they may sometimes be made to shrink, and disappear by the use of a strong opiate lotion, a strong solution of corrosive sublimate, the application of the powder of sabine leaves, &c. It is possible to remove pediculated excrescences only with the ligature; and even in the cases to which this means is applicable, it is less certainly efficacious and more tedious than excision.

971. Syphilitic *onychia*, independently of the general and specific treatment which it above all things requires, may possibly have occasioned such an alteration in the secreting matrix of the nail, as to make some form of local treatment indispensable. In ordinary cases, it is sufficient to envelop the extremities of the diseased fingers in emollient cataplasms, and subsequently to dress them with soft lint spread with a mild mercurial cerate. When ulceration has occurred about the roots, or along the edges of the nails, and they are completely detached from their matrices which have ulcerated, become fungous, or are surmounted on various points of their surface by irregular horny productions, it occasionally becomes necessary to extirpate these horny growths, and even to excise the matrices of the nails entirely.

With regard to the fall of the nails (*alopecia ungueale*), and the other alterations they undergo from a syphilitic cause, these require nothing beyond the general constitutional anti-venereal treatment, and particular attention to local cleanliness.

972. In *venereal alopecia* or baldness, it would be in vain to attempt to provoke the secretion of the hair, by the use of stimulating or aromatic unguents until the general affection had been destroyed; this result once obtained, the secretion of the hair is re-established of itself.

973. I shall confine myself to a few remarks on the treatment of the venereal symptoms which almost always accompany the syphilitic eruptions. Several of these symptoms disappear under the influence of the general means employed against the eruption; there are nevertheless certain symptoms which require measures of treatment peculiar to themselves.

Ulcers of the mouth and throat, in their first stages, and particularly when they have been preceded by fever, are advantageously modified by bleeding, emollient applications round the neck, soothing gargles, and a bland or milk diet for some days. These ulcers, when no longer painful, or when in their chronic state, sometimes heal rapidly under the constant use of mercurial gargles, or even of occasional slight cauterizations with the acid nitrate of mercury.

The acute syphilitic inflammatory affections of the larynx, always extremely serious, for I have seen them produce orthopnea and suffocation, just as simple oedema of the glottis does, require to be vigorously and immediately combatted by general bleeding, followed by the application of leeches to the fore part, and of a blister to the nape of the neck, aided by stimulating baths or sinapisms to the feet, and an emetic of tartar of antimony administered within the first twenty-four hours of the attack. In a case of this kind, I have seen the treatment recommended dissipate symptoms of suffocation of such urgency, that a celebrated surgeon was on the point of performing tracheotomy for their relief. When, on the subsidence of the danger, the voice continues considerably altered, and there is a good deal of laryngeal wheezing, whether these symptoms have preceded the attack of suffocation, (which is most generally the case,) or have succeeded it, and there seems reason to apprehend their continuance, two small issues should be applied to the region of the larynx; this last remedy is also applicable in cases of syphilitic caries of the cartilages of the larynx.

<sup>1</sup> Godart (Diss. sur le nitrate acide de Mercure, 4to., Paris, 1824).—Swediaur (op. cit. t. ii. p. 381).—Hatin (Nouvelle Bibliothèque Méd. 1826, t. iv. p. 188). The deuto-nitrate of mercury entered, in the proportion of the nineteenth part of a grain, into the preparation of the *Sirap de Bellef*, a remedy which is not to be relied on, and which varies in its composition, according to its mode of preparation, its age, &c.

Ward's white drops, celebrated in England, are a solution of one part of the crystallized proto-nitrate of mercury and ammonia, in three parts of rose-water; dose, from two to three drops.

In *ozæna* and caries of the bones composing the nasal fossæ, great dependence should be placed on the insufflation of calomel as a topical means of arresting and curing the mischief.

Syphilitic lachrymal tumours and fistulæ ought not to be operated upon till after a complete mercurial course, by which means I have known several cases cured: moreover, without this preliminary treatment, the operation might be followed by a recurrence of the evil and other serious consequences.

974. Patients attacked with syphilitic *ophthalmia* and inflammation of the *cornea*, and of the *iris*, ought to protect their eyes from the light. Blood-letting should be performed once or oftener, and, in cases of a serious nature, blood should be taken by cupping from the mastoid or temporal regions, and a blister applied to, or a seton inserted into, the nape of the neck. The patient should take in the morning fasting, two drops of croton oil, mixed up in twelve drops of elderberry rob; in some cases perfect abstinence from every kind of solid food should be observed during two or three days, and in all others the very lowest diet ought alone to be allowed.

The inflation of calomel, and collyria containing the *vinum opii*, or extract of belladonna, are often of great service in leading syphilitic inflammatory affections both of the external and internal tissues of the eye to a happy termination.

975. Vapour baths, aromatic baths, and fumigations of cinnabar, and flying blisters, employed either alone or in combination with the internal exhibition of opium, have appeared to me the most powerful of all the therapeutic agents we possess in allaying pains of the bones and articulations. The administration of opium and sublimate in combination, is one of the best means for effecting their permanent cure.

976. With regard to *swellings of the periosteum*, recent and painful *exostoses*, and to subcutaneous gummy tumours, local blood-letting, by the repeated application of leeches, is the most prompt method of procuring relief. Blisters employed as *rubefacients* (*vesicatories volans*) are sometimes useful; but the relief procured by these means can only be rendered permanent by submitting the patient at the same time to a general mercurial course, in combination with arseniated or slightly purgative sudorific drinks.

977. After the removal of the exciting cause, syphilitic *caries* of the bones of the extremities is sometimes arrested in its progress by alkaline lotions if the affection is superficial, or by cauterizations with the concentrated mineral acids, or the application of the actual cautery, if the disease is more deeply seated.<sup>1</sup>

978. The treatment of the syphilitic cachectic state of constitution presents peculiar difficulties: this condition is frequently accompanied by chronic inflammation of the large intestines, or by a diarrhœa which demands the use of emollient hip-baths, *lavements* of poppy-heads, or small doses of opium, several times a day. Too often, also, it is complicated with chronic enlargements of the liver, which must be combated by occasional mercurial frictions of the belly and right hypochondrium.

The diet in this cachectic state ought to be nourishing, and should consist of mutton, beef, and other good meats, broiled or roasted, taken twice a day; a light decoction of sarsaparilla and guaiacum will be found to make by no means an unpalatable beverage, which may be drunk at meals, and in the morning and evening a cup of a stronger and more concentrated decoction of the same substances may be taken. Should nocturnal pains or want of sleep be complained of, a dose of opium should be administered at night.

If, after a month of this treatment, the state of the constitution appears ameliorated, should there still be any traces remaining of syphilitic eruptions or ulcers, the radical mercurial treatment may be cautiously entered upon. In fine, I have several times seen the constitution materially strengthened during convalescence, by the patient being made to take two sulphur baths weekly.

979. It still remains for me to mention some particular modes of treatment applicable to pregnant women, nurses, and new-born infants. A pregnant woman affected with syphilis should be treated so much the more particularly as her infant is exposed to feel the fatal effects of this cruel disease; I am even of opinion that a pregnant woman after being cured of primary symptoms ought to be made to

undergo mercurial treatment, upon the presumption that she is constitutionally infected, although this does not appear from any external manifestation. Pregnant women bear the pills of mercurial ointment, and the use of the *tisane de Feltz*, prepared after the formula of the Hôpital de la Charité, without any apparent derangement of their health. Mercurial fumigations to the genital organs, vapour-baths, and prolonged and repeated sublimate baths ought not to be recommended to them.

980. When a mother suckles her child, and both are affected with the venereal disease, it is sufficient to subject the mother to anti-syphilitic treatment, the curative effects of this being transmitted by the milk of the mother to the child, and rendering it unnecessary that the child should be treated directly. This well-demonstrated fact has induced several practitioners to treat children, who are weaned or suckled by artificial means, by feeding them with the milk of a goat or an ass which has been subjected to mercurial inunction.<sup>2</sup> I have never had occasion to administer mercurial ointment internally to children; I have no doubt, however, but that this might be done successfully, by reducing the dose to about an eighth part of that which is usually prescribed for an adult.

981. Finally, whatever plan of treatment may have been adopted, it is necessary to continue it<sup>3</sup> for a fortnight at least, and sometimes even for a month after the complete disappearance of the symptoms. The cicatrization of a syphilitic ulcer should only be considered complete when all induration has disappeared from beneath and around the cicatrice. The yellow or livid spots which syphilitic pustules, and sometimes syphilitic tubercles leave behind them, are not a symptom of general infection, for they disappear of themselves, in the course of time.

#### History and particular Cases.

982. Our knowledge of venereal eruptions dates from the appearance of the great epidemic of the fifteenth and sixteenth centuries; all the forms now described with so much care were then well known, and their characters briefly but clearly indicated. Massa, so remarkable for the accuracy of his descriptions and the excellence of his therapeutic principles; Sorella, so interesting for his particular cases (*consilia*); Fallopius, whose treatise presents a more complete picture of symptoms and their treatment; and Fernelius whose exposition and division of secondary symptoms are so elaborate, deserve to be consulted above all the writers of their age. Our information on the most efficacious modes of treatment dates also from this period; and the various effects of these were so much the better appreciated, as the extent, the violence and long continuance of the epidemic, afforded opportunities of repeating them on immense masses of individuals. The collection<sup>4</sup> of the principal works published on this memorable epidemic is even now one of the best sources from whence accurate and extensive knowledge of the nature and treatment of venereal diseases is to be acquired.

Forestus,<sup>5</sup> a learned observer, has gathered together a great number of particular facts relative to venereal diseases. Schenck,<sup>6</sup> in a very erudite and methodical work, the fruit of most laborious research, has also collected several rare cases which are well worth consulting;

<sup>2</sup> This plan, proposed by Levret, (*L'art des accouchemens*, etc., 8vo. Paris, 1766.) has been generally approved; *Journal de Méd.*, t. lxi. pp. 290-64, p. 1.—Swediaur, op. cit. vol. ii. p. 120.—Gardien. *Traité d'accouchemens*, etc., 8vo., vol. iv. p. 201.

<sup>3</sup> Massa relates several cases of constitutional syphilitic disease, the treatment of which had been continued for fifty days. Several cotemporary authors restricted the patient to a very low diet, during several months after the disappearance of the symptoms. These opinions still continue to influence practice. Hunter considers it necessary to continue the treatment for a fortnight in the greatest number of cases, and for three weeks or a month, when the symptoms have disappeared very rapidly. According to Swediaur, the treatment should be continued for nearly two months in ordinary cases, and for three or four months in more serious ones. M. Dupuytren advises a continuance of the treatment for as long a time afterwards as had been required to cause the symptoms to disappear.

<sup>4</sup> *Aphrodisiacus*, sive de lue venereâ, &c. Ab Aloysio Luisino edito. fol., Lugduni Batavorum 1728.—Grüner. (*Chr. Gottfr.*) *Aphrod.* sive de lue venereâ; in duas partes divisus, etc., fol. Jenæ, 1789.

<sup>5</sup> Forestus. *Observ. curat. medic.*, t. ii. lib. xxxii. de lue venereâ, p. 519, fol. Rothomagi, 1653.

<sup>6</sup> Schenck. *Observ. med. rariores*, lib. vi., de lue venereâ, fol. Lugduni, 1644.

<sup>1</sup> Boyer. *Traité des Maladies Chirurgicales*, 8vo. Paris, 1814, t. iii. p. 475.

Astruc,<sup>1</sup> too, has dedicated several of his pages to the consideration of venereal affections of the skin and of its dependencies.

Hunter,<sup>2</sup> whose works and opinions have exercised so great an influence upon the views entertained respecting syphilis, says very little on venereal eruptions, and only regards those as truly syphilitic in their nature which require the use of mercury for their cure. Swediaur,<sup>3</sup> who also has not given all the attention they deserve to eruptions of the skin, assures us that a decoction of the husks of the walnut is very effective in several of them, in which the best remedies fail, he says, if not combined with the use of the tepid or vapour bath.

A. L. Petit,<sup>4</sup> who, under the name of pustules, comprised all venereal eruptions, has divided them into *dry* and *moist*, *scaly* and *scabby*, &c. Cullerier<sup>5</sup> and his pupils<sup>6</sup> preserve these species and describe them with more care and precision. M. Alibert classes them all under the name of *syphilides*, and gives representations of several of them of great accuracy;<sup>7</sup> but it must be acknowledged that it is only since Willan's classification<sup>8</sup> has been employed in their study, that their nomenclature, their form, their appearance in different stages, and their diagnostic symptoms, have been shown with all the desirable exactness and precision.

Dr. Carmichael has more particularly studied the syphilides under one point of view, namely, that of their relation to primary symptoms. Close observation of a great number of cases and the almost unanimous testimony of the profession, do not allow me to adopt his theoretical notions, although I acknowledge the merit of his descriptions, and the value of his views in regard to the treatment of primary and secondary venereal symptoms, as well as of his remarks, with reference to the general and constitutional phenomena which accompany them.

Much time has been spent upon inquiries into the origin of syphilis, and the nature of its cause, or of the venereal *virus*. As to the different modes of treating the disease, particularly the simple mode, and that with a thousand known and unknown remedies which have been boasted of as capable of destroying it in all its forms, I refer to the works of Astruc,<sup>9</sup> and to the dictionary of Cooper,<sup>10</sup> for an account of those most worthy of notice, and shall confine myself here to the simple mention of the best works, recently published in France on this subject; namely, those of MM. Delpech,<sup>11</sup> Jourdan,<sup>12</sup> Desruelles,<sup>13</sup> and Devergie.<sup>14</sup>

CASE CXLII.—*Syphilitic, phlyzacious pustules, terminating in ulceration, inflammation of the lungs*.—A child, five and twenty months

old, was admitted to the *Hôpital des Enfants* on the 16th of March, 1825. The parents had already lost one child which had been affected with violent ophthalmia and ulcers of the face; this one, brought up by hand, had thrived well till it reached the age of nine months. At this period several ulcers appeared on the body and were cured by the use of the tepid bath, and a salve of the composition of which the parents are ignorant. In the month of February, 1825, inflamed pustules of about a line in diameter, appeared on different parts of the body of this child, and particularly on the belly, on the buttocks and genital organs, which, after becoming filled with a whitish pus, ulcerated.

On the 29th of March a great number of ulcers, with grayish bottoms, and sharply defined edges, appeared on the hypogastric region, the genital organs, the buttocks and the insides and outsides of the thighs; some of these were oblong, others circular; some, of one line in diameter, others of two, three, or even more. Several ulcers of the same kind, but isolated, and few in number, were developed on the arms, the hands and the chest; in other parts small cicatrices, around which the skin was violet-coloured and furfuraceous, were seen. From the time of entering the hospital, the child's skin was always hot, the pulse frequent, the thirst great: it expressed its sufferings by crying continually.

After eight-and-forty hours, rather profuse diarrhœa came on (bran baths, gum-water for drink). For the last three days the ulcers had been dressed with soft lint, and a perforated linen rag, spread with mercurial ointment, and had assumed a better appearance.

March 30th.—The same general state; pulse very frequent; moaning; cough; rather profuse diarrhœa. Some of the ulcers had become covered with whitish eschars. A mucous rattle was heard in the whole of the posterior parts of the two lungs. March 31st.—The breathing is short; the weakness extreme, profuse diarrhœa continues; the extremities became cold, and the child died without convulsions at five o'clock in the morning of the 1st of April. *Section cadaveris* in the morning of the 2d of April. On the posterior parts of the body, on the region of the loins and buttocks, on the genital organs, on the hypogastric region, and on the insides and upper parts of the thighs, the ulcers of which I have spoken were seen; they were uneven and sharply cut in the edges, as if with a pinking-iron; some were isolated, others had united or very nearly so; they were generally deep and implicated the whole thickness of the skin. The subcutaneous adipose tissue in the seat of the ulcers was injected; the skin in the region of the loins and buttocks was redder than that of the hypogastrium and of the insides of the thighs; on other parts of the skin, small circular cicatrices appeared, proceeding from old ulcers. On the hairy scalp in the left parietal and frontal regions, several yellow incrustations were discovered. Fibrinous concretions filled the superior longitudinal sinus; the blood in the other sinuses was either fluid or simply coagulated. The brain and its investing membranes were healthy, the cineritious and white substances of their natural consistence; there was a little serum in the lateral ventricles. The cerebellum was healthy. The larynx, the trachea and the bronchi were the same. The inter-bronchial glands of the right side were tubercular and of small size. Both lungs were of a pale white colour. The superior and inferior lobes of the right lung and the posterior part of the left lung were gorged (engorgés). The left ventricle of the heart was twice the thickness of the right one. The liver, the spleen, the mesenteric glands, the stomach and intestines, were in a healthy state; some red spots appeared on the descending colon. A thick and whitish mucus had accumulated between the glans and the prepuce.

CASE CXLIII.—*Eruptions of flat tubercles, depressed in their centres, several of which were excoriated in their circumference; syphilitic* remarks on the syphilides and their treatment inserted in the *Journal Hebdomadaire* and other French periodicals, may be consulted with advantage. (a)

Militaires, 8vo. Paris, t. xxv. et xxvii.), has published the results of particular experiments made on a great number of patients; these experiments have proved the promptness of the cure of primary symptoms by simple antiphlogistic treatment.

<sup>14</sup> M. N. Devergie. Clinique de la maladie syphilitique in 4to. Paris, 1826, et 1832. A work rich in cases carefully detailed, and represented with extraordinary accuracy in a magnificent atlas.

The memoirs of Messrs. Abercrombie, Ferguson, Rose, Guthrie, Hennen, Thomson, Baco, &c.; the report upon the *cura famis*, &c., in the German journals, and certain

*exanthema, rapid cure by Sedillot's pills.*—A waiter at a wine shop, of a good constitution, sanguine temperament, born of healthy parents, and twenty-five years of age, contracted for the first time, in 1830, a syphilitic disease, characterized by a chancre on the prepuce, which appeared five or six days after having had intercourse with a woman of the town. The chancre was dressed with strong mercurial ointment, and subsequently cauterized with nitrate of silver.

A general mercurial course was begun immediately; but the chancre being healed up by the fifteenth day, the patient discontinued taking the bichloride of mercury, the preparation prescribed for him. Since 1830, this man did not contract any new venereal disease; in 1834, during the month of May, a number of prominent tubercles appeared on the glans, on the prepuce and in the groins; and shortly afterwards similar tubercles made their appearance on the forehead and hairy scalp also; no treatment had been attempted when the patient entered the Hôpital de la Charité.

Prominent rounded tubercles of the size of a silver three-pence and of a coppery colour, were then visible on the corona glandis, on the prepuce, on the scrotum, on the groins, and about the verge of the anus; those of the scrotum and verge of the anus were excoriated; on one of the groins a brownish exudation had taken place between the dermis and epidermis; the epidermis was not destroyed but merely raised by the fluid exhaled over the surface of the tubercles. Tubercles of very similar character appeared on the forehead and hairy scalp; those of the forehead formed a sort of wreath which extended from one temple to the other, following exactly the line of the roots of the hair; two tubercles only were situated out of this line in the middle of the forehead. All these tubercles, of a circular form, with a coppery and prominent surface, and in general depressed in their centres, were nearly of the same size as those of the groins. A small ulcer or a slight scab of a curved form, was perceived on some of these tubercles, principally towards their circumference, sometimes occupying only the third or the half of their extent. The epidermis covering the remainder of the tubercle, could be raised and removed with the point of a needle.

The tubercles on the hairy scalp, scattered, and few in number were less prominent; they were perceptible by their coppery colour, and the circumscribed tumefaction of the dermis of the spot which they occupied. None of these tubercles occasioned either itchiness or sensations of smarting.

On the body and extremities there were several rosy red spots, which did not rise above the general level of the skin; they were some what larger than a lentil, of a round form, pretty near to each other, unaffected with desquamation, disappearing when pressed upon long by the finger, and separated by narrow spaces, where the skin preserved its natural colour. These spots, more numerous on the upper than on the lower limbs, were of a deeper colour on the latter than on the former; they were not accompanied with itchiness, and the patient, who had not remarked them, could not inform us how long they had existed. This man did not experience any pain in the bones of the extremities; the throat had never been sore; the sleep and appetite were both excellent, and he had no symptoms of a febrile nature. The patient took three of Sedillot's pills every day, with the *tisane de Feltz* as a drink. The tubercles of the glans were dressed with mercurial ointment; baths were administered from time to time, and the patient was put upon the half hospital allowance. From the eighth day the exanthematous eruption had disappeared; the scabs which covered the tubercles were loosened; and the tubercles themselves shrunk; those which were excoriated were cicatrizing, and several were covered with a new epidermis; on the fifteenth day, the tubercles no longer rose above the surface of the skin, and nothing but coppery blotches remained on the points which they had occupied; the patient was not salivated, and experienced no inconvenience from the treatment. On the 23d of July he was well, and requested his discharge; he was advised to continue the treatment for some time longer, although all symptoms of infection had now disappeared.

CASE CXLIV.—*After more than one venereal infection, clusters of prominent tubercles, and ulcers of the leg covered with scabs: cure, by Sedillot's pills, and the tisane de Feltz.* A \* \* \*, thirty years of age, of a good constitution and sanguine temperament, was affected with

gonorrhœa at the age of eighteen; the discharge ceased at the end of a month after antiphlogistic treatment. Four years ago, this man had a bubo, which suppurated, and healed without mercurial treatment; and two years since, after an impure sexual intercourse, he contracted a chancre, which spread over a considerable portion of the glans, and destroyed the frenum.

The patient was treated by means of mercurial inunction, and the chancre healed at the end of two months. Shortly after its cure, prominent tubercles made their appearance on the fore part of both legs. A \* \* \* underwent a second course of mercury, by pills containing the bichloride of mercury; the ulcerated tubercles cicatrized, became depressed, and the cure was completed, or believed to be so, after four months of this treatment. The patient then set out for South America: but shortly after his embarkation, ulcerated syphilitic tubercles appeared afresh on the left leg. He had not recourse to any kind of treatment on this occasion, but returned to Europe, and entered the Hôpital de la Charité on the 9th of June, 1834. A large spot without prominence of the corion still appeared on the right leg, covered with a wrinkled cuticle, the deep colour of which did not disappear on pressure; on this place, a year previously, a very large cluster of syphilitic tubercles and ulcers had existed. On the fore part of the left leg, in front of the tibia, over a space ten inches in length, by three in breadth, the skin was swollen, hard, violet-coloured, adhering to the tibia, thickly beset with large prominent livid tubercles, ulcerated in the centre, and covered with a brownish and shining scab, from under which exuded a quantity of purulent sanies. These tubercles were separated from each other by portions of indurated skin, the colour of which was like that of pale wine lees; the tibia did not appear to be affected, and the patient did not experience pain either in that or any other of the bones and joints; the throat had never been sore, but the different courses of mercurial treatment he had undergone had often produced salivation, and several teeth had fallen out; those that remained were foul and black; the breath was fetid; the sleep was good, and the appetite excellent. This patient was treated with Sedillot's pills and the *tisane de Feltz*, being put upon the half hospital allowance. An emollient poultice brought off all the scabs, and the tubercles were dressed with mercurial ointment. They shortly shrank, and cicatrized; the swelling and induration of the skin, and its coppery colour, decreased a little. The patient experienced no inconvenience from the treatment to which he was subjected for more than a month, after which the tubercles healed. At this period there was still, on the inside of the left leg, a livid-coloured, uneven, and indurated surface in every point where a tubercle had existed. The small cicatrices were prominent, hard, black, ecchymosed, indolent, and did not change colour on pressure by the finger; the cicatrice appeared perfectly sound, and was not painful to the touch; the patient was advised to continue the treatment for a fortnight longer.

CASE CXLV.—*Subcutaneous syphilitic tubercles on the shoulder, with perforation of the skin; exostosis of the clavicle; pills of mercurial ointment; tisane de Feltz; cure.* S \* \* \*, widow, sixty years of age, of a lymphatic temperament, and broken constitution, was not aware of having been at any time affected with the venereal disease; for several years she had suffered much from pains in her limbs, which she attributed to rheumatism. For the last year these pains were principally felt in the right shoulder, the skin of which became ulcerated, at the same time that a considerable swelling of the inner extremity of the right clavicle took place. This patient entered the Hôpital de la Charité, the 11th of May, 1834. At this time the sternal extremity of the right clavicle was about the size of a small hen's egg; it was painful upon pressure, and habitually the seat of a good deal of pain, particularly during the night; there was no swelling of any other bone; the joint of the right knee was the only one in which pain was complained of, and this caused a little difficulty in walking; the skin that covered the acromial region was red over a space about as large as the palm of the hand, and pierced with several round holes from the size of a sixpence to that of a shilling, through which exuded a yellow and thick pus. The skin was thin and detached round each of these openings to the extent of several lines, where it possessed its natural colour; three small, rounded, hard and immovable tubercles, about the size of a large pea, without apparent change in the texture of the skin, but

adhering to it, were perceptible under the dermis. These tubercles were painful upon pressure. The patient was subjected to mercurial treatment; she took each day three of Sedillot's pills, and a pint of the *tisane de Feltz*. Under the influence of this treatment, the exostosis of the clavicle diminished in size, and became less painful; the skin where it was detached and thin, was destroyed by degrees; as a consequence of this, an ulcer of considerable extent was produced, over the bottom of which cellular and vascular granulations were soon developed; as they became rather fungous in their appearance, they were touched with the acidulous nitrate of mercury. The subcutaneous tubercles became more painful; the skin which covered them grew red and inflamed; the tubercles softened; the integuments gave way, and a thick yellowish pus was discharged; at the bottom of the ulcers a yellowish adhering substance was perceived, like the core of a carbuncle or boil, which came away in shreds several days afterwards, from the middle of the small round openings formed. The loosened integument became thin, was destroyed in parts, and larger ulcers appeared, the bottoms of which presented, from time to time, instead of the granulations of a simple sore, a red surface covered with a flimsy whitish pellicle, as if the surface had been slightly touched with nitrate of silver. These ulcers were dressed with mercurial ointment, and before long cicatrized completely. The skin of the acromion then presented several small depressed cicatrices of a livid colour, and adhering to the subjacent parts; there was no longer any tubercular formation round them, and the pains of the shoulder had entirely ceased; the patient left the hospital on the 30th of June, cured. She had continued taking Sedillot's pills during the whole time she remained in the hospital, with the exception of a very few days, when this remedy was suspended on account of a considerable diarrhoea, which speedily subsided under the influence of opiates and mucilaginous drinks.

CASE CXLVI.—*Serpiginous cicatrice on the left side of the back, the consequence of a serpiginous ulcer, treated by simple dressings; serpiginous eccentric ulcer on the right side of the back, developed three months after the cure of that on the opposite side.* Josephine M., twenty-five years and a half old, a girl of the town, who entered the Hôpital Dieu on account of a serpiginous ulcer, situated on the right side of the back, stated, that a large circular cicatrice, waved in its circumference, and covering the whole of the skin of the left side of the back, was the consequence of an ulcer, which, after lasting five months, cicatrized without the use of mercury, by being merely dressed with blotting-paper spread with cerate. This cicatrice, very prominent in some parts, where it was of a coppery red colour, was depressed in others, where it was of a whitish hue. The patient added, that five years previously she had been treated at the Hôpital Saint Antoine, for an ulcer under the arm: and that two years after that, she had had the itch. This girl, sent to the hospital by order of the police, was of very equivocal character; but she persisted in affirming that she was not affected with the venereal disease; her general health appeared very good.

The right half of the back was occupied by an extensive ulcer, four or five times the size of the hand, spreading under the axilla, and covering the outer half of the right breast. This large ulcer was superficial, and seemed only to implicate the skin to a certain depth. The surface of the ulcer was red and granular; its circumference, well defined, was rounded and waved; the skin which bounded it was sharply cut, and healthy beyond the limits of the sore, which was covered with a sanious pus of so offensive a nature, that the patients in the neighbourhood were greatly annoyed; the patient had scarcely any symptom of fever and suffered no pain. On questioning this girl again as to the origin of this horrible ulcer, she informed M. Robert and myself, that she had felt very little the matter with her back eight days previously, but that being detained by the police, the part affected had not been dressed, and that during this time the disease had become rapidly worse. She added that this ulcer, like that which had eroded the skin of the opposite side of the back, had begun by small swellings like pimples or boils (*des clous*), which had soon ulcerated, and that these ulcers had united so as to form one, which then went on extending from its centre towards its circumference.

This woman was bled, and the ulcerated parts were covered with large perforated compresses, spread with cerate, over which a quantity

of soft lint was laid. The inflammation diminished rapidly, and by the third or fourth day, the centre of the ulcer was cicatrized. The cicatrice extended progressively from the centre to the circumference, while the latter continued completely stationary, so that at the end of eight or ten days, there only remained a kind of band or stripe, half an inch wide, which, by waving irregularly, showed the limits to which the disease had reached.

From the first moment, M. Dupuytren conceived this ulcer to be of a venereal nature; the patient, nevertheless, persisted in denying that she had ever had any other affection of the genital organs than a leucorrhœal discharge of a few days continuance; she refused an examination of those parts, saying, that before having been sent to the Hôpital Dieu, she had been examined by a physician, who, had he seen reason for it, would have ordered her to the hospital for venereal diseases.

A sudorific tisan and syrup, and three pills a day, each pill containing two grains of extract of guaiacum, half a grain of gummy extract of opium, and the sixth of a grain of corrosive sublimate were prescribed. Arrived at the state we have just described, the ulcer remained stationary in some points, and cicatrized in several others; it then spread in several places, though slowly, along its external edge, whilst the internal edge cicatrized. M. Dupuytren tried the effects of calomel to the ulcer, but at the end of a few days he was obliged to discontinue this application, as it occasioned a great deal of pain, and several parts of the recent cicatrice had fallen anew into a state of ulceration; baths and emollients were therefore returned to. As soon as the inflammation had subsided, the ulcerated surfaces were touched with a pencil dipped in the acidulous nitrate of mercury; three applications of the caustic were made, and seemed to have produced a good effect, when the patient absconded from the hospital.<sup>1</sup>

CASE CXLVII.—*Serpiginous and phagedenic syphilitic ulcer eroding the face for three years, cured by the tisane de Feltz, and Sedillot's pills.* A man, fifty-one years of age, with a horrible ulcer on the face, which it had eroded in different directions, entered the Hôpital de la Charité, on the 20th of Nov., 1833. This man, of a good constitution, had never had any venereal complaint but once, a gonorrhœa, nearly twenty years since, and I have no reason to doubt the truth of this statement, as he himself informed me voluntarily of the former existence of the gonorrhœa. There were no traces of cicatrices on the genital organs. Three years ago he had had eruptions and ulcers on the face, which were considered as syphilitic, and treated with the bichloride of mercury. The use of this medicine was discontinued immediately after the disappearance of the symptoms, which were not long of reappearing. A renewed anti-venereal course again put them to flight; but the patient being of an irresolute and impatient disposition, did not continue the treatment sufficiently long, and the disease reappeared for the third time. This want of success on one hand, a feeling of shame on the other, and the depression of spirits, occasioned by a disease which obliged him to quit his business, and live apart from every one, had so much affected his mind, that he resolved to enter the Hôpital de la Charité, to make a last attempt to get rid of his infirmity. He was at this time in the following state: the whole of the right side of the nose, from the root to the corresponding ala, was in great part destroyed, and was covered with a brownish scab, flattened and indented on the surface, from under the edges of which, when it was pressed upon, a purulent sanies exuded. A similar scab which also covered a deep ulcer, extended from the lower part of the one first mentioned, towards the chin, following the direction of the zygomatic arch; the cheek on the outside of this band was evidently swelled, and presented several analogous incrustations, and some ulcers which had accidentally lost their scabs.

The upper lip was swollen, and presented several fissures towards the angle of the mouth, besides an ulcer on the right side. The lower lip, swelled in like manner, and drawn to the right side by cicatrices in the form of cords, very similar to those which are often observed after burns, was turned inside out, so that the saliva flowed from the

<sup>1</sup> This woman constantly denied the syphilitic origin of the ulcer under which she laboured, although it had every one of the external characters of the serpiginous syphilitic sore. M. Devergie has given a plate of a remarkable instance of this kind of ulcer. (Pl. 106.)

mouth whilst the patient was speaking. In spite of all this mischief, the parts were but little painful, except during mastication; the patient had no fever; but he slept badly, and was in such a state of despondency as to entertain very slender hopes of recovery.

Cataplasms, for two or three days, and warm baths, in which the patient immersed his head also, detached the incrustations, and we now saw, that under these there existed deep sulcated ulcers with hard edges, and gray or yellowish-coloured bottoms, which poured out a sanious secretion in sufficient quantity to form fresh scabs in two or three days after the fall of the first. This patient was ordered to have the tisanne de Feltz and the pills of Sedillot, in doses of three a day. After the fall of the scabs, calomel was upon one occasion blown over the surface of the sores, which were subsequently cauterized very superficially with the acid nitrate of mercury. A progressive amelioration in the state of the parts affected, was very speedily perceptible. A few sulphur baths were subsequently administered with the view of strengthening the constitution, and there were but two ulcers remaining, when, on the 30th December, erysipelas made its appearance on the face, after an attack of fever. The tisanne de Feltz and the mercurial pills were replaced by lemonade; the erysipelas terminated by resolution at the end of five days; and on the eighth day, the date at which desquamation commenced, the ulcers were found completely cicatrized. The patient was discharged well on the 4th of January, 1834.

I saw this patient eight months afterwards, his health had gone on constantly improving, and the cicatrice was solid and of good appearance.

CASE CXLVIII.—*Serpiginous syphilide characterized by ulcers in the form of C's; rapid recovery under the use of the pills of Sedillot and tisanne de Feltz.*—M. \* \* \*, twenty-three years of age, was admitted the 18th of November, 1834, into the Hôpital de la Charité, where he had already been successfully treated, four years previously, for a serpiginous ulcer on the right leg.

For several months past, several ulcers resembling a good deal the form of the letter C., had formed on the outer and posterior part of the elbow-joint of the right arm; these by coalescing gave rise to a large irregular ring, which covered the skin of the lower third of the outer part of the arm, and the upper third of the outer part of the forearm. The concavities of these ulcerated arcs were turned towards the interior of the ring, with one exception, however, for there was an arc which surrounded with great exactness, the half of the olecranal region. These ulcers formed a deep furrow, irregularly circular in its shape, of a grayish or yellowish colour, covered in part with incrustations of a darkish brown, not very prominent, and strongly adherent to the parts beneath; the edges of the ulcerated arcs were sharply cut, as if the skin and cellular membrane had been deeply chiseled, or taken away with a pinking-tool shaped like the letter C. The exterior edge of these ulcerated sulci was in general broader, more raised, and more sensible than the inner edge. On the following days, we could perceive that it was always by the outer edge, and not by its extremities, that the ulcer spread; a circumstance which distinguished these from serpiginous ulcers in general. At a subsequent period, the work of cicatrization was found to commence with the inner edge, and to advance gradually towards the outer one until it was complete. The interior edge of one of the ulcers was covered with warty excrescences when the patient entered the hospital.

The skin which was circumscribed by this ulcerated ring, was of a purplish-red colour, and in various places exhibited traces of old cicatrices. The elbow-joint was swelled and painful; the limb which was kept in an habitual state of flexion, could not be completely extended, and motion of every kind was attended with pain. The incrustations having been removed by means of emollient cataplasms, the definite chiseled appearance of the ulcers struck us still more than before. In other respects, the health of the patient was pretty good, and he was immediately put upon a course of tisanne de Feltz, and three of Sedillot's pills daily. Farther, the whole of the ulcers, except one, which was touched with a solution of the acid nitrate of mercury, were dressed with mercurial cerate; the elbow-joint, enveloped in an emollient cataplasm, was fomented every morning in a decoction of marsh-mallows. Under the influence of this treatment, which occa-

sioned neither salivation nor any derangement whatever in the health of the patient, all the ulcers, with the exception of the one which had been cauterized, got well so rapidly, that the cicatrization was complete on the 4th of December. The ulcer which had been cauterized, was then dressed with mercurial ointment, and by the 11th of December, it was also skin-whole. The motions of the elbow-joint meantime, had become as free as those of the opposite extremity.

The patient having requested his discharge, shortly after the entire disappearance of the symptoms, I recommended him to continue the treatment, by taking the pills of Sedillot for some weeks longer. (a)

(a) *Case of virulent outbreak of psoriasis.* Treatment of the primary sores had not been mercurial. *Mercury required to repel this attack. Other forms of cutaneous disease and subsequent outbreaks of psoriasis in the same case, yielded to the iodide of potassium.*—[By HERBERT MAYO, in *Med. Gaz.*, 1839.]

"A middle-aged person had been exposed to infection more than eight weeks before, when he discovered a sore upon the inner prepuce, near the glans. He showed it to a surgeon, who assured him that it was not venereal, and gave him an astringent lotion to dry it up. Ten days afterwards, which had been spent in considerable exercise and traveling, the sore presented the following appearance:—It was covered with dark adherent secretion, and the adjacent part of the prepuce was swollen and red. The sore was about half an inch in diameter, circular, one half on the body of the penis, the other on the prepuce, as it appeared when the latter was drawn back. At the bottom, the sore looked as if disposed to spread, by the sloughing of the cellular texture between the integuments and penis. It was not attended with pain. An ointment containing Peruvian balsam was applied on lint to the sore, an aperient given, and decoction of sarsaparilla, with four grains of iodide of potassium, ordered to be taken twice a day. In four or five days the sore had become clean, and had begun to granulate, when I discovered accidentally, the patient having no suspicion of its existence, another smaller sore on the opposite side of the inner prepuce. It was circular, without hardness, very slightly excavated, with a definite raised edge; the surface soft, vascular, and all but granulating. The same dressing was applied to it, and, like the first, it became a healing sore, and both were going on to cicatrize (which they did in three weeks, neither leaving hardness), when, in ten days from the commencement of the use of the iodide, syphilitic psoriasis broke out on the glans penis, on the scrotum, on the pubes, abdomen, and loins. The dose of the iodide was increased, but the eruption advanced, and, appearing upon the head and face, threatened considerable temporary disfigurement. At the same time, it seemed so little controlled by the means employed, that I thought it necessary to recommend a course of mercury. The gums were affected in three or four days, and the spots upon the forehead became stationary. The course of mercury was pursued for five weeks: by that time the spots had everywhere disappeared; but those on the forehead had left broad, yellow, circular stains, which only slowly wore out during the half year following. The character of these spots had been this: at first the upper part of the forehead looked mottled at half a dozen points near the roots of the hair; then distinct circular spots, of a faint red, were seen, a quarter of an inch in diameter; they were slightly raised and convex; as they enlarged they became less elevated, and of a darker colour—a browner shade of red; and thin scales of cuticle began to separate from them. In ten days from the termination of the course of mercury, the integument at the inner part of one eyebrow and one ala of the nose, became thickened, swollen, and red, assuming such an appearance as precedes syphilitic ulceration of those parts. The iodide of potassium was then given for three weeks, first in ten grain doses, and finally half a drachm, three times a day. In four or five days from the commencement of this medicine, the redness and swelling of the integuments had begun to decline. A week had scarcely elapsed from the discontinuance of the iodide, when a new eruption appeared; spots broke out on the face and forehead, spreading with a red or elevated edge, leaving the centre paler: For this the iodide was recommenced, and, as it did not act as quickly as before, five grains of Plummer's pill were given every night in addition. On this attack receding, the throat became troublesome; the tonsils had already been swollen and excoriated, but

## AMBUSTIO.—BURN.

983. Under the general title of *burns*, are usually designated all the injuries produced by the action of caloric on our organs, and in particular on the skin.

According to the degree of their intensity, burns of the skin are characterized by the occurrence of erythematous spots, by the presence of phlyctenæ, blebs or blisters, and by the occurrence of eschars.

1.—The *erythematous burn* (*the first degree of burn*, Dupuytren), is characterized by vivid redness of the skin, which disappears under pressure. This burn is accompanied with acute scalding or smarting sensations, and some slight swelling of the parts *implicated*. These local symptoms may only continue for a few hours or be prolonged for several days; in the latter case, the epidermis is usually detached in the shape of small squamæ. When these superficial burns are limited to small districts of the skin, they do not occasion any derangement in the principal functions; when they are very extensive, they are liable to be accompanied by restlessness, loss of sleep, delirium, and are sometimes even fatal in their consequences. Burns of the description under review may be produced by exposure to the intense heat of the sun, on the hands, face, head or neck; they are sometimes also occasioned in a slow and gradual manner on the legs and thighs of the aged, who, during winter, expose these parts much to the heat of the fire; they occur, too, among women who are in the

now an angry superficial ulceration, with a yellow edge, spread over the soft palate; this gave way at once to a gargle of decoction of bark with half a grain of corrosive sublimate to the ounce. Next a papular eruption appeared upon the forehead and face, and afterwards psoriasis at several recurrences; but these have gone away each time upon a week or fortnight's course of the iodide, and since the first outbreak the attacks have been progressively milder. During the whole period, the patient's general health has been unaffected."

The following case by Mr. Mayo, exemplifies the most *virulent lepra*.—*Cure by iodide of potassium*.

"John O'Shaughnessy, in the autumn of 1828, had a primary ulcer and bubo, for which he took mercury. Before long leprous eruption and ulceration of the throat followed. He was admitted into Middlesex Hospital in January, 1830, with several large leprous spots on his limbs and body; a large ulcer on the instep, another on the shoulder. He took liq. potassæ, with sarsaparilla, and the ulcer on the instep healed. But lepra broke out universally. The patches became covered with a great thickness of papery scales, the skin beneath which felt thickened: the scales became a crust, and falling off disclosed an ulcer. There were many of these ulcers on the limbs and body; the forehead and face were covered with them. The lips, the alæ of the nose, the eyebrows, were equally involved in ulcerated blotches. The patient suffered from burning heat of the body and face, and the ulceration of the lips produced pytalism. The bones were not affected, but there was pain on moving the joints of the legs, and a small depot of serous matter formed in the right calf. Every remedy was now tried in succession, and all did temporary but very transient good, except nitric acid with bark, and mercury: these medicines made him worse. Having had him under my care a year, and the disease being unsubdued, I then ordered (Dec., 1830) at M. Magendie's suggestion, who happened to see the patient, a sixth of a grain of iodine, with ten grains of the iodide of potassium, three times a day. The good effects of the remedy were apparent after a few days: the skin became less red and heated, several of the crusts separated, and the ulcers put on a healthy appearance. In a month the patient had made a great amendment. But now the amendment ceased. The iodide was, therefore, discontinued; upon which the patient became worse. After a fortnight he resumed the medicine, with the same advantage as on first taking it. In a month the disease became again stationary. He then discontinued the iodide, to resume its use in a fortnight. By these means in five months he recovered his strength and health; but a few blotches would occasionally appear, upon which he again had recourse to the iodide. Afterwards a very severe relapse took place, of which he was cured in the Lock by the same medicines. When I last saw him he had been quite well for some years."

habit of using *chaufrettes*.<sup>1</sup> These superficial burns (*éphélides ignéales*, Alibert), present themselves in these cases under the form of spots of reddish brown, and are constantly without any feeling of heat or smarting.

M. Briquet has frequently examined the skin of women of the lower class, whose thighs presented these kinds of ephelis, and found that they were occasioned by a vascular net-work, consisting of enlarged arteries and veins, surrounded by cellular membrane filled with blood.

2. The *vesicated or bullous burn* (*the second degree of burn*, Dupuytren), is a more intense form of this affection of the skin. The blisters or bullæ which characterize it, appear almost immediately after the action of the heated substance, particularly when this happens to be a liquid. Fresh blisters of different sizes afterwards form successively in the vicinity of those first produced, and these become more voluminous in proportion as the inflammation increases and spreads around them, which it does rapidly: the skin is red and tense; the subcutaneous cellular membrane is swelled; the heat and pain are more intense than in erythematous burns. The serum contained in the vesicles and bullæ is of a pale-yellow colour, or slightly turbid; as soon as they break the epidermis shrivels, and is thrown off, when a false membrane is sometimes exposed, covering the surface of the inflamed reticular body. A new epidermis is not long of replacing that which has been destroyed, when the burn is not very extensive, and is treated by appropriate means; but when, after the fall of the epidermis, the excoriated parts inflame and ulcerate, a discharge of sanguinolent serum is established; suppuration goes on for a long time, and a cure is rarely obtained without cicatrices.

3. The *gangrenous burn* (*third and fourth degrees*, Dupuytren), is characterized by mortification of a part or of the whole of the thickness of the skin; by the destruction of the subcutaneous cellular substance, and the death of the tissues still more deeply situated. The least serious degree of this species of burn is almost always announced by the presence of superficial grayish or yellowish-coloured and insensible spots. At the moment of the accident, nothing more is sometimes observed in this degree of burn than an erythematous redness of the skin, or the formation of a few phlyctenæ; after the lapse of three or four days, however, superficial eschars make their appearance, and sores are also subsequently formed which interest the surface, or even the whole thickness of the corion, without any excessive amount of inflammation having occurred to account for this unfortunate result. Complete insensibility, hardness, and a shriveled horny appearance, joined to a yellow or grayish colour, announce the conversion of the entire thickness of the dermis into an eschar. Phlyctenæ or blebs are usually observed immediately around the eschars, and at a greater distance there is a broad band of erythematous inflammation which is the seat of severe and burning pain.

At the end of eight or nine days, seldom sooner, and very frequently later, a line of separation begins to be established between the dead and the living parts. Suppuration becomes abundant, and the discharge is mixed with shreds of sphacelated cellular membrane; the whole of the part injured has now a gangrenous and foetid odour.

When the burn is very severe and extensive, the inflammation is apt to run high, to extend to a great distance around; and by its excess, to cause the mortification of the parts it implicates.

984. Burns of trifling extent, whether they be superficial or extend more deeply, are rarely complicated by general morbid phenomena; but whenever a considerable district of the skin is implicated, burns are accompanied by ardent thirst and extreme heat of surface; the pulse becomes hard and frequent; the urine scanty and high coloured, &c. When nearly the whole surface of the body is burned, the patient invariably dies within a few days, often within a few hours after the accident;<sup>2</sup> the pulse is then small and frequent; the extremities cold; delirium and convulsions supervene; a cold sweat spreads over the trunk and face; the features shrink, &c. Patients who escape these first violent and imminently dangerous symptoms, frequently succumb,

<sup>1</sup> Earthen pans of burning charcoal which the lower order of females in France place under their petticoats during the winter.—*Tr.*

<sup>2</sup> Serrurier. Brûlure suivie de mort au bout de 12 heures. (*Rev. Médic.*, Novembre, 1830, p. 249.)

after extensive burns, under consecutive phlegmasiæ of the pulmonary and gastro-intestinal mucous membranes. (a)

Several of these patients have even been seen to sink at the moment when the injuries they had received were nearly, or even completely, cicatrized.

985. Exclusive of the injuries of the skin, which we have described, the bodies of persons who have died from the effects of severe burns, have sometimes exhibited sanguinolent and purulent effusions into the articulations of the extremities which had been the seat of the injury; occasionally congestion of the vessels of the brain, and now and then manifest traces of inflammation in the serous membranes, but much more frequently in the gastro-intestinal mucous membrane also occur.

986. *Causes.*—Solid bodies occasion burns which are so much the more severe, in proportion as these have been applied at a higher temperature, as they are more dense in their composition, and better conductors of caloric, and as their action, whether mediate or immediate, has been continued for a longer period of time. Some substances, which burn rapidly, and which melt while in a state of ignition, such as phosphorus, sulphur, the resins, &c., produce burns that are both very extensive, and that penetrate deeply in an extremely short space of time. All liquids do not burn with equal violence. Those which require a very high temperature to make them boil, and which have a great tendency to stick to the skin, such as soup, oil, pitch, tallow, &c., are the most dangerous. The burns occasioned by alcohol, æther, or by the explosion of gunpowder, &c., are often very extensive, but generally superficial, in consequence of which they are less formidable.

Lastly.—Under the title of *spontaneous burning* or *spontaneous combustion*, certain effects or changes have been spoken of, analogous to those occasioned by the agency of caloric. The mode in which these spontaneous combustions take place is very little known, even at the present day.

987. *Diagnosis.*—The erythematous spots, blisters and eschars produced by burns, differ in the cause which produces them, from the spots of erythemæ, the bullæ of pemphigus, and the eschars of the skin observed in other diseases.

In some circumstances, nevertheless, the diagnosis may continue uncertain for a time; such was the case with a rheumatic patient, for whom I had prescribed vapour baths in the Hôpital de la Charité, and who presented an eruption in the form of a collar round the neck, consisting of oval spots, from an inch to an inch and a half in diameter, the surface of which was covered with irregular bullæ, which were succeeded, at the end of some days, by superficial eschars of a yellowish-white colour. This man being questioned several times as to the cause of this eruption, continued to assure us that he was completely ignorant of it; and we only learned, some days afterwards, on seeing the eschars, and pressing him anew with questions, that whilst seated in the vapour bath he had experienced a considerable degree of heat about the neck, but no sensation of burning. This last circumstance, strengthened by the appearance and progress of the inflammation, determined us at length as to its cause and nature; although, I repeat, the patient had not experienced the sensation of burning.

Burns ought also to be distinguished from those red patches, vesications and eschars which are produced by the application of the liquor ammoniæ, more or less diluted, to the skin.

Finally, the redness produced by sinapisms, the bullæ or vesications, caused by blisters, the grayish and black eschars engendered by the application of caustics of different kinds, and the concentrated sulphuric acid, those of a yellow colour which result from the action of nitric acid, and those of a blue cast, which are sometimes observed upon the hands of washerwomen who burn themselves with composition blue, have each appearances peculiar to themselves, and are distinguished by these as well as separated by their causes from ordinary burns.

988. The *prognosis* in cases of burns, is unfavourable in propor-

(a) Of the latter, the duodenum is more especially the seat of lesion. Mr. Curling (*Med. Chir. Transact.*, vol. vii., and *Bull. Med. Science*, 1843), gives ten cases of this complication with burns. The change was of an ulcerative character.

tion to the extent and depth of the injury. Burns are most dangerous in children, the aged, and persons of very irritable constitution. Those of the parietes of the abdomen and thorax, and of the face, are more dangerous than those of the limbs and extremities; nevertheless, burns of the hands and feet have been occasionally known to be followed by tetanus.

In burns the extent of injury which the skin has sustained, and the amount of alteration undergone by the subjacent tissues, cannot be precisely ascertained until the inflammation has reached its height, and the eschars begin to separate: even then the extent of injury done to the skin itself is ascertained with much more certainty than that which the subcutaneous cellular membrane has suffered.

989. *Treatment.*—Erythematous burns ought to be treated from the moment of the accident, by the application of cold or iced water, and by compression. Immediately after the accident, the injured part should, if possible, be plunged into cold or iced water, and then covered with compresses dipped in it and kept continually moistened, over which a roller is to be pretty firmly applied.

In cases of very extensive superficial burns, the action of the cold water may be confined to those points where the scalding heat is most severely felt, whilst the other parts are dressed with a mixture of two parts of white of egg and one of oil. When the pain is very intense, a little of the extract of hyoscyamus (*baume tranquille*) may be added to the mixture.

990. In burns accompanied with vesications, when the clothes still adhere to the injured parts, they must be slit open and carefully removed, in order not to tear the epidermis, raised by the effusion of serum beneath it.

The part should be plunged into cold water in order to appease the scalding and smarting sensations, and if it cannot be kept conveniently immersed for any length of time, after being covered with a poultice of grated raw potatoes, it should be bound up with a bandage dipped in iced infusion of althea-root. The pain and inflammation should be allowed to subside in some degree before the vesications are opened; one or more small punctures may then be made at their extremities, but the epidermis is by no means to be removed, as by its presence it protects the tender surface of the skin from the action of the air. If the surface of the corion some days after the serum has been evacuated begins to pour out a purulent secretion, which escapes with difficulty, the epidermis must be removed. Should the suppuration prove very copious, dressings spread with saturnine or Turner's cerate may be applied to the excoriated skin, and a quantity of lint or tow laid over all to absorb the pus. When the ulcerated surfaces are very extensive, saturnine topical applications must be employed with circumspection, to avoid the danger incidental to the absorption of lead into the system.

Carded cotton has been employed successfully in the treatment of burns, quantities being applied layer after layer till a stratum is formed sufficiently thick to render the injured parts insensible to pressure from without. This dressing ought not to be repeated until there is a very considerable discharge with or without the formation and detachment of eschars. The silky tufts of the *typha*, employed in the same manner, have also produced the best effects.

It is in this description of burn that Fernellius recommended the part affected to be exposed to the heat of the fire, *ignis, ipse hic ipsius alexiterium*, and that others have advised the part to be immersed in water as hot as it can be borne.

Sydenham, in the same circumstances, recommended the application of spirits of wine, or of painter's varnish.

Precisely similar measures are required in the local treatment of gangrenous burns, during their earlier stages; such measures become necessary subsequently as tend to bring about the separation of the eschars.

When the toes and fingers have been burnt to such a degree as to occasion disorganization throughout their whole thickness, it is often necessary to divide certain ligamentous connections or shreds of tendons which continue to unite them to the parts whose vitality has not been destroyed.

When a portion of a limb has been disorganized, amputation must be deferred till the symptoms, immediately consequent on the injury, have been subdued. The operation rarely succeeds when extensive

surfaces besides have suffered. Amputation may also become necessary when after, and in consequence of, the separation of the eschars, the interior of a large articulation is exposed, or when the ulcers which result are so extensive and irregular that a cure is not to be expected.

The cicatrization of wounds consequent on burns, does not always proceed regularly from the circumference towards the centre; this process sometimes commences far from the edges in several separate points at once. In every case it is of the greatest consequence to see that the cicatrice be kept of the same or as nearly as may be of the same extent as the skin destroyed, in order that, after the cure is complete, the parts may preserve their natural direction, and the freedom of their motions unimpaired. Tents of different kinds, canulæ, &c., will serve to prevent the contraction of the natural openings, as of the ears, nostrils, &c.; and contiguous parts are kept separate by compresses and dressings appropriately applied. When the fingers are burnt they should be fixed on a splint in the form of the hand, and kept easily separated from one another: splints of the requisite form, and secured with proper bandages, will prevent any undue and unnatural contraction of the extremities, the faulty inclination of the head, the dragging of the lower jaw towards the breast, &c. In order to obtain a smooth and uniform cicatrice, the granulations when too luxuriant must be touched with lunar caustic; but in spite of every precaution that can be taken, the cicatrice will always appear depressed, and will always adhere to the subjacent parts when the burn has been deep.

In burns accompanied with vesications, and sphacelus, when the discharge becomes very profuse, it is advisable to dress the wounds at least twice and sometimes even three times in the course of the day, care being taken only to expose the different inflamed regions in succession; the many-tailed bandage, therefore, is generally to be preferred to the circular roller.

991. The plan adopted by M. Lisfranc, in the treatment of burns, is peculiar: after having opened the phlyctenæ, or blisters, he removes the epidermis from their surface, and then covers the inflamed parts with a soft pledget of perforated linen rag, spread with cerate, over which he applies a compress of lint, dipped in a solution of chloride of lime; and directs the dressings to be sprinkled at intervals with this liquid, so as to be kept constantly wet with it. The solution of the chloride of lime, employed by M. Lisfranc, in general indicates three degrees of M. Gay Lussac's chlorometer. If this application fails to occasion some slight degree of pain at the moment of its use, or if in subsequent stages, the cicatrization advances slowly, M. Lisfranc increases the activity of the solution, by raising it two or even three degrees in strength. If, on the other hand, the contact of the chloride of lime produces severe pain which continues unabated for some time after the dressing has been applied, and if white albuminous deposits occur upon the surface of the inflamed skin, a solution of inferior strength must be used. The action of this application, we are assured, has always appeared to be extremely beneficial.

992. The general symptoms that immediately follow a severe burn, particularly the shock received by the nervous system, and the irregular and prolonged shivering fits with which patients are often seized, as also those inflammatory attacks of the digestive organs, which so frequently supervene, are successfully combated by the exhibition of opium. Burns which are merely superficial, and of small extent, are seldom accompanied by such symptoms, and do not generally require any change of regimen or any peculiar system of internal treatment. In extensive burns, however, rigorous abstinence must be enforced, and soothing beverages, anodyne emulsions, &c., prescribed; general bleeding, and the application of leeches to the head or epigastric region, according as the inflammation of the skin appears to have reacted on the brain or the stomach, are further very constantly indicated in these cases. Very full diet under any circumstances is improper, and will be found to delay the healing of the wounds.

993. When the trunk is the seat of a burn of considerable extent, the slightest motion is extremely painful. It is advisable in such cases to place the patient on a bed which admits of the linen and bedding being changed, and a proper vessel for receiving urine and fecal matter being got under him, without any exertion on his part, or his feeling himself obliged to move in the slightest degree.

Burns with gunpowder are almost always followed by indelible black or bluish stains. Turner mentions a case in which he was so fortunate as to prevent this stain from occurring by scraping the surface of the burn, and afterwards applying a blister and red precipitate to the blackened skin.

994. The indurated bands or cords, formed by the cicatrices of burns, when of no great thickness, may sometimes be so much relaxed that they can gradually be stretched and finally made to disappear almost entirely, by means of oily embrocations, mucilaginous or oleaginous fomentations, &c., or by the repeated use of the douche, and the enforcement of gentle motions; but when these cords are very rigid and of considerable thickness, they must be divided to their base, provided they contain no tendons, and the edges of the wound maintained forcibly apart, until complete cicatrization has taken place. (a)

(a) A great number and variety of applications have been used and are recommended for burns. The author, in the text, says nothing of the stimulating practice, as far, at least, as regards dressing. M. Müller (*Principles of Surgery*), concludes an admirable chapter on "Burns and Scalds," with the following judicious remarks:—"Some strenuously advise stimulating applications from the beginning; and a theory has been made to suit the practice. Neither seem to merit approval. Alcoholic applications may sometimes prove serviceable, in a scalded but unbroken skin, by the cold which the evaporation produces; and, in the severe injuries, any stimulant, at first increasing the pain, may afterwards be said to deaden it by accelerating and aggravating the inflammatory action, so as speedily to overcome the impaired vitality, and convert all into one slough. But such is not wise and prudent surgery. Let stimulants both internally and externally, be retained in their proper time and place; and these will be found in the second, sixth, and ninth indications of cure." The references here are; 1. To the case in which a burn or scald involves a large part of the surface, and in which the continuous use of cold cannot with propriety be had recourse to; a warm solution of opium or other anodyne is preferable; and if the duration and degree of slough be excessive, heat must be applied to the external surface generally, and warm drinks used internally. 2. After granulation is established water-dressing is applied, not hot, but tepid, as a mere detergent and protective; but when the sore manifests deficient action, then may we have recourse to various stimulating dressings. 3. To maintain the powers of the system is an important indication after the suppurative process is begun and the constitution is irritable and enfeebled. "This is done by attention to air, exercise and clothing; by generous diet; and by the use of tonics and stimuli—of the latter, the cantharides is often the most efficient form."

In the first or erythematic stage of a burn, or even in the second or vesicating, after the application of cold until the pain is subdued or removed, well carded cotton or cotton-wadding, is to be applied over the part, so as to exclude the air and to prevent any friction by clothes, &c. The same purpose will be answered by a layer of some bland adherent substance, such as will not irritate the raw or injured surface, and yet will effectually exclude the air, as soap, gum or varnish. The gum is preferable, as in the case of contused wounds. Or, the part may be dusted with flour; but when vesication is expected, this is an objectionable form of protection, inasmuch as the serum bakes it into crusts, which crack, loosen, and are apt to irritate injuriously. A popular dressing is, equal parts of lime-water and lamp-oil, or, as less unpleasant, if not quite so bland, olive-oil. The cerate of the acetate of lead and ointment of the carbonate are soothing applications. Warm vinegar has been found serviceable.

In severe burns, where there is loss of skin, and ulceration is begun, ointment of chloride of lime or lint moistened with the fluid chloride of soda, is one of the best, if not the best application, to produce healthy granulations and to prevent deforming contractions. It is in this stage that other stimulants, such as the salts of zinc, copper, silver, &c., are occasionally serviceable. Tincture of iodine and the compound solution have been recommended in some instances.

Throughout the whole period great attention must be paid to the state of the constitution and particularly to the lungs and gastro-duodenal surface. Blood-letting, antimony, calomel, and opium, will, in

*Historical Notices and particular Cases.*

995. Fabricius Hildanus<sup>1</sup> has given a good description of burns, of which he distinguishes three kinds. Turner<sup>2</sup> has left a useful chapter on burns, and has reported two cases of cure which deserve to be consulted; he made great use of the cerate which still bears his name. Parkinson<sup>3</sup> has recommended the application of spirits of wine, already prescribed by Sydenham. Sir James Earle<sup>4</sup> has shown the advantages of cold applications, early advised by Rhazes and Avicenna. For the last twenty years M. Dupuytren<sup>5</sup> has annually delivered several clinical lectures of the highest interest on this subject. Anderson's<sup>6</sup> paper may be consulted on the employment of carded cotton dressings, and that of M. Vignal on the treatment of burns by the application of the down of the typha;<sup>7</sup> Dr. Christison's observations on the distinction between burns that have happened during life and those that have taken place after death<sup>8</sup> are deserving of particular attention in several points of view. For information on the means of remedying the deformity so often induced by the contraction of the cicatrices of burns,<sup>9</sup> the work of Dr. John Thomson,<sup>10</sup> remarkable for the justness of its practical precepts and its scientific character, the later paper of Mr. James,<sup>11</sup> and the two lectures of Mr. H. Earle<sup>12</sup> may be particularly referred to. The surgical lectures of Abernethy also deserve to be consulted on this point.<sup>13</sup>

Several cases of burns of the skin detailed by Moulinié,<sup>14</sup> Lisfranc,<sup>15</sup> Bretonneau, Velpeau,<sup>16</sup> Borot de Belloy,<sup>17</sup> &c., will be read with advantage; they illustrate the several peculiarities presented by these accidents, at the same time that they present the reader with instances of the practical application of the different methods of treatment I have mentioned. The very interesting observations of Mr. Marshall on scalds or burns of the pharynx and larynx;<sup>18</sup> those of M. Lair<sup>19</sup> on the combustion of the human body; and some singular facts, open, however, to suspicion, on the subject of spontaneous combustion,<sup>20</sup> ought equally to be consulted.

succession, be required in some cases in which inflammatory excitement runs high. After this period has passed, tonics and nutritive stimulants will be proper. For the means by which extreme deformities from burns are removed and new parts substituted for the excised contractions, the reader is referred to works on Surgery, and particularly to Velpeau's Operative Surgery, Townsend's Translation.

PERNIO—CHILBLAIN.

Vocab.—*Chilblain, Pernio.*

997. Under the title of Chilblain, I designate collectively all the affections of the skin and subjacent tissues which are produced by the action of cold. These occur under three forms of progressive gravity; characterized in the first instance by an erythematous swelling, in the second by the formation of the phlyctenæ with or without excoriations, and in the third by the occurrence of gangrene. The two first stages only are usually comprehended under the name of chilblain.

998. *Symptoms.*—Chilblains attack those parts especially which are most remote from the centre of the circulation, such as the feet, hands, ears, and tip of the nose.

1st. In the most simple case, *erythematous chilblain*, the disease is characterized by a simple redness of the skin, accompanied with a troublesome feeling of pruritus, and a slight tumefaction of the subcutaneous cellular tissue.

The affection commonly makes its appearance slowly after the action of cold. The skin becomes pale at first, and afterwards assumes a red tinge, accompanied with swelling, and sensations of tingling and of numbness and stiffness in the parts affected, which increase in a remarkable manner, when these are exposed to the action of heat. Under the influence of the same cause, the swelling increases, and the redness of the skin acquires a livid and leaden cast.

If neglected, this first degree of chilblain is sometimes followed by chaps, and the other symptoms which characterize the bullous stage of the affection.

2d. This last is a severer species or degree of chilblain. The blebs or phlyctenæ most frequently appear on the palmar surface of the last phalanges of the fingers, the plantar surface of those of the toes, or over the hind part of the heel, and are flattened, and filled with a reddish sanguinolent serum. The skin on which they are evolved, has a livid or bluish-red appearance. If the disease is neglected, the epidermis is detached, and leaves exposed, grayish excoriations, of a mingled pallid and sanguinolent aspect, which are the seat of considerable pain. These excoriations are irregular in their shapes, and are occasionally observed of considerable depth and extent. Exposed to cold and moisture, and rubbed and pressed upon by the clothes, these excoriations are apt to chap, and to ulcerate, when they discharge an ichorous pus; they occasionally even become gangrenous in one or more points of their surface. The cicatrization of these sores is always obtained with great difficulty, particularly during the winter season.

3d. Finally, when the action of the cold has penetrated more deeply, the parts affected become cold, insensible, motionless, and assume a livid hue,—*gangrenous chilblain*; the cold sometimes causes a kind of mortification. During the winter of 1812, I attended a Spanish prisoner, both of whose feet, in a state of sphacelus from exposure to cold, had acquired a woody hardness. When patients survive these local congelations, a line of demarkation is by and by established between the mortified and living parts; when the former are not detached within a reasonable period of time, it becomes necessary to remove them with the knife.

999. Erythematous and bullous chilblains of the hands and feet do not usually occasion any disturbance in the exercise of the principal functions. Gangrenous chilblains, on the contrary, are frequently accompanied by very serious morbid phenomena, particularly if the action of the cold has been deep and of long duration, viz.: rigors, paleness of the surface, rigidity and numbness of the body generally, diminution of sensation, of the power of motion and of the temperature, slowness of the circulation, precordial anxiety, and stupor, followed by extinction of life.

1000. *Causes.*—Chilblains, in general, only prevail extensively towards the end of autumn and during the winter; they are particularly apt to attack washerwomen, hatters, dyers, &c., and weak, lymphatic, scrofulous children, over-tenderly brought up, whose skin is fine and delicate, or the children of the poor who, again, are not sufficiently protected against the inclemencies of the weather. They are most

frequently observed in temperate climates, and generally during cold or damp weather, and after sudden transitions from frost to thaw. M. Larrey relates that during the three or four days which preceded the battle of Eylau, the weather was extremely cold, the thermometer having sunk so low as fifty-four degrees below zero. Not one of the French soldiers who had remained in the snow during this intense cold, experienced any pain in the hands or feet. During the night of the 9th of February, there was a fall of sleet, and the thermometer rose to several degrees above the freezing point. From this moment many of those who had been exposed to the severe cold, began to complain of acute pains in the feet, and of numbness, and a sensation of heaviness, and tingling in the extremities. In some, the parts affected were but little altered in size or colour. In others a slight degree of redness made its appearance about the roots of the toes, and over the upper part of the foot. In many, however, the toes lost all sensation, and power of motion, becoming cold, and soon afterwards black, hard, and lifeless.

1001. *Diagnosis*.—The erythematous inflammation, and the puffing of the subcutaneous cellular membrane, the phlyctenæ, chaps and fissures, the ulcerations, gangrene, &c., that occur in consequence of chilblains, differ in their mode of development and the succession of their phenomena, from analogous lesions produced by other causes; to discover the characters which distinguish chilblains from burns, and erysipelas, it is therefore enough to study them comparatively under these two points of view.

1002. *Prognosis*.—Erythematous and bullous chilblains, whether with or without fissures, are affections less dangerous than troublesome. In serofulous subjects they are very rebellious to every kind of treatment. Sphacelation of the fingers and toes is to be apprehended when these parts, by exposure to intense cold, lose their sensibility, when they have a shrunk and withered appearance, and when they assume a purple or livid hue.

1003. *Treatment*.—The preservative treatment of chilblains consists in avoiding sudden transitions from cold to heat; in protecting the parts liable to be affected with them, from the influence of cold and moisture, and better still when this can be done with propriety, in gradually hardening the hands and feet and inuring them to the cold. The extremities should above all things be defended from moisture, and when they have accidentally been wetted with very cold water, and very considerable pain is complained of, they ought to be simply dried and covered, and allowed to get warm of themselves, without being exposed to the immediate action of heat.

Frictions with snow frequently repeated, lotions with salt and water, wine, camphorated spirits of wine, or any alcoholic fluid, tincture of Benzoin, &c.; or what is perhaps preferable to any of these, a solution of alum in water, in the proportion of one ounce to a pint, the artificial sulphureous water-bath, and the disuse of gloves lined with fur, and of woollen stockings, which defend the hands and feet too completely for a time from the action of the external temperature, are powerful preservatives against chilblains.

When the disease is characterized by a simple redness of the skin, and slight swelling of the subcutaneous cellular membrane, the parts affected must be bathed several times a day with a decoction of althea-root and poppy-heads, and the hands and feet enveloped at night in compresses soaked in goulard water.

Emollient and narcotic cataplasms, sprinkled with a solution of the acetate of lead, are useful applications to chilblains, which are accompanied with phlyctenæ, violent pain, and much swelling. The livid and fungous-looking sores that follow in these cases, require to be subsequently touched with the nitrate of silver, and dressed with soft pledgets, spread with saturnine cerate, which, being covered with compresses dipped in any mild astringent and discutient wash, the whole is to be supported by a firm roller. (a)

The parts affected must now be carefully protected from cold and damp; these measures generally prove sufficient to accomplish the cure of chilblains rapidly.

Gangrene may be prevented in parts which have been exposed for a length of time to very severe cold, by rubbing them with snow, or by

bathing them with icy cold water in the first instance, and using every precaution, only to allow the temperature to rise very gradually. When the circulation appears to be in some measure re-established, the parts affected may be fomented with cold spirit lotion, and wrapped in dry flannel, the patient being, mean time, made to take some warm and gently stimulating drink.

When gangrene has taken place, all we can do, is to wait until its extent is indicated by a circle of inflammation, and a line of separation begins to be established between the living and dead parts; this once formed, we may decide whether we shall allow the sphacelated parts to separate of themselves, or perform amputation.

#### Historical Notices.

1004. Celsus<sup>1</sup> has given a very accurate description of chilblains. Plouquet<sup>2</sup> mentions several dissertations on this disease, which I have not been able to consult. Dr. J. Thomson<sup>3</sup> has studied the effects of cold on the human body with particular care, and has given the details of many experiments made on animals, which prove that limbs which have been frozen, whose fluids have been fairly congealed, are incapable of being restored to life. M. Lisfranc<sup>4</sup> has lately recommended compresses dipped in a solution of chloride of lime, to be applied over the ordinary dressings applied to the sores that follow chilblains.

The history of gangrenous chilblains, or of the gangrene which is produced by congelation, has been given, with all its details, in more than one of our recent systems of surgery, as well as in several excellent inaugural dissertations.<sup>5</sup>

#### ANEMIA.

1005. A general morbid paleness of the skin and gums, joined to a state of habitual debility, without any lack of colour in the hair, uvea, or choroid coat, is sometimes observed in young females, affected with amenorrhœa or dysmenorrhœa. This state is familiarly known by the name of chlorosis.<sup>6</sup> In males, also, but much more rarely, a peculiar pallor or sallowness of skin has occasionally been observed, independently of anterior hemorrhage, intermittent fever, a cancerous diathesis, &c., but merely connected with a weakly state of the constitution generally.

These *general anemia*,<sup>7</sup> or bloodless states of the body, may depend on various causes; their history is still incomplete, and I limit myself in this place to simply mentioning these phenomena.

I have observed the hands and feet of many individuals, in all respects in very good health, become suddenly extremely pale and very cold, as if they had been plunged in icy cold water. This species of local anemia evidently occurs without any lesion of the arteries of the extremities, and is sometimes altogether independent of the temperature of the atmosphere, for I have seen it happen during summer, and have known it continue for several days without derangement of the principal functions.

<sup>1</sup> Fiunt etiam ex frigore hiberno ulcera, maximè in pueris, et præcipue pedibus et digitis eorum, non nunquam etiam in manibus. Rubor cum inflammatione mediocri est. Interdum pustulæ oriuntur, deinde exulceratio, dolor autem modicus. Prurigo major est; non nunquam humor exit, sed non multus, qui referre vel pus vel sanie videtur. (Celsus. (a) The chlorides of lime and soda are excellent applications in these cases.

## SANGUINEOUS CONGESTIONS.

1006. Several of the sanguine congestions which are observed on the surface of the body, depend on an impeded or retarded venous circulation. Such are those which may be produced at pleasure by the application of a tight ligature round any of the limbs; of the same description are those also which occur in the feet and in the extremities, in diseases of the heart, in the asphyxia of new-born infants, &c. The sanguine congestions which appear over the cheek bones in pneumonia, and the livid blotches which are observed on the posterior parts of the trunk, at the moment of dissolution, or after death, are in like manner attributable to impeded venous circulation.

It is well known that these livid blotches (*maculæ morientium*) are chiefly found occurring in those parts on which the body has lain during dissolution, or after death, and that they are sometimes observed to extend over the whole posterior surface of the body and limbs. Their bluish tint is in general not so deep as that of ecchymoses.

When the skin of the regions thus marked is incised, it is found gorged with dark blood. It is sometimes even possible to cause these livid marks to disappear, by giving the body, at the time of dissolution, or immediately after death, a position different from that in which they had been formed.

Congestions, again, which are occasionally preceded by morbid paleness, appear to be owing to an anomalous influence of the system; such is blushing or the redness of the face which is caused by emotions of various kinds, and that which is observed in the second stage of intermittent fever.

Whatever the cause of sanguine congestion of the skin, whether the afflux of blood be transient and accidental, intermittent or continuous, it is distinguished from every form of exanthematous inflammation by the latter being constantly accompanied with morbid heat, or followed by furfuraceous desquamation of the cuticle.

Sanguine congestions of the skin are not in themselves of a serious nature, but they are often symptomatic of highly dangerous affections of the heart, lungs, &c. Congestions do not require any treatment other than that proper for the diseases which produce them.

In persons labouring under contraction of the auriculo-ventricular orifices of the heart, or of the pulmonary orifice of the right ventricle, under congenital or accidental communications of the right cavities with the left, or with the principal arterial trunks, &c., a peculiar sanguineous injection of the skin, and mucous membranes, is observed; these present a livid bluish tint, and the state is known by the name of *cyanosis*.<sup>1</sup> It is distinguished from other congestions by its causes, its generality, its continuance, and by a more or less marked disturbance in the functions of respiration and circulation.

## HÆMORRHAGIÆ.

1007. The diseases in which blood is deposited on the surface of the skin, within its substance, or in the cellular membrane underneath it, have received different denominations, according as the extravasations are altogether local (*ecchymosis*, *thrombus*), or general (*purpura*), or phenomena superadded to some other affection more or less serious in its nature (*petechial typhus*, *scurvy*). Further, those effusions of blood which are occasionally observed from the surface of the skin, when accidentally deprived of epidermis, and even when still covered with the cuticle in new-born infants, have been designated by the name of *dermatorrhagiæ*.

<sup>1</sup> M. Gintrac (Observations et recherches sur la cyanose, in 8vo., Paris, 1825), has published a very good monograph of cyanosis; and has collected and compared a great number of facts for the purpose of determining the organic conditions, which may give rise to this phenomenon. M. Louis (De la communication des cavités gauche du cœur, Mémoires d'Anatomie Pathologique, in 8vo., Paris, 1826), and Messrs. Bertin and Bouillaud, (Traité des maladies du cœur et des gros vaisseaux, 8vo., Paris, 1824,) have made some observations on this disease which deserve to be consulted.

*Petechiæ* are minute red or violet-coloured spots formed by small quantities of blood deposited within the substance of the skin. The name of *ecchymoses* has been given to spots of a larger size; these are generally of a ruddy violet-colour, often livid and sometimes quite black; they are commonly of a deeper hue in the middle than in their circumference, and they vary in extent from a diameter of a few lines to one of several inches. These two varieties of spots are to be observed in all cutaneous hæmorrhagiæ, whatever their causes and characters.

The sanguineous infiltrations which take place in scurvy and in petechial typhus,<sup>2</sup> as well as those which occur incidentally in certain diseases of the skin, in severe erysipelas, in malignant scarlatina, and in the eczema rubrum of the inferior extremities, can only be studied in connection with these diseases. The ecchymosis traumatica, or ecchymosis which occurs in consequence of a blow, &c., is described in all treatises of surgery.

## PURPURA.

Vocab. Art. *Purpura*, *Hæmorrhæa*, *Hæmaceliosis*, *Land Scurvy*, &c.

1008. I comprehend under the general name of *purpura*, several diseases whose common and generic character is to manifest themselves internally by hæmorrhage, and on the external surface of the body by petechiæ or ecchymoses, independently of outward violence.

This group comprises two *species*, which are very distinct from each other in their progress, and in the symptoms associated with the common hæmorrhagic phenomena which characterize them; viz., *purpura sine febre*, and *purpura febrilis*.

*Purpura sine febre* itself comprehends three varieties (*purpura simplex*, *purpura urticans*, *purpura hæmorrhagica*), to which *purpura senilis*, and *purpura cachectica*, must be added as sub-varieties. *Purpura febrilis* may present the external and hæmorrhagic characteristics according to which the varieties of *purpura apyretica* have been established. The disease which has been described under the title of *febris hæmorrhagica* must be associated with febrile *purpura*.

1009. *Purpura simplex*. This disease almost always commences independently of any known causes, and without marked derangement of the principal functions. Some patients, nevertheless, complain of lassitude and dejection some days before the appearance of the spots. These are generally true *petechiæ*, sometimes intermixed with *ecchymoses*; in some very rare cases ecchymoses only are to be distinguished on the exterior of the body.

1010. When the eruption is petechial<sup>3</sup> only, the disease may present a considerable variety of appearances according to the number of the spots, as they are disseminated over nearly the whole surface of the body, or limited to a certain number of regions, and as the petechiæ have all been evolved at once, so as almost everywhere to present the same hue, or as they have appeared successively, during the course of several days, when they present a mixture of recent and old spots, and vary in colour, from a reddish-brown to a clear yellow.

In ordinary cases, the petechiæ show themselves principally on the

<sup>2</sup> Petechiæ frequently supervene in typhus between the second and tenth day. According to the report of Messrs. Raickem and Bianchi, out of a hundred and ninety-four subjects attacked with typhus at Volterra, in 1817, a hundred and fifty-six exhibited petechiæ. In typhus, the petechiæ generally show themselves on the lateral parts of the neck, on the shoulders, thighs, and especially on the interior of the forearms from the elbows to the wrists. True petechiæ are rarely observed at Paris in typhus fevers—(dothinerites)—they supervene more frequently in variola and scarlatina. They are sometimes observed with ecchymoses in those animals, into whose veins putrid animal matters have been injected.

<sup>3</sup> Sauvages describes simple petechial *purpura*, under the title of phænigmus petechialis: "Est exortus macularum purpurearum in universa cute—sine pruritu, tumore, alioque symptomate. Differt a publicum morsu quod in maculis phænigmi non sit punctura vestigium, ut in pulicem, apum morsibus, quos delet cataplasma ex farina, aceto et oxymelite. Hunc affectum vidi aliquoties in pueris ob calorem æstivum enasci sine ullâ notabili functionum læsione, et potu refrigerante et dein levi cathartico adhibito, inter paucos dies evanescere. Illust. vero, Professor Haguénot similem observavit in tribus mulieribus, quas quidem ille morbus defœdabat, sed aliunde nullatenus molestabat, quique intra aliquot dies spontè recessit (Sauvages, Nos. Meth. t. ii. pp. 594-95).—Voyez.: Acta phys. med. nat. cur., 1757, p. 386.—Cusson. Diss. de purpura, 1762. Monspel. (Purpura apyretica).—Parry. Edinb. Med. and Surg. Journ., vol. vii.—Bree. Medic. and Physic. Journ., vol. xxi.

legs; a great number are sometimes seen upon the face, which, at a certain distance, appears pricked with blackish and yellowish points, as if it had been bitten by a host of fleas. In this case the conjunctivæ are apt to exhibit a number of ecchymoses.

The distinguishing character of petechiæ, which are, as has been said, formed by a very small quantity of blood shed into the substance of the skin, is that they undergo no change of colour under the pressure of the finger. In this, consequently, they differ from other small red or rose-coloured spots observed in typhus and typhoid fevers, which are immediately effaced by pressure, and return when it is removed. The greater number of these petechiæ are not quite so large as a flea-bite; for the latter, besides the small ecchymosis produced by the suction of the insect, is surrounded by a narrow pink areola, capable of being obliterated by pressure, which is not observed in the spots of purpura. Some spots, of larger dimensions, and even proper ecchymoses, are often interspersed among the ordinary petechiæ. These petechiæ and ecchymoses are developed without local heat or pain, or any implication of the principal functions; children affected with them continue their play, and persons of more advanced age do not cease, in general, to occupy themselves with their ordinary affairs; the pulse remains undisturbed, and the digestion, respiration, excretions, and nervous functions, continue to be performed as in a state of health.

Shortly after its formation, each petechia undergoes a change of colour; from a reddish brown it passes through various intermediate shades to a yellow; and, unless where there is a cachectic state of the constitution, the blood which has formed it is generally reabsorbed in the course of a fortnight. This reabsorption almost always proceeds from the circumference towards the centre of the spots; I have, however, seen it take place in a contrary direction, so that the spots, in the last stages of their duration, assumed the appearance of little yellow rings or arcs. These spots are not prominent, except in those very rare cases in which the blood is not only shed into the skin, in the form of a dark point, but where a minute drop of the fluid is effused beneath the epidermis, which it raises; this little eminence, of the size of a pin's head, dries up into a small dark crust.

1011. When the eruption of petechiæ is considerable, they occasionally appear collected in different places into irregular clusters. This disposition is very rare. Finally, in a few very rare cases, a kind of marbling, of a light violet colour, like the eruption in *rubeola nigra*, is observed disseminated among the petechiæ.

1012. The petechial eruptions which characterize this form of purpura *simplex*, of infinitely more frequent occurrence than the other eruptions of the same nature, are not accompanied by epistaxis, hæmatemesis, hæmoptysis, nor by any other internal hemorrhage; they are, however, pretty frequently intermingled with real ecchymoses of the skin and subcutaneous cellular membrane.

1013. There are even cases in which purpura *simplex* is characterized by considerable numbers of ecchymoses disseminated over the body and limbs, on which very few or no petechiæ are to be seen. When the blood is thus more widely effused into the substance of the skin, it is almost always over the dorsal surface of the feet and hands, and on the internal aspects of the limbs that the broader spots are encountered. These never exhibit any thing like regularity of shape, and sometimes bear no slight resemblance to the marks left by the strokes of a whip, or violent bruises. In the intervals between the ecchymoses the skin preserves its natural colour, temperature and sensibility. The colour of these spots, which is a dark or livid blue, remains stationary for several days, and fades more slowly than that of the subcutaneous ecchymoses. They are sometimes succeeded by an exfoliation of the epidermis, particularly when a certain quantity of sanguinolent serum has been effused under it, so as partially to detach it; this happens to such an extent in some cases that the skin appears beset with a number of sanguinolent bullæ or phlyctenæ.

1014. When the blood is effused into the subcutaneous and intermuscular membrane, the skin commonly presents a number of broad and slightly prominent spots, dark in the middle and of a greenish-yellow towards the circumference. These spots are little, if at all, painful; but when the blood has been shed in large quantities into the subcutaneous cellular substance of the lower extremities, as sometimes happens, more especially in purpura hæmorrhagica, the tumefaction

and tension of the parts may be so considerable as to produce a rather intense degree of pain. In this case, the entire skin of the inner aspect of the leg is of a greenish-yellow hue, which only disappears with extreme slowness. A sort of œdematous swelling has been observed to occur on the back of the hand in certain cases of purpura *simplex*, characterized by similar ecchymoses.

In purpura *simplex*, the petechiæ and ecchymoses sometimes return suddenly in a single night, just as the disappearance of a first eruption seemed to indicate the complete re-establishment of the health. These hemorrhagic phenomena may be repeated at periods so little remote from one another, that each succeeding attack appears like that which has gone before it; some of the spots are then yellow or nearly effaced; others, very recently evolved, are of a reddish-brown; while others of intermediate standing are of a paler red. It often happens, too, shortly after an apparent cure has been accomplished, that a new eruption shows itself; so that the duration of purpura *simplex* can never be predicted: it varies from a few weeks to several months.

1015. There is a last variety of purpura *simplex* in which the extravasation of the blood is preceded by the formation of reddish oval or circular-shaped spots, prominent and accompanied by smarting or tingling sensations similar to, but much less decided than, those of urticaria (purpura *urticans*).<sup>1</sup> These little spots, usually of the size of a lentil, sink at the end of two or three days to the level of the surrounding skin; their colour, which was pink at first, becomes at the same time deeper and livid. New spots appear while the first are going off. They appear most frequently upon the legs, and sometimes in other regions of the body, intermixed with true petechiæ; the lower extremities in these cases are often œdematous; or they become affected with a sensation of stiffness or heaviness. The eruption is generally of a month's duration, but may continue beyond that term.

Purpura *urticans* can only be distinguished from hemorrhagic urticaria, *i. e.*, urticaria in which a little blood is effused into the wheals, when numbers of true petechiæ are found interspersed among the larger raised spots. Cases of urticaria have been met with, which were followed by an attack of purpura sometimes of a pretty severe character.

The spots of purpura *urticans* are broader than those of petechial purpura; but are not so extensive as the ecchymoses of purpura hæmorrhagica, which are besides more irregular in their outline. The spots of purpura *urticans* sometimes exist on the skin without being accompanied with true petechiæ and without primary ecchymoses; but there are cases in which these three appearances are found united in the same individual.

When purpura *simplex* shows itself under the form of ecchymoses, it is generally a more serious disease than when it appears under the petechial form. Purpura *urticans* is the least important of all the forms of purpura.

1016. Purpura hæmorrhagica (*morbus maculosus Werlhofii*). This species of purpura is of a much more serious nature than the species first described. It is sometimes preceded for several weeks by a sensation of lassitude and debility, by pains in the limbs, &c.; but it often makes its attack suddenly<sup>2</sup> upon persons apparently in the enjoyment of good health.

Purpura hæmorrhagica is characterized by the same external appearances as purpura *simplex*, sometimes by petechiæ, often by ecchymoses, still more frequently by both of these hemorrhagic forms at the same time, but very rarely by an actual dermatorrhagia.<sup>3</sup> In the ma-

<sup>1</sup> Macmichael has seen a case of purpura which appears to have been preceded by an intermittent urticaria, for six or eight months, and which was cured by means of purgative medicines. Lond. Med. Gazette, vol. ii. p. 90. A case of purpura *urticans* has been inserted in the Edinb. Med. and Surg. Journ., vol. xii. p. 243. Bate-man, Reports on the Diseases of London, 8vo. London, 1819, p. 181.

<sup>2</sup> Joannes Doleus speaks of a child: "Cujus omne corpus, absque dolore, febre aut lassitudine prægressâ, subito unâ cum facie, labiis, et lingua, ubi mane adsurgere, numerosissimis maculis lividis et nigerrimis obsitum fuit," etc. (Ephem. Nat. Cur., Dec. ii. ann. iv. obs. 118.) Zwinger (Act. Nat. Cur., vol. ii. obs. 79), P. G. Werlhof (Commerc. liter. Norimberg, ann. 1735, Hebd. 7 et 2) have reported analogous facts. Sauvages mentions this disease under the title of Stomacace universalis. (Nosol. Meth., t. ii. p. 296.)

<sup>3</sup> I have not observed this transudation of blood through the skin. It is asserted that in the majority of cases, the skin from the surface of which the blood flows, is not sensibly injured. Nevertheless, in a case reported by Doctor Whytt, the end of a finger whence the blood flowed was painful, and exhibited a red spot. Plouquet (Art. Hæmatidrosis, sudor cruentus) mentions several authors who have observed

majority of cases the ecchymoses appear before the petechiæ. The body has been seen to become covered with livid spots similar to those that follow bruises; in children actual thrombus occasionally forms under the hairy scalp, and the blood has even been seen exuding from behind the ears and the vertex, and the eruption of such extent as to cover nearly the whole of the skin. The disposition to hemorrhage is so great in some patients that the mere act of feeling their pulse, the pressure of a bleeding fillet, or that occasioned by the weight of the body in sitting or lying down, is sufficient to produce actual ecchymoses. In these cases the slightest punctures, the most trifling injuries that merely graze the skin, are always followed by a far greater amount of hemorrhage than usual; blood also occasionally flows copiously from the surface of blisters, issues, ulcers, &c., in such subjects. The number of petechiæ and ecchymoses in purpura hæmorrhagica is likewise almost always more considerable than in purpura simplex; and they recur with more promptitude and intensity, and continue longer than in the latter.

But the essential or distinguishing feature of purpura hæmorrhagica consists in the hemorrhage from the viscera or internal membranes, which invariably precedes, accompanies or follows the ecchymoses or effusions of blood into the skin or subcutaneous cellular membrane. The disease is always complicated with epistaxis, intestinal hemorrhage, hæmoptysis, hæmatemesis, hæmaturia, and, in females, with metrorrhagia.

Of all internal hemorrhages, epistaxis is that which occurs most frequently, particularly in children; metrorrhagia in females, and pulmonary and intestinal hemorrhage are common in adults. Several of these varieties of hemorrhage often occur simultaneously, or they alternate at different times in the same patient. (a)

1017. The general characters of the disease, which are always striking, are modified by diversity in the local symptoms, and, indeed, these vary themselves, according as the hemorrhage occurs from organs of greater or less relative importance in the economy, as the blood lost is small in quantity or very large, as the flux is frequently repeated or occurs at distant intervals, or as the hemorrhage takes place from one point in succession or from several simultaneously.

1st. Purpura hæmorrhagica with epistaxis<sup>1</sup> is the most common of all the varieties. Bateman has seen it accompanied by hæmatemesis and followed by death, from sheer loss of blood.

2d. Purpura hæmorrhagica with hemorrhage of the throat, or only of the amygdalæ,<sup>2</sup> is rather a rare variety; sometimes the whole fauces appear of a deep red and the blood issues from every part; after the hemorrhage has ceased, the parts appear dark. In one case in which there existed but an inconsiderable number of petechiæ on the skin I have seen purpura complicated with angina membranacea; this complication has even been observed under an epidemic form.<sup>3</sup>

3d. Purpura hæmorrhagica, with hemorrhage from the mouth and gums,<sup>4</sup> is often accompanied by epistaxis<sup>5</sup> and hæmatemesis.<sup>6</sup> The gums are livid, spongy, and the blood exudes from their free edge;

(a) Dr. Huston (*North Amer. Med. & Surg. Jour.*, vol. ii.), gives an account of a case of purpura occurring in an infant forty-eight hours after birth. A few hours afterwards there was a discharge from the vagina resembling the menstrual flux in its colour, want of coagulability and in its being accompanied by mucus. This discharge continued at intervals until the time of death, which took place on the eighth day after birth. When the vaginal discharge ceased, the patient was tormented with spasms.

<sup>6</sup> Harty (*Edinb. Med. and Surg. Journ.*, vol. ix.).

the tongue is livid and blackish,<sup>7</sup> bleeding and fungous in appearance, and twice its natural size; the inner surface of the cheeks presents some blackish and soft patches, and the palate is covered with blackish spots. Children have been seen to die in a single night after excessive hemorrhage from the mouth or nose; but they more commonly sink from the effects of bleeding, which, though less abundant at any one time, has recurred frequently during several weeks. The epithelium is sometimes raised on the tongue, palate, inside of the cheeks, lips, &c., in consequence of ecchymoses. It then forms irregular phlyctenæ or bullæ filled with blackish blood; by and by the epithelium bursts, and the blood flows from the surface of the excoriation; the mucous membrane often ulcerates more deeply, and hemorrhage to a greater amount is apt to take place.

4th. Purpura with hemorrhage from the stomach is sometimes accompanied with pain in the left hypochondrium, and an increase in the size of the spleen: symptoms which have been more particularly observed in individuals who have been attacked with purpura after having suffered from intermittent fever.

5th. Patients more frequently pass blood by stool; the blood is rarely pure, and of a bright colour; it is often a blackish-looking matter, of a sooty colour: this variety of purpura is less serious than the preceding one.

6th. When the blood flows by the urinary passages,<sup>8</sup> the urine is tinged with the blood, or the fluid is passed unmixed, partially coagulated, and sometimes in considerable quantities, without even the urinous odour. Blackall<sup>9</sup> has found the urine coagulable by heat, or nitric acid in four cases of purpura without hæmaturia; all the patients had the legs slightly infiltrated with serum. In one case of purpura hæmorrhagica, with febrile symptoms, Doctor Coombes remarked, that the urine which was very coagulable in the height of the disease, becomes less so after blood-letting, and abundant loss of blood; these evacuations of blood were of evident advantage, and when the cure was effected, the urine ceased to be coagulable.

7th. In purpura with hemorrhage from the uterus, the vagina,<sup>10</sup> or the pudenda,<sup>11</sup> patients often experience pains in the loins. These hemorrhages of the uterus are almost always serious; I have seen a case in which the bleeding was mistaken for a miscarriage, and the patient died. It very rarely happens that such hemorrhages are salutary, or critical; nevertheless Bateman met with a woman affected with purpura simplex, who recovered after an attack of uterine hemorrhage.

8th. When hemorrhage takes place from the lungs,<sup>12</sup> patients have fits of coughing, spit blood or bloody matter, and feel great pain in the præcordia and chest. Duncan and Bateman have seen the description of hemorrhage under review prove rapidly fatal.

9th. Finally there are cases in which hemorrhage occurs successively, and in a few days from the nasal fossæ, from the mouth, from the lungs, from the stomach, the intestines,<sup>13</sup> &c.; in some cases the bleeding recurs at particular hours, in others there is a slow and almost continual exudation of blood.

If hemorrhage recurs frequently or proves very abundant, from whatever channel it may flow, the lower limbs become œdematous, the face pale, and the body generally assumes a livid and yellowish hue; the petechiæ and the ecchymoses, greater in number, have a deep brown tint, the blood becomes more and more serous, the extremities cold, the patient experiences weakness, the pulse becomes small and frequent; nervous symptoms, sometimes convulsive movements, trembling of the whole body, and fainting fits occur; and if the hemorrhage is repeated, the patient dies ex-sanguine, unless febrile symptoms supervene and give rise to some other form of fatal termination. In fact, after a certain number of attacks of hemorrhage,

an acute fever, with symptoms of a typhoid character, sometimes comes on, and patients frequently sink on or about the twelfth day.<sup>1</sup>

1018. *Purpura febrilis*. This description of purpura may be sporadic or epidemic;<sup>2</sup> its ordinary duration is from two to three weeks. *Purpura febrilis* attacks persons of all ages, and of every variety of constitution.

A feeling of great lassitude and depression, shivering fits, of longer or shorter duration, followed by heat, pains in the back and limbs, headache, and oppression, sometimes a sensation of great heat over the whole of the body, nausea, retching, quickness of the pulse, and other febrile symptoms, are the precursors of the petechiæ or ecchymoses. They appear from the third to the sixth day, sometimes without hemorrhage from the mucous membranes, or the viscera (*purpura febrilis simplex*).

Frequently, in *purpura febrilis*, after the initiatory fever, the eruption of petechiæ is preceded by *exanthematous spots*,<sup>3</sup> analogous to those of *urticaria febrilis*. The skin, already red, is then covered with petechiæ of a purple colour, the dimensions of which vary from that of the head of a very small pin to that of the tip of the little finger. These last are slightly prominent.

1019. *Purpura febrilis* may appear under the form of *ecchymoses*. M. Ollivier d'Angers<sup>4</sup> observed a curious case of this kind in an infant, three years of age, which he gave me an opportunity of seeing, in whom the cutaneous ecchymoses made their appearance on the limbs at the same time that these became œdematous. The skin was hot and painful; the pulse from 120 to 130 in a minute; the child experienced pain in the abdomen; the pressure of a garter, or of the finger, was sufficient to produce an ecchymosis. This child was cured after a month's illness.

1020. In *purpura febrilis*, after the primary fever, hemorrhages occasionally occur from one or other of the different passages of the body, at the same time that petechiæ and ecchymoses are formed in the skin, and subcutaneous cellular tissue (*purpura febrilis hæmorrhagica*).<sup>5</sup> In some patients the urine is highly tinged with blood; the pulse, small and contracted, in the first instance, sometimes ac-

quires more strength and softness after a first hemorrhage; but upon further loss of blood, all the symptoms which I have mentioned in treating of *purpura hæmorrhagica non-febrilis*, may occur.

*Purpura febrilis* may present, from the commencement, very serious symptoms, and terminate, in a few days, in death, when blood is extravasated, in large quantity, into the tissue of the lungs or substance of the brain.<sup>6</sup>

1021. We must assimilate a species of *hemorrhagic fever*<sup>7</sup> to *purpura febrilis*, inasmuch as it only differs from *purpura febrilis hæmorrhagica*, by the absence of ecchymoses and petechiæ. In this fever, after symptoms of a more or less violent character, hemorrhages from the nose, mouth, intestines, urinary passages, &c., take place. These general hemorrhages are sometimes not accompanied with fever in the beginning, but it generally appears after an interval of a few days.

These general hemorrhages have been seen to alternate with determinations of blood to particular organs, as the tonsils, &c.

1022. *Purpura senilis*. Under this name, Bateman has described a variety which he has only observed in old women, and in which ecchymoses, of a very deep-red brown colour, irregular in their form and dimensions, appeared principally along the outsides of the forearms. Each of these spots lasted only from ten to twelve days; but in one case, Bateman saw them return at different times, during the space of ten years, all the while, without any particular derangement of the health occurring. I have myself, several times, observed similar spots on the same parts, and on the backs of the hands of elderly people of both sexes. I ought to add, that in all these cases, this description of ecchymosis lasted much longer than in those mentioned by Bateman, generally longer than a month. The spots were of the colour of wine lees, and bore a pretty strong resemblance to particular nævi; they did not disappear upon pressure.

This *ecchymosis senilis* must not be confounded with true purpura which may also attack the aged.<sup>8</sup>

1023. Certain eruptions of petechiæ and ecchymoses may be regarded as marking states approaching to *purpura senilis*, which is sometimes seen in individuals labouring under enteritis, chronic peritonitis or other serious diseases, followed by the cachectic constitution. As for the ecchymoses and petechiæ, which appear on the lower limbs of patients, affected with asthma, or diseases of the heart and in dropsy, the sanguineous infiltrations are probably the effect of two causes: an impediment to the venous circulation, and some modification of the blood.<sup>9</sup>

<sup>6</sup> Zacutus Lusitanus speaks of a patient whose whole body was livid, and who, during two days, was in a general bloody sweat, and became covered before death with a perfectly black eruption. In another place, he relates that several persons, who had been cupped in this disease, bled so profusely that it was impossible to stop the hemorrhage by any means, so that they all died. [Praxis medica miranda, obs. 41, 42.]

<sup>7</sup> M. Littré showed me a young man who for several days had laboured under hæmoptysis, and hemorrhage from the nose, intestines and urinary passages [Gazette medic. de Paris, 1833, p. 263]. Petrus Poterius, (obs. et curat. insig. cent. iii. 60,) has published a similar case. Morgagni states, that in the year 1200, a great number of men died in Etruria and Romagna, in twenty-four hours, in consequence of a flow of blood from the nostrils. [De sedib. et caus. morbor. Epist.]

<sup>8</sup> Latour, op. cit. t. xi. p. 27.

<sup>9</sup> The patient Pierre, sixty-nine years of age, had been for several months at the Hôpital de la Pitié, when he was attacked on the 6th Feb. 1826, without any apparent cause, with pain in the epigastrium, diarrhœa, and loss of appetite; the tongue was red and dry, the thirst great, the pulse weak, and not frequent. These symptoms were met by abstinence, demulcent drinks, and emollient poultices applied to the abdomen; the symptoms continued, and the patient sank more and more. On the 23d, the tongue was dry and brown, the pulse slow and weak; large ecchymoses appeared on the inside of the lower limbs, and he died the 7th Feb., 1826.—Secto cada-veris, thirty-six hours after death. On the right leg towards the anterior and inner surface of the tibia, the skin appeared livid, and below it was a large ecchymosis, six inches long and three inches broad. Black blood was extravasated into the subcutaneous cellular tissue, with which it may be said to have been combined; similar subcutaneous ecchymosis had taken place in the sub-aponeurotic cellular tissue of the leg; the subcutaneous cellular tissue of the whole of the outside of this leg was infiltrated in the same manner with black blood. This infiltration was much more considerable than would have been imagined from the external appearance of the limb. There were no ecchymoses in the cellular tissue of the sole of the foot: but it was bathed in a reddish serum. The vena saphena contained very little blood. There were ecchymoses in the tibialis posticus, and similar sanguineous infiltrations in the subcutaneous cellular tissue of the outside and inside of the thigh. Some were also discovered under the crural aponeurosis, and in the cellular tissue between the rectus femoris, and the triceps; the lower left limb presented similar alterations, and was surrounded under the skin with an infiltration of black blood. The right arm presented subcutaneous, sub-aponeurotic, and inter-muscular ecchymoses. The left arm did not present any. Thorax. A great quantity of adipose tissue, deposited

<sup>1</sup> Duncan, jun. (case of *purpura hæmorrhagica*, Edinb. Med. and Surg. Journ., vol. xviii. p. 405).

<sup>2</sup> Lordat observed in the prison at Montpellier, a hemorrhagic petechial fever which appeared in the spring of the year 1800, lasted five months, reappeared towards the middle of September, 1804, and continued till the month of January, 1808. This description of fever attacked nearly one half of all the women who were confined there, and no more than two men. It began by a shivering fit, followed with intense fever and depression, pain in the head, acute suffering in the epigastrium, redness of the face, white tongue, scanty and scalding urine, constipated bowels, &c. This state continued for three days; on the fourth, the fever abated, and an eruption of petechiæ took place on the neck, breast, upper part of the arms, trunk, &c. After the eruption had appeared, the fever and the hemorrhage, which was generally from the nose and the uterus, subsided at the same time; towards the ninth day the spots usually disappeared. After several days of apparent convalescence, a relapse often occurred, and these relapses were sometimes repeated: no one died. Some women, after several relapses, became decidedly scorbutic. Latour (op. cit. p. 170). Vandermonde, Journ. de Med., t. vi. p. 339, *maladie noir d'une espèce particulière*, has recorded a remarkable case of *purpura febrilis*. We must assimilate to these cases the accounts we have of a disease observed among deserters who were brought by forced marches to a place of confinement, and whose bodies became covered with petechiæ and ecchymoses, and in whom nothing succeeded in stopping the nasal and intestinal hemorrhages. (Latour, op. cit. t. ii. p. 469.) See a case of Sporlus, cited by Fabricius Hildanus (obs. chir. cent. vi.). Th. Schwenck, Sang. Hist., p. 130.

<sup>3</sup> During the summer of 1797, Latour saw at the Hôtel Dieu of Orleans, a great number of reapers, the whole of whose bodies, after great lassitude in the limbs, irregular shivering fits, and vertigo, became redder and hotter than usual, whilst the head was heavy and painful, the pulse very full, and the beating of the carotid arteries extremely violent; the tongue was at the same time red and dry, the thirst urgent, the urine scanty, the bowels relaxed, the breathing occasionally interrupted by sighing, &c. On the second and third days of the attack, exanthematous patches appeared over the skin, which looked as if it had been whipped with nettles. Towards the fifth or sixth day innumerable brown and black petechiæ, of a lenticular shape, appeared in the middle of the exanthematous blotches; the fever commonly subsided about the fourteenth or fifteenth day, and always before the one and twentieth, and the petechiæ vanished, becoming yellowish, like ecchymoses, as they declined; the disease was not fatal in its tendencies. Latour (Hist. Philosoph. et med. des hæmorrhagies, vol. ii. 8vo. Paris, 1828, tom. ii. p. 172, and Sequent) relates another case of this species of hemorrhagic nettle-rash, which after beginning with delirium, and other serious symptoms, terminated happily on the fifteenth day. See an analogous case published by Johnston, (Edinb. Med. and Surg. Journ., vol. xviii. p. 402,) who very justly remarks that this case of *purpura febrilis hæmorrhagica* differs materially from the ordinary *purpura hæmorrhagica*.

<sup>4</sup> Ollivier d'Angers. Développement spontané d'ecchymoses cutanée avec œdème aigu sous-cutané et gastro-entérite. (Archives génér. de Med., t. xv. p. 206.)

<sup>5</sup> Reil (observations quædam de hæmorrhœa petechiali.—Memorial Clinic. fasc. v.), relates three remarkable cases of *purpura febrilis hæmorrhagica*.

1024. *Purpura sine febre* is more frequently complicated with *rupia* than with any other eruption. *Purpura febrilis* and the *hemorrhagic fever* occasionally appear in the course of several acute diseases, and particularly during *small-pox*.<sup>1</sup> *Purpura* may complicate *jaundice*<sup>2</sup> and *peritonitis* (Watson). I have seen it occur in the course of a fatal case of internal strangulation of the small intestines, and in several other diseases very different in their nature from *purpura*.

1025. *Anatomical observations*.—Cutaneous and subcutaneous ecchymoses and petechiæ, observed in *purpura*, neither increase nor decrease at the instant of dissolution. In dissecting the skin after death, the petechiæ and ecchymoses are found not to be all similarly situated. Some are very superficial and on the surface of the skin, others occupy the internal areolæ of the dermis, and the larger and deeper are seated in the subcutaneous cellular tissue. All these spots are formed by the effusion of blood which is coagulated in the largest and blackest, and fluid in the smaller ones. The vascular ramifications in the neighbourhood of the small effusions are not more developed than in their natural state; the blood is easily removed by the aid of washing or maceration.

The mucous membranes of the mouth, stomach, and intestines present in some point or other, petechiæ and ecchymoses similar to those of the skin. The exterior surface of the lungs generally presents a certain number of ecchymoses, which are rendered particularly distinct, as in the spaces between them; the colour of the lungs is natural. Beneath the ecchymoses, the tissue of these organs is of a reddish-brown colour, homogeneous texture, harder than the healthy part which surrounds it, and presents a small circumscribed infiltration from which black blood is easily forced out by pressure, a character altogether analogous to the hæmoptoe or apoplectic dispositions described by Laennec. The same description of ecchymosis is sometimes found between the mesenteric laminæ, under the peritoneum, pleura, pericardium, &c. Positive effusions of blood have been seen also into the membranes of the brain, and sanguineous infiltrations into the diploë of the broad bones, and into the medullary membranes of the long bones.<sup>3</sup> When patients have sunk after profuse or repeated hemorrhages, the heart only contains sanguineous serum without clots; the arteries and veins present no peculiar or regular alteration, and the same may be said with regard to the other organs, which may present accidental, but not characteristic lesions.

1026. Askow, having analyzed the blood of patients affected with *purpura*, affirms that it is in no way different from that of a healthy person; Johnston, however, has seen it remain fluid, not separating into serum and coagulum, although there was some appearance of coagulable lymph. In a case seen by Duncan, the blood, in flowing from the vein, had a most extraordinary appearance; he compares it to arterial blood mixed with water; it was half transparent, and of a bright red colour. The blood coagulated very slowly, and the coagulum was not very firm; the serum did not separate, and the coagulum had the appearance of a shaking jelly, through which the red globules, which had fallen to the bottom, could be perceived. The red colouring matter was in smaller proportion than in ordinary blood, probably from the frequent recurrence of the hemorrhage. There was no trace of coagulable lymph. At the commencement of *purpura hæmorrhagica*

between the muscular tissue and the pericardium, surrounded the heart, particularly the right ventricle; the organ was small in size. The mucous membrane of the larynx and trachea was of a livid red colour; the lungs were healthy and crepitating; the abdominal and thoracic aorta was ossified in parts along its whole extent. This artery contained a large fibrinous clot. The thoracic and abdominal vena cava contained no blood; a number of small lymphatic inflamed glands were perceived in the neighbourhood of the aorta; the sub-peritoneal cellular tissue and the epiploons were loaded with fat. The peritoneum was healthy; the mucous membrane of the stomach was covered with numerous blood-vessels; deep red-coloured spots were found on the duodenum; the rest of the intestines did not present any alteration. The urinary and biliary organs, and the spleen were healthy; the psoas and iliacus muscles were deeply ecchymosed, and loaded with black blood; the muscles of the body and of the face did not present any particular appearance; the articulations were healthy; the brain appeared loaded with transparent serum; the cerebral sinuses contained fibrinous concretions.

<sup>1</sup> Haller speaks of an epidemic small-pox in which the patients, at the moment the eruption appeared, experienced pains in the back, and hæmoptysis: petechiæ and ecchymoses appearing at the same time among the pustules. [Opuscul. Patholog., obs. 44.]

<sup>2</sup> Dr. Elliotson has related two cases of this complication; one was successfully treated with calomel in doses of 12 grains, and half an ounce of castor oil repeated for several days; the other terminated in death.

<sup>3</sup> Journ. complém. des sc. méd., t. xxxvi. p. 434.

*sine febre*, I have never been able to discover any thing in the blood that differed from the natural state; after repeated hemorrhage, it only became more serous. In *purpura febrilis*, I have several times seen the blood present a well-marked buffy coat.

1027. *Causes*.—The mode of formation of the ecchymoses and petechiæ in *purpura*, is still unknown. The vessels in which the blood circulates, having been found unaffected, and no obstacle to its flow being discoverable, it has been supposed that the transudation of the blood was owing to a change in its composition, to a greater tenuity of its molecules, &c. Others have supposed that the blood flowed from the dilated pores of the capillary arteries and veins, whose sensibility was increased or diminished, or the sides of which had given way, &c.

The disease, not of very frequent occurrence, attacks all ages; but more frequently appears before puberty. I have particularly noticed it in children of weakly constitution, ill fed, kept at sedentary occupations, inhabiting low and damp places, or in women of a nervous temperament, and of great mental susceptibility. *Purpura* sometimes occurs, without any appreciable cause, among the higher classes of society, and in persons apparently of the finest constitutions; it appears that it may be hereditary.<sup>4</sup>

1028. *Diagnosis*.—Ecchymoses produced by external violence, and certain extravasations of blood<sup>5</sup> into the subcutaneous and intermuscular cellular tissue of fractured limbs, the consolidation of which they either retard or prevent, must be distinguished from *purpura simplex*. Nor must this disease be confounded with the petechiæ or ecchymoses which sometimes appear on the lower limbs after standing for a considerable length of time, or in consequence of a mechanical obstacle to the return of the blood.<sup>6</sup>

*Purpura febrilis* and *hemorrhagic fever* may easily be distinguished from scorbutus, which is a chronic affection. *Purpura sine febre* cannot be confounded with scorbutus, when the hemorrhage occurs from any other passages than the mouth, if the gums are healthy, &c.; but it appears to me to be almost impossible to distinguish *chronic hemorrhagic purpura*, in which the blood flows from swelled gums, and the insides of the cheeks, from true scurvy. To be satisfied of this position, no more is required than to consult the account which Poupert and Thibaut have published of an epidemic scorbutus, which attacked great numbers of the patients in the Hôtel Dieu.<sup>7</sup> Still in scorbutus the gums are swelled, softened, and, as it were, putrefied; whereas, in *purpura*, they are simply the seat of true hemorrhage, and do not generally present any of these appearances.

The alteration of the gums is much more extensive in scorbutus, where it is most commonly preceded by swelling and inflammatory redness, as it is followed by the loosening and loss of the teeth.<sup>8</sup> Scorbutus has further been most frequently observed on ship-board, in prisons and in besieged fortresses.

In yellow fever, as in *purpura hæmorrhagica*, spontaneous hemorrhage, blackish bloody evacuations and vomiting, sanguineous infiltration into the muscles, into the cellular substance under the skin, into its substance, or over its surface, occur; but yellow fever differs from *purpura* in its cause, and the severity of its symptoms, of which profuse hemorrhage is never one of the most alarming.

<sup>4</sup> Davis's Edin. Med. and Surg. Journ., t. xxvi. p. 291.

<sup>5</sup> Cloquet (Jules). Du scorbut qui se manifeste d'une manière locale pendant le traitement des fractures. (Archiv. génér. de méd., t. i. p. 470.)

<sup>6</sup> Pringle having bled a person labouring under jail fever, petechiæ appeared, during the time of bleeding, on the forearm, below the ligature, and in no other part. (Vide Latour, op. cit. t. ii. p. 345.) I attended in 1829, at the Hôpital Saint Antoine, a man in whom, after death, the right iliac vein was found filled with fibrinous clots of recent formation. There had appeared during life, a serous infiltration of the whole of the right leg. This infiltration, which was very considerable, happened about thirty hours before death, and was accompanied after eighteen hours by a considerable development of petechiæ and ecchymoses which appeared only on the infiltrated parts.

<sup>7</sup> Poupert (Mémoires de l'Académie des Sciences de Paris, 1699).

<sup>8</sup> Escarbot has left us a description of an epidemic scorbutus with which Cartier's fleet was affected on a voyage of discovery to Canada in 1535. "Et à aucuns leur devenaient les jambes toutes sursies de gouttelettes de sang comme pourpre, puis montoit ladite maladie aux hanches, aux cuisses et espauls, aux bras et au col, et à tous venoit la bouche si infectée et pourrie par les gencives, que toute la chair en tomboit jusqu'à la racine des dents lesquelles tomboient presque toutes, et tellement sesprint ladite maladie à trois navires, qu'à la my-février, de cent dix hommes que nous estions, il n'y en avoit pas dix sains." Les navigations, etc., faites par les Français es-Indes Occidentales. Paris, 1618.

The same observation applies to small-pox, measles, scarlatina, typhus, severe hospital or jail fever,<sup>1</sup> and the plague, diseases all of which are sometimes accompanied with petechiæ and ecchymoses. But the morbid miasmata or poisons which produce these different diseases, give them peculiar characters and distinguishing features, which the mere community of a single serious phenomenon, that of hemorrhage, will not permit us to overlook or to misunderstand.

1029. *Prognosis*.—Purpura hæmorrhagica, which shows itself by ecchymoses on the skin, is, generally speaking, a more serious disease than that which appears by petechiæ, and this latter form is of a more dangerous nature than purpura simplex. Purpura febrilis and hæmorrhagic fever are generally less serious than those forms of hæmorrhagic purpura which commence without fever, but become febrile after hemorrhage has recurred several times. A small, hard, and very frequent pulse (from 130 to 140 a minute) is often a precursory sign of a renewal of the hemorrhage or of other serious symptoms.

Ecchymoses on the nose are often the forerunners of profuse hemorrhage from the nose or the nasal fossæ; palpitations or pulsations of the epigastrium are indicative of hæmatemesis; oppression about the chest, and cough often precede hæmoptysis.

1030. *Treatment*.—The treatment varies with the varieties, the forms, and the periods of this disease. Purpura simplex sine febre sometimes gets well spontaneously after lasting several weeks, when the petechial eruption is not very considerable. Antiscorbutic medicines—infusion of wild radish, antiscorbutic wine and syrup—are applicable in the greatest number of cases, and are beneficial above all to individuals of a pallid complexion and of weakly constitution.

Purpura hæmorrhagica sine febre should be treated by acidulated drinks, chalybeates, the decoction and extract of rhatania, sometimes by the acidulated decoction of cinchona, and often by lotions, cold ablution and aspersion, if the hemorrhage is very profuse, and if, as is usually the case, there is no indication that the loss of blood is necessary or supplementary to some other evacuation. At this period and under such circumstances, blood-letting is rarely advisable, unless the pulse be strong and full; hæmoptysis, hæmaturia, and bleeding from the uterus, sometimes render it necessary to have recourse to the detraction of blood; but when, after several attacks of hemorrhage, the primary symptoms remain or reappear, bleeding ceases to be applicable, even with a hard and frequent pulse. (a) In this case purgatives become very useful, and have been particularly recommended by Storck, Burserius, and a great many able practitioners. Some prefer cathartic vegetable, others mercurial purgatives.<sup>2</sup> Oil of turpentine<sup>3</sup> combined with calomel, with castor-oil or syrup of senna, has been mentioned as a good form of laxative; I generally make use of jalap combined with calomel. (b)

When purpura occurs where the individual is already affected with intermittent fever,<sup>4</sup> if the petechiæ and ecchymoses have appeared

(a) Dr. Elliotson and Dr. Latham give cases of successful results after blood-letting, followed by purgatives. Aware of the different states of the system associated with purpura, we should have recourse to treatment correspondingly various. As a general rule, neither venesection nor the early use of tonics is advisable. Purgatives, mild salines, with the other parts of an antiphlogistic regimen, are preferable.

(b) Acetate of lead and opium, and sulphate of quinine and calomel (Dr. Wright—*N. Y. Med. & Surg. Jour.*, vol. i., p. 456), have been found to succeed in some cases.

<sup>1</sup> Latour says, that a great number of deserters died at the Hospital of Orleans in 1806 and 1807, of a violent fever, sinking in some cases whilst vomiting quantities of blackish and fetid blood, in others in consequence of a nasal or intestinal hemorrhage so profuse that it only ceased with death. Several of these patients were covered with black and violet-coloured petechiæ; others had the whole surface of the nose only as black as charcoal.

<sup>2</sup> Harty (W.). On the efficacy of mercurial purgatives in purpura. *Edinb. Med. and Surg. Journ.*, vol. xxiv. p. 57.

<sup>3</sup> Whitlock Nichol. Obs. on the treatment of purpura hæmorrhagica. *Edinb. Med. and Surg. Journ.*, vol. xviii. p. 540. Magee, Jos., (case of purpura hæmorrhagica successfully treated with spirit of turpentine, *Edinb. Med. and Surg. Journ.*, vol. xxiv. 1825, p. 307,) appears to me to have used both scammony and turpentine in too large doses.

<sup>4</sup> I had a man twenty-seven years of age under my charge in 1829, at the Hôpital de la Charité, who had been long ill with quartan ague, and for the last six weeks had been passing blood in his stools, without pain, upon whose belly and lower limbs petechiæ had appeared at the same time. The fever quickly yielded to the adminis-

during the attack, sulphate of quinia, by preventing the return of the fit, often renders all other remedies unnecessary.

If purpura occurs after privations of all kinds, more generous and wholesome food, composed of rich soups, boiled and roast meats, wine, jellies, and good wine mixed with water for drink, contribute materially to the cure.

1031. Each variety of hemorrhage which occurs in purpura, further requires a different mode of treatment.

1st. Ecchymoses and petechiæ should be treated by stimulating spirituous lotions or lotions of the chloride of lime. The limbs may also be wrapped in rollers dipped in cold vinegar and water.

2dly. In cases of frequent or very profuse epistaxis, cold lotions applied to the head and between the shoulders, astringent lotions, mustard foot-baths, and above all, plugging the nostrils, should be made use of.

3dly. Dry cupping in different parts of the body has often proved very serviceable in hæmoptysis.

4thly. Lotions and styptic injections, ice, and cold applications to the epigastrium, are useful in uterine hemorrhages.

5thly. Cold water strongly acidulated with vinegar, injections of a strong acidulated decoction of gall-nuts, ice enclosed in a bladder and applied to the belly, should be made use of in intestinal hemorrhages.

6thly. Hemorrhages which take place from the surface of issues, blisters and ulcers, may be arrested by compression and styptic lotions; and, finally, other hemorrhages are to be treated by similar means, and according to the general principles that are applicable under other circumstances.

1032. The antiphlogistic treatment generally,—low diet, &c., is usually applicable in purpura febrilis and hæmorrhagic fever. The temperature of the body and of the outward air should be kept very moderate. Cold water, whey, and slightly acidulated mucilaginous drinks are the best means we possess for reducing fever; if the first febrile symptoms are of a serious nature, if the hemorrhages which have taken place have not been very profuse, and, as a still stronger reason, if the pulse be strong and full, bleeding should be had recourse to once and again, should it appear to be indicated.<sup>5</sup> Bleeding from the foot is particularly recommended in epistaxis, and bleeding from the arm in hæmoptysis, hæmatemesis, metrorrhœa, &c. When purpura has been preceded by amenorrhœa or dysmenorrhœa, the application of leeches to the genital organs is preferable to bleeding from a vein. Immediately after bleeding, purgatives are extremely useful; a bolus of rhubarb and calomel, and of jalap and calomel, with whey for drink, may be prescribed immediately, and followed up by the use of injections of oil of turpentine.<sup>6</sup> The symptoms have sometimes been known to disappear after salivation, and hypercatharsis occasioned by large doses of calomel. To conclude, bleeding and purgatives are the principal remedies in purpura febrilis and hæmorrhagic fever.

1033. Ecchymoses occurring in the aged, require nothing more than simple local measures, the use of spirituous and tonic lotions, &c. Petechiæ and ecchymoses occurring in persons of cachectic constitutions are the results and indications of serious and deeply-seated diseases towards which the whole attention of the practitioner should be directed.

#### Historical Notices and particular Cases.

1034. Hippocrates<sup>7</sup> describes a species of disease of the spleen with fetid odour of the mouth, swelling of the gums, and large bleeding ulcers of legs, which seems rather to be scurvy than purpura. Celsus<sup>8</sup> repeats this passage almost literally and makes further mention of hemorrhages of the nose and other parts. The ancients speak of universal hemorrhages, not only proceeding from all the principal orifices

tration of sulphate of quinine, when the petechiæ disappeared and did not return. I have quoted, after Stoll, in the first edition of this work, a case of purpura complicated with intermittent fever, which terminated in death. *Stoll. Ratio medendi. Pars prima*, p. 110, 8vo. Parisii, 1787.

of the body, but even through all the pores of the skin, and which they attribute to the bite of the serpent *hæmorrhoids*.<sup>1</sup>

Rivière or Riverius<sup>2</sup> had distinguished purpura from the petechiæ which are observed in malignant fevers, long before Werholf<sup>3</sup> devoted some lines to the description of this disease in the celebrated Nuremberg collection. Graff<sup>4</sup> published, in 1775, the first inaugural dissertation on this affection, the history of which has since been rendered more complete by the researches of Behrens,<sup>5</sup> Car. Strack,<sup>6</sup> Adair,<sup>7</sup> Berenger,<sup>8</sup> J. G. Acrel,<sup>9</sup> Osthoff,<sup>10</sup> Havinga,<sup>11</sup> Willan,<sup>12</sup> Bateman,<sup>13</sup> Pickel,<sup>14</sup> Groeser,<sup>15</sup> Gauthier-Bellefonds,<sup>16</sup> Pierquin,<sup>17</sup> Brachet,<sup>18</sup> Fourneaux,<sup>19</sup> A. Keller,<sup>20</sup> Conradi,<sup>21</sup> and several others.

CASE CXLIX.—*Purpura hæmorrhagica; nasal hæmorrhage, numerous spots upon the skin; death; petechiæ in the cerebral substance, on the heart, and lungs; collection of blood in the substance of the liver.*—Joseph Roullier, thirty-two years of age, a porter, had been extremely subject to attacks of epistaxis for two years. About three months ago he had been admitted into the hospital Cochin. At that time he was very much debilitated by a copious bleeding from the nose which had continued for a fortnight; he had, moreover, small red spots upon the skin. At the end of a fortnight the bleeding at the nose had ceased, and the patient being better, he was discharged on the breaking out of the epidemic cholera; he remained about a fortnight after leaving the hospital without any fresh attack of hæmorrhage; subsequently to that period, however, he rarely passed four days without one; he did not the less continue at his work, although his strength diminished daily. The pituitary membrane still continued the only part towards which the hæmorrhagic effort was directed; the patient had never had hæmoptysis, nor had he ever voided blood in his stools. He presented himself for admission at the hôpital de la Charité on the 26th October, 1833. For eight days previously he had been continually losing blood, and his debilitated state had obliged him to give up work. The following is the state which he presented the day after his admission:—Considerable paleness of the face; the nasal cavities continue to discharge drops of blood, excessively liquid and serous, and slightly inclined to a pink colour. The hæmorrhage is, however, rather diminished since yesterday, compresses steeped in vinegar having been applied to the face since the patient's admission into the hospital. The tongue and lips are pale; the gums, perfectly healthy and firm, as in the normal state, are blanched; the appetite is pretty good; the patient asks for food; there is no nausea; the stomach is perfectly healthy. The alvine evacuations are natural, occur regularly, and present no appearance of blood. The chest, after careful examination, is found to be in the most normal state. The pulse is quick, giving a hundred pulsations in a minute. The chest, neck, arms, and legs, are covered with a multitude of deep red spots, scattered here and there in an irregular manner. These spots, which are regularly rounded, are for the most part a line in diameter; on some

points they are isolated, in others they are united by twos and threes, and in several places are more closely connected, being clustered in large numbers, so as to form patches of various dimensions, which at first sight resemble ecchymoses. The greater number of these spots are of a deep red, others present a paler russet colour, and others have a slightly yellowish tinge like an ecchymosis that has almost entirely disappeared. On examining attentively such of these spots as are thus in process of resolution, it is easy to perceive that they fade from the centre towards the circumference, as they leave at length a thin marginal ring. The arms and thighs exhibit only a few detached spots, scattered here and there. The chest and abdomen, on the contrary, present a much greater number; the spots, indeed, are confluent over these two regions, and in some places form continuous patches of ecchymosis. (Decoction of bark with acid; half a drachm of extract of rhatany in pills.)

28th. The nasal hæmorrhage diminished; the general condition the same as yesterday; the intellect of the patient is observed to be slightly affected.

29th. Fresh epistaxis, which is very copious: the blood flowing from the nasal cavities is very serous; face extremely pale, pulse very weak; vomiting in the morning, the patient drowsy; the spots upon the skin neither larger nor more numerous than on the preceding day; (*acidulated decoction of bark, as before; draught, with decoction of rhatany, and eighteen grains of alum; a lump of ice to melt in the mouth; compresses dipped in vinegar to the face; sinapisms to the feet.*)

30th. Extreme paleness; continued hæmorrhage, but less copious; drowsiness; the patient talks incoherently on being waked from sleep, and exhibits a considerable degree of excitement; pulse very weak. The spots had faded considerably; on the arms and thighs they have disappeared; but are still to be found on the breast and belly, though paler than before. These spots still continue to fade from the centre to the circumference, thus forming little rings, which become effaced gradually. (*Acidulated decoction of bark; four ounces of Malaga wine; draught, with a decoction of rhatany, and eighteen grains of alum; compresses dipped in vinegar and water.*) On the following days, nothing occurred worthy of remark; the bowels began to act; the patient was less depressed.

3d of November.—The old spots have almost entirely disappeared, and no fresh ones have been thrown out; the face still rather pale; the patient feels much better; the pulse is stronger than on the preceding days; it is easy to trace in the spots which yet remain, all the various shades of colour through which they pass before they disappear. (*Acidulated decoction of bark and Malaga wine, &c., as before; quarter diet.*)

5th. Fresh nasal hæmorrhage, but not copious; the face pale; the pulse weak and quick; the skin does not, however, exhibit any new spots; and it is with difficulty that a few small discoloured rings, the remains of the brown spots which the skin formerly presented, can still be perceived; the chest and digestive organs do not appear to be affected; the patient talks much, but does not seem anxious about his situation; (*mucilaginous draught, with sixty drops of the essential oil of turpentine; mucilaginous lemonade; mustard bath to the feet; compresses, wrung out of vinegar and water, to the nose and forehead.*) Nothing new on the following days; the hæmorrhage stopped completely; the patient is still pale and weak; he attempted to rise, but felt giddy, and nearly fainted.

9th of November.—The spots on the skin have completely disappeared. The patient has expectorated several times; the mucus, which appears to come from the posterior nares, is slightly tinged with blood, but there is no actual hæmorrhage. The dose of turpentine is increased to a drachm; the patient has half diet, which he eats.

10th. Fresh nasal hæmorrhage.

11th. The hæmorrhage continues; the blood is very liquid and pink-coloured. The patient is extremely pale and feeble; the pulse weak and quick; tongue white; no derangement of the digestive organs, nor of the chest; the patient is drowsy, retains all his faculties; in other respects there is nothing remarkable. With regard to the skin, the old spots have completely disappeared, and no new ones have shown themselves. (*Acidulated decoction of bark; wine and water for drink; four ounces of Malaga wine; sinapisms; compresses wrung out of vinegar and water.*)

<sup>1</sup> Lucan has drawn an appalling picture of these symptoms. (Pharsal, lib. ix. v. 810.) Several naturalists have doubted the existence of the hæmorrhoids.

<sup>21</sup> Diss. de morbo maculoso hæmorrhagico Werlhofii. Gottingæ, 1829.

12th. The debility is extreme; the nasal cavities continue to discharge a small quantity of blood of a very pale colour, which does not coagulate, and is entirely serous; the face, lips, and tongue, are blanched; the patient complains of his chest; the respiration is embarrassed; with the stethoscope, the respiratory murmur can be heard, but it is feeble and indistinct; the chest generally sounds satisfactorily; the pulse is very weak and quick. (*Acidulated decoction of bark; wine and water, &c.*, as before.) The bleeding from the nose continued very slowly; the patient became gradually weaker and weaker; and after sinking into a tranquil kind of delirium, he died in the course of the day.

*Secio cadaveris thirty hours after death.*—There is nothing remarkable in the external appearance. *Head.*—The arachnoid membrane is rather thickened; the sub-arachnoid cellular tissue is infiltrated with serum. The cortical substance of the brain is pale, and very moist; in one point of the anterior convolutions, there is a small bloody effusion, of the size of a large pin's head. The white substance presents a great number of petechiæ, disposed in patches here and there. These red points are surrounded by a small gray circle; in another point there is a second effusion, of the size of a common pea. *Chest.*—The right lung is affected with a kind of ecchymosis towards its base; the pleura which covers it presents numerous petechiæ. The pulmonary tissue is highly œdematous; on being incised, numerous points of sanguineous suffusion appear on the surface of the cut. Towards the posterior parts of the lower lobe, there is a point where the pulmonary tissue, apparently indurated, is infiltrated with blood. The left lung does not present any petechiæ on its external surface; it is not very crepitating, but loaded with fluid, and also presents a great many extravasated points of blood. The heart is of the ordinary size; numerous petechiæ appear on the anterior surface of the right ventricle; on the left ventricle they are rare; the posterior aspect of the auricle is very thickly beset; the cavities of the heart contain a very small quantity of fluid blood; the aorta also contains a small quantity of blood, which is excessively pale and serous, and a fibrous clot of small size, entirely colourless. *Abdomen.*—The stomach is softened about the great *cul-de-sac*. Its mucous membrane presents a great number of small reddish points, resembling petechiæ. The remainder of the alimentary canal does not offer any thing remarkable. Towards the extremity of the small intestines, a very decided follicular eruption is perceived, precisely analogous to that which is met with in cholera, although our patient had presented no symptom of the kind, not having even had liquid stools towards the close of his life. The liver presents internally a circumscribed collection of blood, a sort of apoplectic cell, the size of a small hazelnut; throughout the remainder of its extent, the substance of the liver is pale and bloodless. The spleen presents externally a great number of small pink spots. The other organs contained in the abdomen have nothing remarkable in their appearance. (a)

(a) "*Purpura hemorrhagica* in an infant three weeks old. Dr. Post gives (*N. Y. Jour. of Med. & Surg.*, vol. i, p. 222), the following description of a *post-mortem* examination of this case:

"On the 25th Feb. 1839, I was invited by Dr. B. B. Coit, to examine the body of an infant three weeks old. There had been hemorrhage during the first and second days of its life, from the sides of the umbilical cord, which had been checked by the application of powdered galls, and by pressure. It had then exhibited purple spots, apparently formed by the extravasation of blood, beneath the skin in different parts of the body; these spots were an inch or more in diameter. The evacuations from the bowels continued for eight or ten days of a black colour, and of a tar-like consistence. Small doses of calomel were then administered, and the evacuations began to assume a healthy appearance. The ecchymosed spots then began to fade away, and no new ones made their appearance. But about the 10th day, a fluctuating tumour began to form about the posterior part of the occipital ridge, which continued to increase during a period of ten days, when it had acquired about the size of a hen's egg, and was very tense, and seemed to cause much irritation. The tumour was opened with a lancet, and black fluid blood flowed from it. On the following day, the child died.

"The following appearances were found on examination: body

CASE CL.—*Purpura hemorrhagica preceding small-pox.*—F. C. Sorel, three years and nine months old, admitted into the *Hospice*

not emaciated; surface extremely pale; ecchymosed spots in several places beneath the skin, scarcely perceptible on its external surface, but very distinct on the internal surface; there was a fluid tumour at the posterior part of the occipital ridge, containing a soft coagulum of blood; this sac was found beneath the periosteum and the bone; small quantities of bloody fluid were found beneath the arachnoid membrane on the surface of the pia mater; bloody serum and small quantities of coagulated blood in the ventricles of the brain; cineritious substance of the brain of a pure white colour, so that I could not, in any situation in which I examined it by broad day-light, distinguish it from the medullary substance; lungs remarkably pale; cavities of heart empty; stomach and intestines very pale and distended with gas; liver of about the usual size and consistence, but of a yellowish-brown colour, without any shade of red."

"*Purpura subsequent to eczema mercuriale.*—Mr. Adams said that with the permission of the Society he would communicate a case of purpura which had occurred in the Jervis Street Hospital, where the notes of it had been taken by the late Dr. Coulter. The appearances, at different periods of the progress of the case, were accurately delineated, in the four drawings on the table. The subject of the case had been affected with syphilis six weeks before his admission into the hospital, and had used mercury pretty freely; he became affected with eczema mercuriale. After the tenth rubbing in of the mercurial ointment, small, very minute vesicles appeared. Some of these dried up; others discharged a fluid which excoriated the parts about the scrotum, a circumstance formerly observed by Pearson, and described in his work: dyspnoea and cough supervened. On the seventh or eighth day after his admission into the hospital, the dyspnoea became more oppressive; there were rigors, and afterwards bleeding from the gums, and from the fissures about the serotum: during several subsequent days, ecchymoses appeared on different parts of the body, and in all these there was a great disposition to slough: there were ecchymosed spots on the lips, which rapidly sloughed: about the sacrum, in the same manner, sloughs formed, and from the sloughs there were bleedings: he died on the 16th day. The body was carefully examined after death: there were no hemorrhagic petechiæ within the cranium, nor on the surface of the heart; the lungs, anteriorly, were very anæmic and white—posteriorly they were congested; the mucous coat of the stomach and intestinal canal was ecchymosed.

"Mr. Adams considered that purpura was rather a symptom of peculiar debility than a disease itself. In proof of this, he mentioned a case of pemphigus gangrenosus, in which purpuric spots appeared on the skin, and in a case of cancrum oris they had been observed towards the close of the disease. It was well known that they appeared in scarlatina maligna, in plague, and in some other diseases. Indeed, purpura corresponded very much to the descriptions which authors give of the land scurvy."—*Proceedings of Path. Society of Dublin, in Dublin Journ. of Med. Science*, vol. xxiv.

*Purpura hemorrhagica—fatal.*—William Hunt, æt. 45, admitted into the Westminster Hospital, January 13th, under Dr. Bright. On the elbows, down the course of the spine, inside of the thighs, and generally over the legs, the purple *maculæ* are dispersed: in some places the patches are so large as to seem like the result of bruises. The colour is most decided in the centre of each spot, and gradually fades towards the margin. The pulse is 84, feeble; tongue clean; bowels torpid, motions clay-coloured; urine scanty and high-coloured, depositing a sediment like carmine. The man has a sallow complexion; the white of the eye is tinted gamboge. There is no tenderness in the hypochondrium. The abdomen is tense over fluid. The legs are œdematous.

"Hunt is an old soldier; he served in Spain and at Walcheren. At this last place he had the well-known epidemic. Being an habitual drunkard, he was exposed, about six weeks before admission into this hospital, to cold, whilst in a state of inebriation. When he came to himself, he had pain in the right hypochondrium and throughout the muscles of the body; these symptoms gradually evanescenced, and were succeeded by dropsy of the belly and legs. Contemporaneously

*des Enfants Maladies* on the 19th of August, 1825, had enjoyed perfect health till within two months of the above date, when measles made its appearance, without, however, presenting any thing unfavourable in its character. During the last fortnight, the patient has had a slight cough, and the skin has been burning; but she has made no complaint, although evidently dull and listless; for six days she has experienced great difficulty of breathing; in the evening of the 9th and following day, she complained of pain in the epigastrium (*four leeches applied*); on the 11th the difficulty of breathing increased (*blood taken from the arm; gum water*); no improvement; the 12th, an eruption of purple spots over the whole body, which still continue

an attack of hæmoptysis occurred. About a week before he showed himself at the hospital, the petechiæ just described made their appearance. Ordered the following medicines:—

R. Ext. Coloc. Comp. gr. x., hâc nocte et pro re nata sumend.

R. Pulv. Rhæi, gr. iij; Pulv. Cinchonæ ʒj. M. fiat pulv. ter die sumendus.

Decoct. Cinchonæ et Acid. Nitric. 6tis horis.

"January 14th.—The abdomen is still tense; water not increased; bowels confined.

Rep. Pulv.

"15th.—The petechiæ unaltered; copious rosaceous deposit falls from the urine; anasarca swelling of the legs diminished.

"16th.—Fresh petechiæ have appeared on the calves of the legs. The older petechiæ are of a paler colour; the œdema has diminished; abdomen still tense; urine of a dark madder colour, depositing the purpura of ammonia. During the day considerable hemorrhage took place from the lungs. *Calomel and squill pills* to be taken daily, and cream of tartar solution to be drunk *ad libitum*.

"17th.—The purple spots have diminished as regards intensity of colour. Epistaxis took place to some extent this morning. The bowels torpid. To take a dose of spirit of turpentine, qualified with oil of peppermint.

"18th.—Complains of some pain in the left side, increased on coughing. The purpura has appeared in some fresh places. The bowels are freely open.

"20th.—Bowels again torpid, the maculæ spreading generally over the back. Urine increased in quantity, but of the same madder-like colour, and still depositing the purpura.

"23d.—The patient much harassed by cough. The sputa consist of mucus, floating in a greenish fluid. The yellowness of the eye has remained undiminished. The urine has increased to *three* pints daily. To be purged with jalap and calomel.

"24th.—Abdomen less tense. The maculation diminishing in colour and extent; urine clearer and more lightly coloured.

"25th.—This morning about nine o'clock sudden hemorrhage from the mouth occurred. It proceeded apparently both from stomach and lungs. The blood was of a bright vermilion hue, and streaked with dark lines. The face of the patient is contracted. Pulse very weak. Laudanum and dilute mineral acid is administered in proper doses.

"10 A. M.—The hemorrhage returned in ten minutes after the exhibition of the draught, to the extent of nearly a quart. No pulse was perceptible at the wrist. A glass of wine given. The hemorrhage remained uncontrolled, and the patient died at half-past ten o'clock.

"*Sectio cadaveris thirty-six hours after death.*—The entire body was dotted with petechiæ, and all the surface was of a yellowish tint; the lungs were slightly œdematous, but in other respects healthy. The mucous surface of the stomach, and small intestines throughout, covered with blood; this membrane, when sponged, was of a red colour, and infiltrated with blood. The liver was granular, and adherent by membranous bands to the adjacent viscera. The gall-bladder distended with bile; the cystic duct thickened, and almost impervious. The contents of the gall-bladder consisted apparently of blood mixed with cystic bile of a sweet mawkish taste; staining red rather than yellow. The surface of the gall-bladder was ecchymosed; all the other viscera were sound, except the muscoli recti abdominis, which were completely infiltrated with blood."

to-day, the 14th; the variolous eruption was not remarked till the 13th. The following is a description of the patient's state at the time of her admission: The variolous pustules, in inconsiderable numbers, are small, blanched, shriveled, and centrally depressed. On the surface of the skin, and particularly on the forehead, upper eyelids, back, and posterior aspect of the limbs, a number of spots are observed, irregularly scattered, rounded, and well defined, but not prominent; some, of a bright purple colour, are about the size of a lentil; others, of larger size, are of a deep violet hue. The lips and nostrils are covered with a dark sanguinolent incrustation. It is impossible to examine the inside of the mouth, so as to ascertain the state of the gums. The orifice made in the vein of the arm, three days ago, is still open, and discharged a little very serous blood this morning. The pulse is very languid; the extremities cold. The child retains its consciousness, notwithstanding the extreme depression; (*sinapisms*.) Death at three o'clock in the afternoon. *Sectio cadaveris* at eleven o'clock on the morning of the 15th. *External appearance.* Cadaverous stiffness of the inferior members; none of the superior. The colour of the skin, and of the spots, is precisely the same as during life. On incising the skin, it is easy to perceive that all the spots do not penetrate to the same depth; some are very superficial, and situated directly under the epidermis; others occupy the areolæ of the corion; finally, there are some (and these are the largest and deepest), whose seat is entirely in the subcutaneous cellular membrane. All these spots are formed by extravasations of blood, coagulated in the larger and darker kind, and liquid in those of smaller size. Examined with the assistance of a powerful glass, the vascular ramifications in the neighbourhood of these ecchymoses and petechiæ, are not observed to be more developed than in the ordinary state. If, after laying bare one of these effusions, a stream of water is directed upon it, the blood is soon washed away. A piece of skin, put into water to macerate, did not present any appearance of spots on the following day. There are no ecchymoses in the deeper strata of the cellular membrane generally; the right arm, however, where the puncture made in a recent venesection, still continues open, is the seat of an universal sanguineous infiltration, to which its tumefaction and livid appearance are owing. The veins and arteries of this extremity, traced into their most minute ramifications, do not present any visible alteration; the median cephalic vein, on which the operation of bleeding was performed, does not even exhibit any redness on the edges of the orifice; its walls are thin and transparent, and its external membrane is smooth and grayish, as in the healthy state. There is no ecchymosis into the substance of the scalp. Limpid serum, in small quantity, appears on the surface of the cerebral hemispheres; the subarachnoid vessels are empty; the cortical substance is pale; the medullary substance firm; the superior longitudinal sinus empty; the sinuses of the base of the cranium are filled with a liquid vermilion-coloured blood; traces still remain of a slight sanguinolent effusion, converted into dark incrustations, upon the lips and nostrils. The tongue and gums are pale and blanched; the palate is violet-coloured; the epiglottis swelled, as well as the edges of the glottis; the latter are covered with a very thin false membrane; the tracheal and bronchial mucous membranes are apparently healthy. The external surface of the lungs presents a great number of bright red circumscribed points, and several ecchymoses of a deeper colour; one of these, on the summit of the left lobe, is four lines in diameter; there are three smaller ones on the lower part of the same lobe, which also presents another, much more extensive, at its base. These spots are the more striking, on account of the lungs retaining their natural grayish colour. On examining the spots, they are found to correspond to a kind of dense circumscribed nucleus, which, on being cut across, presents a reddish-brown, homogeneous, granular tissue, in which the blood appears as if combined with the proper substance of the lungs. The parenchyma of both lungs contains several formations of the same kind, circumscribed in like manner, and situated in the midst of a perfectly crepitating tissue, from which, when incised, a quantity of blood, mixed with serum, escapes. Several of the glandular bodies of the bifurcation of the bronchi are red and enlarged. The pulmonary artery at its origin, and the right ventricle and right auricle of the heart, present three lenticular ecchymoses of a bright red, approaching to the natural colour of these parts, and another violet-

coloured one, nearly of the size of a sixpence, with irregular edges, situated on the posterior aspect of the apex of the heart. These effusions are situated entirely in the subserous membrane, and do not extend to the muscular tissue of the heart. A sanguineous suffusion, two inches in breadth, exists under the pericardium on the right side. The substance and cavities of the heart as in the healthy state; the internal membrane of the aorta and pulmonary vessels perfectly healthy. The stomach appears contracted; its mucous membrane very much wrinkled, particularly in the direction of the great curve, and beset with numbers of small red points, of a vermilion tint, like the pricks of a pin. Within three inches of the pylorus, there is a lenticular soft-ened spot, of a dark-yellow colour, limited to the thickness of the mucous membrane, under which there is a small ecchymosis of the same size; the duodenum presents, for the space of an inch, from the pylorus, a number of small petechial spots, closely set together like those of the skin; they are far fewer in number towards the lower portion of this division of the intestines. The mucous membrane of the small intestines is of the natural dirty gray colour; the glands of Peyer are slightly developed; the ileum contains green, flaky, muco-bilious matter. From the ileo-cæcal valve, the great intestines present a general violet red colour, which increases in intensity towards the sigmoid flexure of the colon; they are covered by an infinite number of red points; some, which are white in the middle, appear to be follicles; others are very small ecchymoses, which, towards the commencement of the colon, follow the circular folds of that intestine; in this situation they are covered with a grayish secretion, and are much less numerous than in the transverse and descending colon. Numerous trichocephala in the cæcum and its vermiform appendix, which is rather red; the fecal matter contained in the large intestines firmly moulded; mesenteric glands, of small size, intensely red, brownish in their centres. Some purple marblings are observed on the liver, but no spots; spleen small and healthy; kidneys pale; bladder contracted and healthy.

CASE CLI.—*Pulmonary tubercles, chronic pneumonia and peritonitis; purpura characterized by epistaxis, subcutaneous, submucous, subpleural effusions of blood, &c.* Ferd. Hélène, seven years of age, of a very feeble constitution, was admitted into the "*Hôpital des Enfants*," on the 14th of March, 1825. He had been a long time ill, was subject to diarrhœa and colic, and the belly was distended and painful. For the last four or five days the cough had increased, the fever was higher, and the thirst more intense. At the time of entering the hospital, this patient was labouring under chronic pneumonia and peritonitis. In spite of the active measures immediately employed, the patient continued to suffer from frequent cough, constant diarrhœa, and intense fever.

After being about twenty or twenty-five days in the hospital, the respiration became very laborious and short; the respiratory murmur was scarcely to be heard on the left side, and posteriorly to the right it could not be perceived at all. A blister applied a few days previously to the right side of the chest, became gangrenous, and was surrounded by crissipelatus inflammation of the most vivid red. At the same time a number of small violet-coloured circumscribed spots, were remarked on the upper and lower extremities, some circular, others oblong, and about a line, or something less in diameter. The patient had had several attacks of epistaxis; his pulse was very weak, the extremities were cold; (*mucilaginous decoction of bark; lavement of the same.*) The patient died in the course of the day. *Sectio cadaveris.*—Externally, a number of dark purple spots were observed on both forearms, some the size of flea-bites, others of grains of millet. There were also several on the legs and thighs, but these were much less dark in colour, and smaller in size. On cutting into, and dissecting off the skin of the forearms, hands, thighs and legs, we perceived that the subcutaneous cellular membrane was much injected, and very red, and presented a number of small sanguineous effusions, corresponding to the spots upon the skin, though none of these small ecchymoses were seated in the tissue of that membrane. The lymphatic glands of the armpit were injected and swelled. The subcutaneous veins of the extremities were pale and void of blood; externally they were white; the muscles were healthy. *Respiratory organs.*—Larynx, trachea and bronchi in a healthy state; inter-bronchial ganglions tubercular, softened in the centre, and very voluminous; agglomeration

of tubercular ganglions in front of the trachea. *Right lung.*—Upper lobe healthy, crepitating, spotted internally by an infinite number of small ecchymoses; middle lobe hepatized, and filled with pus, which flows out when the part is compressed; several hepatized points in the inferior lobe; two cavities in its centre, of the size of a hazelnut, containing yellow pus. *Left lung.*—Superior and inferior lobes crepitating, but filled with a much greater number of ecchymoses than the right lung. On several points the surface of both lungs presents spots analogous to those observed upon the skin; subpleural ecchymoses. Some miliary tubercles were found in the lungs. *Digestive organs.*—The mucous membrane of the mouth is pale. Several small submucous (similar to the subcutaneous) ecchymoses are remarked at the root of the tongue. Pharynx and œsophagus healthy; stomach healthy. The mucous membrane of the large and small intestines presents a few spots not much injected. The liver and spleen are healthy. The peritoneum is thickened at all points, and its folds adhere together. A number of small whitish tubercles, some of which are soft, occur at intervals between the layers of the epiploa. The great epiploon adheres throughout its whole extent to the abdominal parietes; all the intestines are agglutinated, and it is very difficult to separate them. The mesenteric glands are swelled and purple-coloured. *Urinary organs,* healthy. *Nervous system.*—The membranes of the brain are in a healthy state, the cerebral substance is of the natural consistence; there is very little serum in the ventricles; the cerebellum is perfectly healthy.

CASE CLII.—*Inflammation of the mouth; amygdalæ with pseudo-membranous deposits. Purpura hæmorrhagica.* A pale and delicate girl had been in bad health for a long time; she was in a very feeble condition, when red, livid spots made their appearance on her body; the amygdalæ at the same time became covered with dark spots, and a species of false membrane, of a black colour, and rather pulpy consistence. This young person had hemorrhage also from the mouth and nose. The dark hue of the amygdalæ gave reason to suspect her of being affected with gangrenous angina; the left tonsil was scarified, and the right touched with hydrochloric acid and water in equal proportions. The abdomen was not painful; the respiration was unaffected. On the evening of the 23d July, 1829, the skin was hot, burning, dry; the pulse quick and weak; the face swelled, particularly in the lower part, and the region under the jaw. This swelling was owing rather to a sort of œdematous puffing than to inflammation; the skin was straw-coloured; lymphatic glands could be felt under the swollen angles of the jaw, more to the right than the left. The lips were swelled, thick, and glossy, particularly the lower one, the mucous membrane of which, from its origin to the gums, was black and swelled. In the same situation a salient spot of the size of half a crown was observed, the centre of which was of a darker colour than the circumference. This prominent spot was formed by a kind of false membrane which could be removed with forceps without causing pain, excepting at the middle of the patch. This false membrane, of a grayish or dirty white colour, extended over the gums, diminishing in thickness, and less and less adherent to the parts beneath: it was easily removed piece-meal. On each side of the mouth, a dark, irregular skinny substance was observed attached to the gums by one extremity. These false membranes did not emit the offensive gangrenous odour. Beneath them, the tissue of the gums was red, and glossy, like the mucous membrane of the lip. The colour was not very bright. On the false membrane being removed, blood was seen to flow from the surface of the lip, and to coagulate in a short time afterwards. The teeth were white, and not loosened; and the false membrane insinuated itself between several of them; the upper lip was swelled in like manner, and also presented some dark points; the tongue was covered with a dark thick mucus. The patient was unable to open her jaws; a purulent, ropy liquid which had nothing of the gangrenous odour, flowed from her mouth. Over the whole surface of her body were scattered red, livid spots of the size of a lentil, which could not be effaced by the pressure of the finger; there were also many others of smaller size which appeared of more recent formation. *Draught with pulvis cinchonæ; drink acidulated with muriatic acid; astringent gargle.* Died at one o'clock in the morning of the 24th. *Autopsy eighteen hours after death.* The skin presented here and there spots of a deep colour, formed by the effusion of blood

into the substance of the skin only. There were none in the subcutaneous cellular membrane. The tongue, right amygdala, and gums, were covered by a thick, black, false membrane, which was removed without difficulty; the tissue of the amygdala was yellow, and soft, internally it was black; there were a kind of flaky filaments on its surface. The left amygdala was swelled in like manner; its tissue was yellow; the neighbouring cellular membrane was black; the amygdalæ did not emit the gangrenous odour. The epiglottis and glosso-epiglottic ligaments, presented black spots under the mucous membrane; there was an effusion of dark blood into its substance; the glands of the neck on both sides were swelled, without being the seat of any effusion; the nasal cavities did not contain blood.

The larynx, the trachea and bronchi were healthy; the lungs presented several black spots on their surface, varying in size, but never exceeding the dimensions of a sixpence; they were evidently owing to blood deposited underneath the pleura, and infiltrated superficially into the tissue of the lungs. The lungs were crepitating, except at their base, where they were loaded with fluid. The whole surface of the heart, more particularly in front, and more on the left ventricle than elsewhere, as well as under the serous membrane, presented purple spots of the size of a pin's head, in very close contact. The pleura under the third and fourth ribs, near the sternum, presented a considerable patch tinged with effused blood.

The stomach, rather livid, presented a small dotted patch; its mucous membrane presented the natural thickness and consistence. The intestines, liver, and spleen were healthy. The upper part of the right kidney was a little spotted with black under its proper membrane; the left was pale and less consistent. The uterus and bladder were healthy.

On the dura mater was found a large, red irregular patch, formed by blood deposited under the arachnoid membrane; on the side of the left lobe of the brain, between the arachnoid, and the pia mater, a slight sanguine infiltration; the corpus striatum, and corpus callosum presented a dotted appearance. A similar infiltration was remarked in the whole of the right lobe; the same disposition in the left lobe of the cerebellum. The muscles were red and healthy; the cellular tissue exhibited no traces of extravasation.

CASE CLIII.—*Purpura hæmorrhagica febrilis; petechiæ and ecchymoses, preceded by a kind of erysipelatous attack, &c.*—Madame Robert, 70 years of age, a washerwoman, of a sanguine temperament, with a coarse, ruddy skin. This woman inhabits a healthy lodging, lives well, leads a very regular life, and has not suffered from illness for a great many years. She began to be affected with headache in the beginning of May, and afterwards by general indisposition, and itching of the lower extremities, which swelled slightly. Some days afterwards the face looked puffed, and she became a patient in the hôpital de la Charité on the 31st of May, 1834. Both cheeks were swelled, tense and red as in erysipelas, and strewed with specks of a darker red, the size of a lentil, and not to be effaced by the pressure of the finger. These dark ecchymotic specks were also discovered on the nose and eyebrows; the eyelids were infiltrated with black blood, as well as the lobe of the right ear, which was mottled like marble. There was also a large black ecchymosis under the chin, but without any elevation of the epidermis. The body only presented two or three black spots on its posterior surface; both the superior and inferior extremities were swelled, hard, and covered with large black patches, the epidermis of which was raised by a sero-sanguineous liquid, and surrounded by a pink areola. These patches existed principally on the dorsal aspect of the forearms, and on the anterior surface of the thighs. On the latter there was also a hemorrhagic petechial dotting, particularly on the right thigh. The palms of the hands and soles of the feet were livid or black, swelled and slightly œdematous; an effusion of blood had taken place under the corion, and even into its outer surface but without any detachment of the epidermis; the patient complained much of pricking sensations in these parts.

All the spots had existed for six days. The lips were swelled. The gums were without any appearance of redness, and did not bleed. The patient had had no epistaxis, hæmoptysis, or hæmatemesis; neither had she ever remarked blood in her stools or urine. The tongue was moist and natural in colour. There was no sensible derangement of the functions of digestion. The respiration was free; there was no

cough. The sound of the chest on percussion, however, was somewhat dull; and the respiratory murmur in one particular spot of the posterior surface of the left lung was only heard very indistinctly. The patient was feverish (the pulse eighty-eight per minute). The temperature of the skin was higher than natural. The beat of the heart was regular; near its apex a single sound could alone be distinguished; the bellows sound (*bruit de soufflet*) at the base of the organ; the same bellows sound was heard synchronous with the first sound of the heart; the second sound was natural. Under the sternum and near its right margin both sounds of the heart were heard as in a state of health. The cerebral functions were intact. (*Sherbet of sulphuric acid for drink; half an ounce of Epsom salts.*) The bowels acted once during the day. On the following morning, the 1st of June, a great number of new hemorrhagic patches made their appearance on the limbs; they were purple, irregularly circular, and formed by sanguineous serum effused under the raised epidermis; some pain in the throat was complained of; the pulse was very full and hard; the skin hot; (*half an ounce of Epsom salts, drink as before, decoction of rhathany acidulated with nitric acid*); tormina, and several stools in the course of the day. On the 2d the tumefaction of the cheeks and limbs had diminished a little; that of the hands only still continued as before; but fresh hemorrhagic spots had been thrown out upon the limbs, principally in the line of extension. *The pulse continued full, the skin hot; the pain in the throat was not abated. Drink as before; venesection.* Little blood was obtained, the swelling of the arm having rendered the operation difficult.

On the 3d the fever continued; the left lung gave a dull sound on percussion; posteriorly, a slight bellows sound was heard; the expectoration was mucous without any mixture of blood; (the same drink; fifteen leeches to the epigastrium). The leeches drew little blood, yet gave relief; the spots of the forearm disappeared from the centre towards the circumference, as in lichen circumscriptus hæmorrhagicus; the fever had abated; (the same drink; leeches to the anus.) On the 5th the amendment continued; the swelling of the extremities subsided; the sanguinolent fluid effused beneath the epidermis, had either escaped or been absorbed; the epidermis had become dry on some of the patches; and the violet red of the skin had faded into a yellow: the redness and tumefaction of the face had diminished greatly; the pain in the throat had ceased; a little cough still remained.

On the 6th, the internal surface of the epidermis raised by the sanguineous serum was observed to be covered by a reddish coating, while the surface of the dermis retained its natural colour. The dark or yellow discoloration of those patches the epidermis of which had not been raised, continued to disappear from the centre towards the circumference, which assumed a jagged appearance. The same drink was continued through the following days; the spots from purple became yellow, and they afterwards disappeared completely. The swelling of the extremities subsided, but the cough and mucous wheezing or rattle in the left lung continued. There was still some expectoration. These trifling symptoms ceased some days afterwards, and the health was improving, when the hands became swollen afresh, but without any new hemorrhagic spots. A few doses of rhubarb put all to rights again, and the patient was in good health when she was discharged from the hospital. Auscultation of the heart gave the same results as when the patient was admitted. At no stage of the disease did the urine, treated with nitric acid, let fall any albuminous precipitate.

#### MORBID SECRETIONS OF THE SKIN.

1035. Exclusive of the formation of the epidermis, two species of extrinsic secretion occur in the skin, namely the cutaneous perspiration, and the follicular secretion. These secretions are liable to be modified by different diseases.

## PERSPIRATION.

Vocab. Art. *Ephidrosis*, *Dysodia*.

1036. The study of the cutaneous perspiration as a symptom of various diseases, cannot be separated from the history of these complaints themselves, particularly in a therapeutical point of view: the sweating that accompanies intermittent fever yields to the action of cinchona, that which attends phthisis to white agaric,<sup>1</sup> &c. But there are ephidroses or profuse sweats, which appear independently of any other lesion, and which must therefore be considered as peculiar affections.

1037. M. Dupont<sup>2</sup> has published an account of a curious case of a chronic *general ephidrosis*, which lasted upwards of six years. The woman who was thus affected became pregnant during this time, and was happily delivered of an infant which she nursed herself. This ephidrosis, which, according to him, was independent of any other affection, after having been fruitlessly combated by various remedies, yielded at last to extract of aconite, given at first in doses of half a grain, and gradually raised till sixteen grains a day were taken. Hartmann<sup>3</sup> cites the singular fact of a woman who, during pregnancy, perspired only on the right side of her body.

1038. Instances of excessive habitual cutaneous exhalation from the axillæ and feet, without any appreciable alteration in the texture of the skin or other organs, are more frequent. A man twenty-nine years of age, presented himself at the hôpital de la Charité to consult me with regard to an habitual ephidrosis of the feet, with which he had been affected for nearly four years. This exhalation was more copious in the right than in the left foot. From time to time he experienced, particularly during the night, transient pain in the right heel, similar to what might have been produced by the introduction of the point of a nail into the skin. The soles of the feet were slightly red, and looked macerated, as though they had been immersed for a long time in hot water. This appearance of the skin was less remarkable in the left than in the right foot. The patient assured me that the perspiration from the feet was equally profuse in winter as in summer, and that he was obliged to change his stockings three or four times a day. This man, who was of a sanguine-bilious temperament, and robust constitution, was not affected with any other disease of the skin. Foot-baths of cold Barèges water were recommended, and used with success in abating the ephidrosis complained of.

These profuse, and often fetid ephidroses of the feet<sup>4</sup> sometimes continue to a very advanced period of life. They are more copious and emit a more disagreeable smell during the heats of summer, and after the person affected has walked far. The sudden suppression of these ephidroses is liable to be followed by colicky pains of the bowels, toothache, various affections of a nervous character, and other bad effects.

I had a man about forty years of age under my care in the hôpital de la Charité, who, after the suppression of an habitual ephidrosis of the feet, so copious that the soles always looked white, and as if they had been macerated, became subject to headache; and I am at the present time attending a young man who has been attacked with chronic pleurisy, in consequence of the suppression of an habitual ephidrosis of the same parts.

Ephidrosis of the feet requires that the stockings should be frequently changed. When it occurs among persons of vigorous constitution, it may be rendered more endurable by the use of sulphureous foot-baths. Should the diminution or suppression of this secretion be attended with injurious effects, the secretion may be restored by covering the feet with worsted stockings and oil-silk overalls.

Ann. vi. app. p. 4.—Dec. iii. ann. i. app. p. 125.—Ann. ix. et x. obs. 96.

1039. The perspiration, by being changed in its composition, may acquire a sour or rancid odour, or a smell very similar to that of musk. I had a woman, under my care in the Hôpital de la Charité, affected with chronic peritonitis, and who, some time before her death, exhaled a very decided odour of musk; the pupil who called my attention to this circumstance, had observed the smell for several days, while dressing the patient who had been blistered, but thought it owing to a bag of musk put purposely into the bed to overpower other bad smells; the woman, however, assured us, that she had no description of perfume about her, and I satisfied myself that no musk had been brought to her from without, and that her linen, which was frequently changed, was not impregnated with any perfume before being delivered to her from the laundry of the hospital. The odour of musk, the existence of which was fully ascertained by myself and several physicians, and which was very perceptible on the arms and other regions of the body, did not become more powerful from rubbing.—After continuing for about eight days, the smell became fainter, and nearly vanished the evening before the patient's death. Speranza<sup>5</sup> relates a similar case. Schmit has inserted in the Ephemerides Naturæ Curiosorum, an account of a journeyman saddler, three and twenty years of age, of rather robust constitution, whose hands exhaled a smell of sulphur so powerful and penetrating as very soon to infect any room in which he happened to be. I was once consulted by a valet-de-chambre who could never keep a place in consequence of the unpleasant odour he left behind him in the rooms which he had been occupied in cleaning. There have been instances of individuals who, to obtain their discharge from military service, have simulated these offensive perspirations, by rubbing their axillæ with the animal oil of dippel, assafetida, a piece of much decayed cheese, putrid fish, &c.

1040. Finally, the colour of the cutaneous respiration may also be modified by changes in its composition. Instances are recorded of green,<sup>6</sup> black,<sup>7</sup> blue,<sup>8</sup> and yellow,<sup>9</sup> perspirations, &c. Not having myself met with any thing of the kind, I merely refer to the works in which mention is made of such cases. With regard to the urinous perspiration observed among persons suffering from retention of urine, I do not think this a proper place for making any farther mention of the circumstance.

## MORBID SECRETION OF THE EPIDERMIS.

1041. The secretion of the epidermis is modified under a great variety of circumstances; it is active and very abundant in the squamous inflammations generally; it is remarkable, though unaccompanied with desquamation in ichthyosis; it is thrown out in greater quantity on those parts of the skin which are habitually exposed to repeated pressure, as on the palms of the hands; and soles of the feet, where it occasions callosities, bunions, and corns, above the knee in shoemakers, on the elbows of paper stainers, and on the instep of the persons who polish oaken floors, &c., in all of whom it causes appearances very similar to what is seen in ichthyosis. Finally, the epidermis is sometimes observed to be secreted in excess after the use of blisters, in the neighbourhood of the cicatrices of ulcers, and of certain cutaneous eruptions, being in some instances characterized by increased thickness of the membrane, in others by its constant renewal and exfoliation. The skin, on the termination of certain acute diseases, is also known to renew its epidermis several times successively, this covering being detached in many instances in almost insensible furfuræ.

It is necessary to distinguish the furfuraceous desquamation which very commonly takes place from the skin of the aged, from exfoliations

<sup>9</sup> Ephem. Nat. Cur. dec. i. ann. vi. et vii. obs. 78.

of the kind under consideration, as well as from that of the squamous inflammations generally, and particularly of pityriasis.

New-born infants from three to five days old, almost always present an exfoliation of the epidermis.<sup>1</sup> In fact, some days after birth, the epidermis loses its elasticity, becomes dry, brittle, and less firmly attached to the skin; it then cracks, and by and by is detached in various modes according to the region. Thus, from the folds of skin about the articulations, from the groins, popliteal regions, &c., it is thrown off in linear shreds; from the chest, soles of the feet, and sometimes from the abdomen, the desquamation takes place in large flakes; finally, from the sternum, cheeks, between the shoulders, &c., the epidermis is detached in small furfuraceous scales. The skin of the parts which have recently exfoliated is red, and inflames with the greatest readiness; the epidermis is soon restored in its normal state, excepting in the folds of the skin, which continue for some time to secrete a mucous matter.

This exfoliation of the epidermis has been known to occur twice conspicuously in the same infant; in other cases the desquamation is often almost imperceptible.

The duration of these exfoliations varies from one to two months, but they may extend to a longer period, and become very considerable in children which have fallen into a state of marasmus. The epidermic exfoliation of new-born infants, requires no peculiar medical treatment. The skin has only to be kept clean and dry.

## NEUROSES OF THE SKIN.

1042. The sensibility of the skin may be diminished (anæsthesia), or augmented (hyperæsthesia), or vitiated.

1043. Anæsthesiæ of the skin may be either local or general; the former are sometimes strictly limited to the parts supplied by the branches of a single nervous trunk: at the hôpital de la Charité, I have met with three cases of paralysis of the skin of one side of the face, evidently depending on a lesion of the fifth pair of nerves. The first case was that of a young woman suffering from a disease of the heart, who, during her stay in the hospital, without any known cause, lost all sensation in the right side of the face, the power of seeing with the right eye, that of smelling with the right nostril, and that of tasting with the right half of the tongue. These serious symptoms were completely subdued by bleeding, cupping over the mastoid processes, and perpetual blisters applied to the forehead and cheek. Another case was that of an elderly woman labouring under dropsy with albuminous urine, and having a tumour deeply seated in the left temporal cavity. She was simultaneously affected with insensibility of the corresponding cheek, loss of smell and taste, and also with paralysis of the muscles of the face of the same side, and of the rectus externus muscle of the right eye. After death, I ascertained, that the anæsthesia was owing to an alteration of the plexus of the fifth pair of nerves, which had become red, and adhered strongly to the dura mater and neighbouring parts, particularly to the nerve of the sixth pair. There was also a tumour deeply seated in the zygomatic fossa, which compressed the neighbouring parts. The left lobe of the cerebellum near its peduncle, was yellowish, and rather soft; and its membranes, which presented granulations, adhered to its surface. The third case was that of a man, and was altogether similar to the first as far as the phenomena accompanying it went, but it was not successfully treated.

1044. Under other circumstances, anæsthesia has been seen to affect various portions of the surface of the skin, receiving branches of nerves from several different sources. In other cases, the anæsthesia has appeared to be limited to certain branches of a single nerve, the phenomenon not extending to other ramifications of the same trunk. I remember to have been consulted by a man, the whole of the skin of whose right thigh, from the hip to the knee, was so insensible that it

could be pierced with needles, without his experiencing any pain. Rubbing the part with nettles produced the appearance of urtication, but without smarting or itching. Finally, anæsthesia has been observed to be limited to a portion of the trunk, to a leg, a hand, &c.; and, as in the preceding cases, without the motion of the regions affected being implicated. Among these local anæsthesiæ, there is another which I have only observed in a single instance; it was a case of paralysis of the skin of the belly, in a man labouring under colica pictonum. I communicated a curious case to Mr. O'Brien, which he has inserted in his inaugural dissertation; this was anæsthesia of the skin of the arm, produced by the presence of a clot of blood in the brachial artery, which had occasioned a cessation of the radial pulse, and a diminution of the temperature of the arm during life. In several cases of gangrene, accompanied with the formation of clots in the principal artery of a limb, I have observed diminution of temperature, and absolute insensibility of the skin, without there being any appreciable change in its outward appearance.

1045. Insensibility of the skin may sometimes be *general*, or extend to almost all the regions of the body, without being attended with any evident affection of the organs of motion. But more frequently anæsthesia of one or more regions of the body, is symptomatic of important lesions of the brain or spinal marrow,<sup>2</sup> and coincides with paralysis of the motive powers; at the same time, it must be observed that, in the case of cerebral hemorrhage, with loss of sensation and motion, it is not unusual to find sensation return, even when paralysis of motion continues. (a)

### Historical Notices and particular Cases.

1046. Galen<sup>3</sup> having remarked the loss of sensation in a man who had had a fall on the neck and upper part of the back, gave the name of *ἀναισθησία* to this paralysis of sensation. Ferdinandus<sup>4</sup> mentions

(a) Anæsthesia of the skin may, as M. Andral justly remarks, (*Cours de Pathologie*, &c.) be present without any other symptom of disorder of the nervous centres, and also without any perceptible lesion of these parts. He instances, under this last category, the case of a woman, fifty-six years old, in whom there was complete insensibility of both hands and both feet. This disorder came on after sleeping in the sun; the skin was covered with a phlyctenoid eruption. So great was the cutaneous insensibility, that this woman frequently burned her toes without knowing it.

Still more anomalous cases are those in which, at irregular distances, there occur disseminated insensible spots, of a circular form.

Anæsthesia may result from lead poisoning. The proportion of cases of this disorder, to those of paralysis of motion, recorded by M. Tanquerel, (*Traité des Maladies de Plomb ou Saturnines*), was 19 to 50. In seven of the former, the insensibility was confined to the skin. In one of these was superficial anæsthesia, with hyperæsthesia, or exalted sensibility of the parts beneath, and paralysis of the corresponding muscles.

The loss of sensation, from lead poisoning, is always limited in its extent—being sometimes confined to certain parts of the abdomen, or of the chest or neck, and sometimes occupying the limbs. It may be complete or partial—frequently shifting its place, or varying in extent. Sometimes the attack is preceded by slight numbness, but more commonly it reaches its maximum with great rapidity.

The treatment of cutaneous anæsthesia will vary according to its presumed cause. If it depend on lesion of a nervous centre, recourse will be had to purgatives, and cutaneous revulsives, such as friction, irritating liniments, blisters, &c., either to the part or to the spinal column. Strychnia is represented to be a medicine of considerable power. Sulphureous baths and douches, and electricity, are also among the therapeutical means resorted to in cutaneous anæsthesia.

the case of a young man, twenty-four years of age, who, after having been seized with insensibility of the whole body (the head excepted), was cured by purgatives, and other remedies. A remarkable example of anæsthesia occurs in the *Ephemerides Naturæ Curiosorum*.<sup>1</sup> Thomas Bartholin<sup>2</sup> cites the case of a young man who had lost the senses of taste and feeling; and that of a young girl who could allow the skin of her forehead to be pricked, and that of her neck to be burned, without experiencing any pain. Lamothe<sup>3</sup> mentions a case of insensibility of the hands and feet, in consequence of a kick from a horse in the head, without any external wound. In the *Mémoires de l'Académie des Sciences*, for the year 1743, we read an account of a soldier who, after having accidentally lost all kind of sensation in his left arm, continued to go through the whole of the manual exercise with the same facility as ever. It is known, also, that La Condamine was able to use his hands for many years after they had entirely lost their sensation. Finally, many observations on, and cases of, anæsthesia published by Daniel,<sup>4</sup> Hébréard,<sup>5</sup> Alexander Reid,<sup>6</sup> John Yelloly,<sup>7</sup> and Mathacus, which are all cited by O'Brien,<sup>8</sup> who has detailed numerous very interesting additional cases in his inaugural dissertation, may be consulted with advantage.

**CASE CLIV.—Paralysis of the skin of the left side of the trunk, without affection of the muscles.** George Pilavoine, forty-three years of age, a cartwright, was admitted into the Hôpital de la Pitié on the 16th of January, 1827. Languid temperament; apoplectic constitution; a little above the middle size; stoutly built; short neck; face red and injected. For the last three days, total loss of sensation in the skin of the left side of the trunk. This paralysis extends from the left mammary region to the haunch, and from the vertebræ to the linea alba.

Throughout this whole extent the skin is insensible; it may be pinched or punctured without the patient being even aware that he is touched. The paralysis is not quite so complete in those parts of the integument that are in connection with the healthy skin. Even the parts most completely paralyzed, do not present any perceptible alteration in their colour or texture. The subjacent muscles of the trunk, as well as those of the other regions of the body, possess all their powers unimpaired. The patient is free from fever, and makes no complaint except of slight headache. The pulse is strong and full.

This patient informed us that, five years previously, he had occasionally experienced, on going to bed, an involuntary spasmodic contraction of all the muscles of the back part of the body, which deprived him of the power of changing his position or of speaking; and that, on these occasions, he had scarcely time to give warning to his wife who, by dragging him from his bed, always succeeded in arousing him from the kind of benumbedness into which he had fallen. He then walked about the room, and afterwards returned to his bed, little fatigued by the attack, which was sometimes preceded by sensations of pricking, and confusion of head. These attacks recurred for a period of two years, particularly during the spring, when they happened almost once a fortnight, and sometimes even twice in the same day. Besides these attacks, he was also subject to headaches, for which he used to get bled. These headaches had become less frequent, when, about four months ago, while he was at work, he was seized with a violent attack of giddiness, fell upon a wheel, and received a wound of considerable size upon the right side of his forehead, for which he became a patient during two months in the Hôtel Dieu. Since that period, the right eye has continued inflamed, the headache has returned, and after three attacks of benumbedness, similar to those with which he had already been affected, the patient became affected with the paralysis of the skin of the trunk, of which mention has been made. (*V. S. ad* 3xii.; *low diet*; *lemonade*.) 18th

and 19th. The insensibility of the skin continues; the headache has left him; tingling in the whole of the left side of the body, and in both of the thighs, which are affected with involuntary convulsive motions. 20th and 21st. Same state, but the twitchings of the thighs occur more rarely. 22d. (*V. S. ad* 3xvi.; *water gruel*; *acet. morphiae*, one-sixth gr.) 23d and 25th. The same insensibility of the skin of the trunk; but the muscular twitchings of the thighs have ceased. The right eye is more highly inflamed (*eight leeches to the right temple*); it became less painful afterwards. 25th. The skin of the left side of the trunk is somewhat more sensible; the sensation seems to return from the circumference of the part affected towards its centre. The eye is again inflamed and painful. A seton in the nape of the neck, a plaster of antimon. tartaris. to the paralyzed district. Feb. 1st. The plaster had scarcely produced any irritation of the skin. The paralysis was now gradually abating; on the 7th the patient was still under treatment.

**CASE CLV.—Insensibility of the skin of the whole body without implication of the power of voluntary motion.** A. A. Barbier, aged 60, a worker in marble, became a patient in the hôpital St. Antoine, on the 9th May, 1829. This man had been bitten severely in the arm, three years before, by a dog which was not mad, and he still continued to speak of this accident; the attack of the animal having evidently frightened him greatly. Every time he saw a dog, indeed, his limbs trembled, and he occasionally even suffered a convulsive attack, with foaming at the mouth, which lasted for an hour and a half. These attacks occurred at least once a month, and sometimes oftener. Since the date of this fright he has also been subject to headache, and is occasionally seized with involuntary fits of laughing like a child or a paralytic person; these laughing fits often precede the epileptic attacks. He has lost his memory and often talks incoherently in the intervals between the fits. He has been bled several times at the periods of the epileptic attacks, but this does not seem to have done any good. On the 19th of May, this man's intellectual powers were evidently very much affected; his senses were dull; he was almost deaf; his tongue when thrust out trembled; he had two small wounds on the head; one above the left eyebrow, the other on the hairy scalp, occasioned by a fall on his entrance into the hospital. Here he was bled once. Several days afterwards a great degree of insensibility of the skin of the whole body was observed. This was greatest in amount over the arms, less over the legs, abdomen and thorax. If the attention of the patient were otherwise engaged, he might be pricked with a pin, and pinched without his appearing to know any thing about it. He moved the limbs freely, making no complaint of weakness in any of them. The pulse was full; he had no headache; no uneasiness in the chest or abdomen. (*V. S. on the 26th of May*.) The blood was buffy; but it was serous. The alvine and urinary discharges are natural, and preceded by the usual sensations announcing a call.

On the 29th, the soles of the feet were less insensible than any other part of the body. The scalp was completely void of sensation. On the 6th of June the anæsthesia was cured, and the patient tranquilized on the subject of the bite he had received, left the hospital well satisfied.

1047. *Hyperæsthesia*,<sup>9</sup> or exaltation of the sensibility of the skin, is a phenomenon observed in the current of several nervous diseases, and especially in connection with inflammatory affections of the spinal cord. The sensibility of the skin is also perverted or exalted to a great extent in urticaria, in prurigo, and in several other cutaneous eruptions. But I have here only to make mention of those cases in which the sensibility of the skin is increased without any apparent change in its outward appearance, in its thickness, &c.

I have occasionally observed the skin affected with pruritus of a very violent description, without being the seat of papulæ or any other form of eruption, in patients labouring under chronic diseases of the liver, complicated or not with icterus. We also know that in certain of the prurigos to which the aged are subject, the pruritus attains such a degree of intensity that patients tear themselves with the fury of madness or despair, and afterwards tremble almost convulsively from head to foot, without there being more than a very

<sup>9</sup> Chomel. Sensibilité exagérée des tégumens des membres inférieurs. Gazette Méd. de Paris, 1831, p. 140.

small number of papulæ, the presence of which is altogether inadequate to account either for the violence of the pruritus or for its continuance after their destruction. It is with justice that those cases of pruritus, which are independent of papular eruptions, have been separated from those that are connected with the presence of these affections.<sup>1</sup>(a)

## ALTERATIONS IN THE COLOUR OF THE SKIN.

[DISORDERED CHROMATOGENOUS FUNCTIONS OF THE DERMIS.—E. Wilson. MACULÆ.—Willan.] (b)

1048. Besides the morbid tints occasioned by inflammatory affections of its tissues, and hæmorrhagic effusions into its substance, the

(a) "*Anæsthesia of the trigeminus nerve.*—A woman, 42 years of age, had the misfortune to fall and strike the back of the head on the edge of a stair. A year afterwards the catamenia ceased altogether, and from this time she began to suffer from frequent attacks of most violent sneezing. No unusual appearance could be detected in the nostrils; and it was therefore suspected that there was an irritation of the fifth pair of nerves in the cranial cavity. Along the course of the first and second divisions of the trigeminus there was no loss of sensibility; but the third division was decidedly *anæsthetic*.

"The left half of the under lip, both on its inner and outer surface, and the left half of the chin, were quite insensible, even when pricked deeply with a needle: the inner portion of the muscle of the corresponding ear and of the meatus auditorius were equally dead to all impressions. The teguments of the left temple near the hair, and also the entire left half of the tongue, were perfectly insensible alike to injury and to changes of temperature: this side of the tongue, too, had lost its sense of taste. But when the skin of the temple near the forehead was pricked, the patient immediately complained—in consequence of this part being supplied with twigs from the *frontalis* nerve. On the right side all the corresponding parts were quite sensible; and even in the left eyelids the other sensory nerves retained their integrity, both as respected sensation and power of motion. The organic and nutritive functions of all the parts, which were insensible, were not at all impaired. The patient eventually died of dropsy.

"*Dissection.*—At various points on the surface of the brain there was an exudation of lymph; and on the lower surface of the posterior lobe the cerebral substance was found in a state of *ramollissement*, to the extent of an inch or so. The third, or submaxillary branch of the trigeminus pair on this (the left) side, where it entered the foramen ovale, appeared to be enveloped with a red vascular network, composed partly of fibres and partly of transparent vesicles. On close inspection, it seemed to be either an exudation on, or an hypertrophied state of, the neurilemma: the substance of the nerve itself was swollen, of a yellowish colour, and somewhat harder than it usually is. But it was only that portion of the third branch which arises from the Gasserian ganglion, that was so altered. The motory portion on the inner side was unchanged, and coalesced with the larger division beyond the diseased point. The various twigs to the pterygoid and buccinator muscles, to the temple, the tongue, and the lower jaw, were throughout in a normal condition, as well as the third branch of the right trigeminus, and also the glosso-pharyngeal on both sides."—*Med. Chir. Rev.*, 1841—from *Medicinische Jahrbücher*, t. xxix.

(b) The disorders of the Chromatogenous Functions are divided by Mr. E. Wilson into: 1. *Augmentation of pigment*, which includes nigrities, pigmentary nævi and moles; 2. *Diminution of pigment*, or leucopathia, albinismus and vitiligo; 3. *Morbid alterations of pigment*, embracing ephelis or sunburn, lentigo or freckles, chloasma or liver spot and melasma; and 4. Chemical discoloration of the dermis; as in the oxide of silver stains.

skin of the human body is subject to various alterations in its colour.<sup>2</sup> Some of these depend on a deficient supply or diminished secretion of the pigmentary matter (*albinismus leucopathie*): others upon an adventitious or accidental accessive deposit of the ordinary pigmentum (*nigrities, ephelis, lentigo*), or of an unusual colouring matter (*chloasma, melasma, pigmentary nævi*); a third class is owing to the introduction of foreign substances into the tissue of the skin (*icterus, artificial stains, the slate tint that follows the use of the nitrate of silver*).

## LEUCOPATHIA. [DIMINUTION OF PIGMENT.]

Vocab. *Albinismus, Leucopathia.*

1048. General or partial, congenital or accidental colourless states of the skin, arising from absence or deficiency of the pigmentum, and of the colouring matter of the hair, are designated under the name of *leucopathia* or *albinismus*.

1049. In *general congenital leucopathia (albinismus)*, the skin is usually of a dull white, which has been compared to the colour of milk, and sometimes of an extremely pale-yellowish tint. The hair of albinos is smooth, silky, generally straight and flowing, but sometimes crisp like that of negroes; it is of a peculiar white colour, like cotton or bleached silk, and different from the snowy whiteness which age produces, and from the golden yellow tint of light hair. The eyebrows, the beard, and the hair of the pubes, are equally blanched; the rest of the skin is covered with a down of extreme whiteness and softness. The iris is almost always of a light blue or pale rose colour, and the pupil of a decidedly red hue, which arises from the absence of pigmentary matter in the choroid membrane and uvea.

Albinos are generally of weakly constitution, middling stature, and limited intelligence, although some examples to the contrary have been quoted. The great sensibility of the eye does not allow them to go out in the middle of the day with comfort, unless the weather be cloudy; they are then constantly winking, and the pupil contracts and dilates, oscillating continually. The edges of the eyelids are often covered with glutinous exudation, and tears run from their eyes when exposed to the light of the sun. The moral constitution of albinos is in relation with the general weakness of their organization.

1050. *General accidental leucopathia* has never been observed except among negroes. Whites, after long confinement in places from which light is excluded, undergo a blanching which must not be confounded with albinismus.

1051. *Partial leucopathia* may be congenital; negroes who are affected with it, and who are known by the name of *piebald negroes*, present on different parts of the body, white spots, of various shapes and sizes. In the Museum of Natural History of Paris, there is a portrait of a young piebald negro, whose skin in the colourless parts was of a pale rose colour instead of the usual dead white. When these spots are on the hairy scalp, the hairs growing from them are also colourless. These cases of partial congenital deficiency of colour in the skin have never been observed among whites.

1052. Both blacks and whites may be accidentally affected with similar partial colourless states of the skin, the extent of the patches augmenting progressively.

I have often remarked, that these colourless patches, wherever they appeared, occurred simultaneously with considerable depositions of pigmentary matter within the skin of some other region or of the neighbourhood of the white spots. A young girl in the Hôpital Saint Antoine had spots of lentigo on the face, and leucopathic patches on the neck and body, which had only appeared within a few months. I have observed accidental local albinismus in all parts of the body, but more frequently on the genital organs and in their immediate neighbourhood than elsewhere.

1053. Not having had opportunities of making anatomical researches into the state of the skin affected with general or partial leucopathia, I shall confine myself to stating, that the whiteness of the skin is attributed to the absence of pigmentary matter. In the body of an albino who died in the hospital at Milan in 1783, the absence of the uvea

<sup>1</sup> J. Wilson. A Familiar Treatise of cutaneous diseases: Sense of itching without eruption, p. 147. London, 8vo. 1814.

<sup>2</sup> Bose. De mutato per morbum colore corporis humani. Lipsic, 4to. 1758.

and of the colouring matter of the choroid membrane was ascertained; neither could any traces of pigmentary matter be detected on the external surface of the dermis.

1054. *Causes*.—Except in cases of an hereditary nature, the etiology of leucopathia is very obscure; it is generally attributed to weakness; it occurs in all the races of the human kind, in all parts of the globe, and among a great many animals.

The children of an albino and a person of colour are generally mulattos, but sometimes albinos. Although albinos are more common in Africa, still they have also been met with in other southern latitudes inhabited by blacks, in the isthmus of Darien, in Brazil, in Sumatra, in New Guinea, &c.; and even in Europe among whites, in Denmark, England, France, Switzerland, &c.

*Accidental partial leucopathia*, like the blanching of the hair which occurs independently of age, is most generally the consequence of some mental emotion. I was very recently consulted at the hôpital de la Charité by a man thirty years of age, who, upon the loss of what was to him a considerable sum of money, became affected with partial leucopathia, characterized by white, milky spots, disseminated over the body and limbs, with partial blanching of the hair, whiskers and eyelashes.

1055. *Diagnosis*.—General leucopathia differs from chlorosis in the tint being of a more dead white, and the latter disease not being accompanied with blanching of the hair or of the uvea and choroid membrane; the paleness of the skin in leucopathia results from the absence of the pigmentary matter, while in chlorosis the pale hue of the integuments would seem to depend in a great measure upon the small quantity of blood distributed to them.

At a period when the diseases of the skin were little studied, some analogy was supposed to exist between the state of this tissue covered with the white squamæ of lepra and leucopathia; but at the present day the idea of associating alterations so different in their natures is impossible. Partial leucopathia, which has also been described under the name of *ephelis alba*, is very different from every other description of colourless state of the integuments. Certain colourless states of the skin, however, occasioned by slight, but long-continued pressure, particularly those which are sometimes seen below the pads of the bandages worn by persons effected with hernia, bear some analogy to partial and accidental leucopathia.

1056. *Treatment*.—General congenital leucopathia has been very little studied in a therapeutic point of view; this congenital malformation is generally looked upon as incurable. In partial and accidental absence of colour of the skin, if the patches are in the face, and it is the wish of the patient, attempts may be made to promote the secretion of the pigment, by exciting the blanched patches with flying blisters or stimulating liniments.

#### *Historical Notices and particular Cases.*

1057. Lecat,<sup>1</sup> Buffon,<sup>2</sup> Buzzi, (Fr.),<sup>3</sup> and Blumenbach,<sup>4</sup> were the first who instituted inquiries of any importance into the subject of general albinism. A great number of new cases have been published lately.<sup>5</sup>

Observations on accidental partial leucopathia are more rare. Several affections in which the colour of the skin is changed are indicated

under the name of *vitiligo*;<sup>6</sup> and although the description of λευκοι bears considerable analogy to that of partial leucopathia, many translators and critics have been led, from a passage in Hippocrates (*Procrhet.* lib. 11, *ad finem*), to imagine that under this name the ancients meant to indicate a very serious disease, to wit, elephantiasis *anathesiaca*, the Greek or Jewish leprosy.

Hamilton, Bree, &c., have reported cases of accidental partial leucopathia.<sup>7</sup> M. Alibert has lately described leucopathia under the name of achroma.

CASE CLVI.—*General congenital leucopathia in a negress*. A white negress, born in Dominica, in 1759, of black parents, has all the features of a negro; the hair, eyebrows, and eyelashes are also those of her race in all except the colour; the hair is of a very short woolly kind, and slightly coloured; the eyebrows, as well as the eyelashes, are of a more golden hue; the general appearance of the skin is a dull white, with a slight pink tint on the cheeks, lips and nose, which becomes deeper under the influence of mental emotions; the skin of the face is slightly spotted over the cheeks by small marks of a violet hue, similar to that of the complexion in a fresh-coloured aged European; the edges of the eyelids are long, and the external angles slope upwards; the eyelids themselves are very narrow, and the parts over them are raised; the iris is gray, with an orange-coloured tint towards the crystalline lens; the eyes are in continual involuntary and irregular motion; the sight is weak without being short; the light of the sun, that of a fine day, or even of a torch is distressing. But this girl neither sees better, nor later than others, as the day declines. The breasts seemed very large for this young woman's age; she is of the ordinary height and rather well made, except that the right shoulder is somewhat larger than the other; the hands are large, the feet strong and also very large; the little toes are broad, the skin appears rather wrinkled, and upon the arm there are several freckles; her voice is sweet like that of negresses generally; she has the odour of the race also, but her skin is less soft than it is commonly in blacks.—(*Journ. Physique de l'Abbé Rosier*, 1777.)

CASE CLVII.—*General congenital leucopathia in a white*. I went, in March, 1827, to the Hôpital de Bicêtre, to see a man named Roche, an albino, better known in the hospital by the name of the *white rabbit*. This man, then forty-three years of age, at first sight had the appearance of an aged person: the hair, eyebrows, eyelashes, eyelids, beard, &c., are of a milky white; the uvea is very little coloured, and traversed with small red and gray streaks; the pupil is as red as blood. The skin is nearly of the tint peculiar to persons of a very fine skin, and without the dull white colour generally seen in albinos. The mucous membranes of the eyelids, the tongue and the genital organs are not at all blanched, but of the same red tint as among well-constituted Europeans. The nails are of the usual form and size. The eyes of this man are very sensible to light; his eyelids are generally half closed, and he winks continually. The muscles of the limbs and body are pretty well developed; his intellectual faculties are limited; he understands the questions which are put to him, but his short or monosyllabic replies are comprehended with difficulty. He articulates badly, almost like a person affected with chorea or a congenital cleft of the palate. Roche was sent to Bicêtre at nine years of age, in 1793, on account of his very limited understanding. The organs of generation are well developed, and the principal functions regular. A man engaged in the hospital, and who had known the parents of this albino, informed me that they never had any other children, and that the mother, according to the vulgar notion, attributed the defective constitution of her son, to her having been alarmed, during her pregnancy, at the sight of a large white cat. This woman was a native of Picardy, and of a dark complexion; the father was of Auvergne, and of good constitution.

CASE CLVIII.—*General congenital leucopathia in a white*.<sup>8</sup> We have had this year, 1809, at Paris, two individuals, brother and sister, the one ten, the other twenty years of age, born in the Bourbonnais,

<sup>8</sup> Gaultier (G. A.). *Recherches sur l'organisation de la peau de l'homme*, etc., 8vo. p. 71. Paris, 1819.

whose skin was of a dead white, without apparent vitality, and like wax. The hair of these individuals was soft, very long, and of a whiteness equal to that of the skin; the iris was reddish; the eyes appeared distressed by the bright daylight, and both the eyes and the eyelids were in almost constant and involuntary motion. The skin was soft and flabby; the muscles very small. Both of these individuals were alike apathetic and dejected.

We know two other children, the one eight, the other ten years of age, who are affected in the same way; they have soft fair hair, which becomes whiter as they grow older. They are born of perfectly healthy parents; their brothers are not similarly affected.

CASE CLIX.—*Congenital leucopathia; the iris blue, the pupil red, skin of a pinky white.* Louisa de Brun, three years of age, was born in Paris, an albiness; the mother has hair of the very lightest kind; the father's hair is of a light brown colour. This child has always enjoyed good health, is lively and pretty, talks a great deal, and has never shown any symptoms of idiocy; her hair is of a brilliant white, almost colourless, of the usual strength, straight and not woolly. Her eyes are in constant motion. The iris is of a blue colour, the pupil red, the eyebrows very thin, short and extremely white; the eyelashes, particularly those on the upper eyelid, are long; the skin is white, with a slight rose tint. This child has only eighteen teeth; the two upper small incisors are wanting; she has two fistulous sores in the left leg and is affected with eczema of the hairy scalp and ears.

The mother of this child informed me that she had another daughter fifteen years of age, also born an albiness, whose hair was now of the very fairest description.

CASE CLX.—*Lentigo of the trunk from childhood, leucopathic spots, and reddish-brown hue of the skin in their vicinity, of one year's standing.* Thirion, a porter, forty-six years of age, had several kinds of spots on the skin. Some (*lentigo*) reddish, lenticular and very superficial, had existed in great numbers on the upper part of the chest and back, since childhood. Other spots of a dull white colour, superficial, irregular, and mostly circular, were very numerous on the skin of the back shoulders and chest; in fact, the skin of the chest, upper extremities, back, posterior parts of the neck, and of the loins and sides, was of a reddish-brown hue, while that of the buttocks, and the posterior aspects of the upper extremities, was of the usual white. The dull white spots mingled with the pervading brown hue of the skin, gave a remarkable marbled appearance to the back of the body, shoulders, calves of the legs, &c. These white patches had only appeared within a year; they followed an eruption of blebs, accompanied with itching. Thirion declares that six months ago, the skin was white, and that it had only assumed the reddish-brown appearance it now presents since that time. The spots of lentigo only had existed since childhood.

CASE CLXI.—*Congenital partial leucopathia in a black.* Artaud informs us, that he had seen a mulatto, nineteen months old, who had a tuft of white hair on the top of the head, a little to the right; there was also in the centre of the sinciput another white tuft, two inches broad, and in the middle of the forehead, a white band running obliquely to the eyebrows, which were half white. Between the pectoral muscles and the umbilicus, there was a white star with seven cusps upon the skin; the right heel was white, and there was a white spot on the vagina, &c. (*Mem. sur les albinos*, Journ. de Physique, t. xxxv.)

CASE CLXII.—*Accidental general leucopathia in a black.* One of Colonel Filcomb's negroes, having been burnt in several parts of the body, in stirring a boiler of sugar, the new skin which was formed over the burnt parts became white, and the whiteness gradually spread over the other parts of the body, until he became as white as an European. The new skin was so tender as to blister when exposed to the sun. The master, astonished at this change in the colour of his negro, had him dressed like his white servants. (*Histoire des Voyages*, t. xv. p. 614.)

CASE CLXIII.—*Accidental partial leucopathia in a black.* Franck, born in Virginia, in 1758, forty years of age, of a robust constitution, and enjoying excellent health, cook to Colonel Barnes, had in her youth as black a skin as the most swarthy African; about twenty years ago, however, she remarked that the skin, in connection with the nails, began to whiten; the same change took place afterwards

around the mouth, and this phenomenon continued by degrees to spread over the body until the whole of the skin had partaken more or less in this singular change. Four-fifths of the surface of the body are now actually white, smooth, clear and transparent, and all that remains black is losing that colour by degrees; the neck and the back along the vertebral column are the parts which are darkest; the head, face, breast, abdomen, arms, legs, and thighs are almost entirely white; the private parts and axillæ are variegated black and white; where the skin of these parts is white, it is covered with white hairs, where black, it is beset with black hairs. The face and neck become inflamed if she is excited to anger or is under the influence of shame. When she has been long exposed to the heat of the fire, red spots appear on the parts which have become white. This woman has never suffered the least inconvenience from this change; no stoppage of the catamenia ever occurred, except during pregnancy; she has never had any disease of the skin, nor made use of any topical application, which could have accomplished the change which has taken place equally on the parts sheltered from the fire, as upon those exposed to it. Perspiration takes place most naturally, and as freely from the white as the black parts of the skin; a blister was applied to the arm but did not rise. *Philos. Trans.*, vol. 51.

CASE CLXIV.—*Accidental partial leucopathia in a white.* Charles Ferron, hackney coachman, sixty years of age, exhibited several spots on the skin as white as snow, and which are rather symmetrically disposed. On the groins they are broad, extend irregularly, and blend with each other. Three-fourths of the penis, and of the scrotum, the skin of the upper and inner parts of the thighs in contact with the scrotum, a portion of the outer aspects of both thighs, the lumbar and dorsal regions, and that of the linea alba, over an extent of surface twelve inches in length by about three in breadth, also present this snow white appearance, which forms a strong contrast with the natural brownish colour of the skin in other parts. In places where the skin is white the hairs are white also. On several parts in the neighbourhood of those which are blanched, small white spots are seen at the roots of the hairs; some of these are broader than others, and appear by spreading to have formed the larger white spots. Although this man has been engaged during thirty-five years in an occupation in which of course he has been subject to great exposure, he has never had any serious illness; neither has he ever laboured under skin disease of any kind; he is in short a very healthy subject. The blanching process began in the spring, at the age of forty-five, and advanced slowly. The spring and summer have always been the seasons most favourable to this change of colour, which took place without pruritus or pain. Various means have been had recourse to, but ineffectually, to restore the colour of the skin and stop the progress of the alteration. Since he attained the age of puberty he has had a considerable tuft of hair on the ridge of the nose. (*Gauthier*, op. cit., p. 76.)

#### NIGRITIES. [AUGMENTATION OF PIGMENT.]

1058. The skin of the European, white in childhood, of a brown hue in manhood among the inhabitants of the South, sometimes accidentally assumes upon some particular district, or over the whole surface of the body, a black hue, similar to that of the negro or mulatto (nigrities).

1059. Local nigrities is most frequently observed on the genital organs. It is not uncommon to see the scrotum and the skin of the penis of adults or full-grown men, almost entirely black, so as to form a strong contrast with that of the pubes, and of the upper parts of the thighs. Haller<sup>1</sup> met with a woman in whom the pubic region was as black as that of a negress.

The nipples of nurses while suckling, are very often of a deep black colour which disappears after weaning. The skin of the face may present a like phenomenon. A lady, says Lecat,<sup>2</sup> about thirty years of age, became pregnant; about the seventh month, the forehead assumed a dusky hue, of the colour of iron rust; by degrees the whole face became entirely black, except the eyes and the edges of the lips, which retained their natural colour. This hue was deeper on some

<sup>1</sup> Haller. *Element. Physiolog.*, t. v. p. 18.

<sup>2</sup> Lecat. *Traité de la peau humaine*. Amsterdam, 8vo., 1765, p. 136.

days than on others. This lady, being naturally of a very fair complexion, had the appearance of an alabaster figure with a black marble head. Her hair, too, was naturally exceedingly dark, but the part of it which grew from the dark-coloured skin appeared coarser, and filled with a blacker sap than the rest, to the height of about a line or two above its roots. She did not suffer from headache; the appetite was good; the face, after becoming black, was very tender to the touch; the black colour disappeared two days after her accouchement with a profuse perspiration, by which the sheets were stained black; the child was of the natural colour. In the following pregnancy, and even in a third, the same phenomenon reappeared in the course of the seventh month; in the eighth month it disappeared, but during the ninth this lady became subject to convulsions of which she had an attack each day.

1060. I have seen several cases in which the tongue became black; the colouring matter, of a bluish-black, is generally deposited on the edges of the organ, in small close spots, from whence it gradually extends over its upper surface. The tongue is otherwise perfectly healthy. It is necessary to distinguish these pigmentary discolorations from the artificial blackening, produced by food or medicine, and from those which the reaction of two substances, the one containing tannin, the other iron, might produce on being taken into the mouth at the same time, or shortly after each other.<sup>1</sup>

1061. *General congenital nigrities* has perhaps never been seen. A case is related<sup>2</sup> of a woman who, like her husband, was of the white race, being delivered of a black child, in consequence of the portrait of an Ethiopian having been accidentally before her eyes at the time this child was conceived. P. Albrecht<sup>3</sup> speaks of a woman who, at the latter end of her pregnancy, was much burned, and buried for a time under the ruins of a house, which had been on fire, and who a month after, gave birth to a child whose skin was as black as that of an Ethiopian. M. I. Geoffroy Saint Hilaire, who mentions these two cases, adds with reason that the first seems susceptible of another interpretation, and that the second is incredible.

1062. On the other hand the existence of accidental nigrities rests on well-established facts. M. Chomel<sup>4</sup> quotes a case of a very apathetic old soldier, whose skin, without any appreciable cause, became as black in some parts as that of a negro, and of a yellowish-brown in others. Goodwin<sup>5</sup> relates a case of an old maiden lady, whose complexion, up to the age of one and twenty, was of the ordinary whiteness, but who then gradually became as black as an African. M. Rostan<sup>6</sup> has published a case of a woman, seventy years of age, who became as black as a negress in a single night, after great mental agitation. Wells has also published a case of accidental nigrities.<sup>7</sup> I have myself met with two cases of this kind.

1063. This accidental blackening of the skin, more frequently seen in women than in men, and occasioned by a deposition of pigmentary matter on the outward surface of the dermis, must be distinguished from the more or less dark brown or yellowish hue, which the skin assumes in old age; nor must it be confounded either with the ecchymoses which appear in purpura, sometimes to a great extent, with the blackish-green tint which appears in certain forms of icterus, nor with the superficial blackness which the sulphuret of mercury produces, &c.

General nigrities differs from melasma, in this latter disease being accompanied with considerable desquamation of the skin.

1064. The black and partial discolorations of the skin, as well as the yellow tints it sometimes assumes during pregnancy, commonly disappear after delivery. General nigrities rarely disappears either spontaneously, or through the influence of therapeutic agents. Chlorine baths make the skin yellow, instead of whitening it.

CASE CLXV.—*General nigrities*. Renaud, a sailor, sixty-three years of age, was admitted into the hôpital de la Charité on the 28th of August, 1827. This man, whose parents were healthy, had never had more than two diseases of the skin: the small-pox at ten years of age, and scabies at seventeen. Being drafted into the military service, he bore the fatigues attached to it for sixteen years, without his health being in the least degree impaired. He was engaged in the Spanish and Flemish wars. In Flanders, he was attacked with intermittent fever, which lasted for a year. The skin became of a sallow-yellowish colour, as is generally the case after this disease; and notwithstanding the immense quantity of quinine which was administered, the cure was only effected by his return to his native country. Since this period, the skin had resumed its natural colour. After having obtained his discharge, this man married a woman who had always enjoyed good health, and who was of a strong constitution; he now indulged in eating a great deal, but never committed any excess in spirituous liquors. On the 7th of July last, he perceived that his skin, which had always been white, had assumed a darker appearance approaching to a yellow. This change began on the inner aspects of the extremities, and extended progressively over the whole surface except that of the face, which only presented the bronzed appearance occasioned by the heat of the sun. At the end of six weeks this dark colour had become general over the trunk and limbs. Renaud then perceived that small solid elevations of the same colour as the skin, were forming on the body, the itchiness and smarting of which were so violent as to disturb his sleep. These papulæ covered the shoulders, the upper parts of the chest, and the posterior aspects of the limbs, without extending over the belly or buttocks. This eruption lasted three weeks. Laceration of the papulæ from scratching was followed by the effusion of a small spot of blood, which coagulated, and formed a minute black and circular scab; this was readily removed, and left a white cicatrice a little depressed behind it. A fortnight after the appearance of these papulæ, a perspiration broke out over the whole body, which lasted for two whole weeks; far from relieving the patient, this only rendered the smarting and itching more violent. The skin from that time, has gone on acquiring more and more the appearance of that of a mulatto, becoming darker and darker every day. The skin of those parts which are least exposed to the air is of a bronze colour, exactly similar to that of mulattos. The face is much lighter than the rest of the body and of a reddish-yellow hue. The conjunctive and the sclerotic coats are of their usual whiteness; the nose, lips and cheeks are not deeper than the rest of the face; the lips are white as in elderly people. The external mucous membranes have generally their natural tint. The whole of the skin of the neck is bronzed, deepening gradually in colour from the upper to the lower part, and passing from a dark yellow to a black bronze colour; it is, however, lighter in front, where it is habitually exposed to the air. The chest, of a pure bronze colour somewhat deeper than the anterior part of the abdomen, is covered with small white circular cicatrices, from two-thirds of a line to a line in diameter, which are evidently consecutive to the papulæ of prurigo. On the skin of the back, which is of a dark brown, white lines or linear cicatrices are also seen, the results of the excoriations produced by scratching; the arms are of a darker brown than the chest, particularly on the outsides; they are of a deep yellow on the insides, and literally covered, particularly on the upper part, with an immense number of irregular cicatrices. The back of the hand is dark, but less so than the outside of the arm; the palm is nearly of the natural colour; the nails of both hands and feet are of a clear yellow; the colour deepens continually from the lower towards the upper part of the thighs, so that the posterior part of the pelvis is almost black. The skin is shining like that of negroes, and soft to the touch, without being moist from perspiration. The hair which grows on the outsides of the legs and arms, and is scantier than it was at the beginning of this affection, seems harsher and blacker, and to have acquired a disposition to curl; the hair of the head has become of a deep black; on the breast there are several white spots.

The pulsation of the heart, and the arterial pulse, are strong, regular, and slow; the radial arteries, which are very large, are tortuous. The veins of the legs have been for a long time very prominent. On the 30th of August a blister was applied to the left arm, which rose

in the ordinary manner. The external surface of the dermis was of a yellowish-red, and appeared to be the seat of the accidental discoloration of the skin. The epidermis did not differ from that of whites generally, except that its internal surface appeared in some points of a yellowish-white. The blister was kept open for four days. A new epidermis was then allowed to form on the surface, and the skin assumed very nearly the same appearance which it presents in whites, after the application of cantharides, the colouring matter having very probably been discharged with the serum and pus. 1st, 2d, and 3d of September, lotions of chloride of lime were applied, but produced no effect on the skin. From the 14th to the 20th, sulphureous water baths, and after the 20th, simple tepid baths were administered. On the 22d, the patient appeared less black; the backs of the hands resembled copper which had been long exposed to the air; the anterior parts of the neck, breast, and abdomen, the inner part of the extremities, and the other regions, which were of a deeper colour, changed from brown to bronze. Since this time the state of the skin has not undergone any change, and the principal functions have experienced no derangement.

Fourcroy (*Système des connaissances chimiques*, t. ix. p. 259), assures us that a negro, after having placed his foot in a solution of chlorine in water, and held it there for some time, drew it out bleached and almost white. He adds, that the skin did not resume its black hue for several days.

Beddoes (Considerations on the Medicinal Use of the Factitious Airs, &c.), having stated that he had made a similar experiment on the hands of a negro, I myself tried the effects of this agent in the case just related. A pint of water, saturated with chlorine, was poured into an arm-bath, and the right hand and forearm were immersed in it for twenty minutes. This bath occasioned slight smarting, and considerable redness of the skin. The parts immersed appeared less black when removed; the hairs of the forearm were yellowish and brittle. During the day the arm became red and very hot. Two days afterwards, this erythematous inflammation had subsided, but it was followed by slight desquamation, attended with this peculiarity, that the detachment of the epidermis was accompanied in some places with the removal of the colouring matter of the skin. I afterwards tried general chlorine baths, by which the skin was rendered yellowish, but was not restored to its natural colour.

CASE CLXVI.—*Nigrities after weaning and amenorrhœa, in a woman of a choleric disposition.* C \* \*, thirty years of age, a laundress, of a very violent disposition, born at Mezieres, of French and white parents, had several times suffered from nervous attacks, after fits of passion. After having suckled her infant a year, she weaned it in the month of May last, and made use of a variety of drinks to carry off the milk. Since that time she has continued weak; she entered the Hôpital de la Charité the first time with pains of the abdomen, which were treated with anodynes. She was admitted again on the 29th of August, 1834. She had menstruated for the first time at the age of nineteen, married, and became the mother of two children, but the catamenia had not appeared since her last confinement, upon which occasion she informed me that she had been very ill for six weeks.

The skin of this woman, who, in every other respect—in the form of her cranium, the colour of her hair, &c.—has the appearance of an European, was of a generally blackish hue, like that of a mulatto. She assured me that this change of colour had only taken place since the weaning of her last child, had occurred very suddenly after an attack of illness which she had then experienced, and had gone on increasing in intensity so long as she continued very ill. Since then it had diminished a little. The black colour is almost uniformly diffused over the whole surface of the body except under the knees where it ceases suddenly; the lower limbs are much less deeply tinged than the other regions; the colour is rather deeper on the outsides than on the insides of the extremities. It is darker over the joints in the sense of extension. The lips and lower eyelids are particularly black. On the left side of the lower lip there is a small irregular spot about the size of a sixpence, considerably lighter than the integuments around it. On the left arm, where a blister had been applied five months since, and kept open for twelve days, there is a spot which is much darker than the surrounding skin. The whole surface

of the skin is not of equal blackness; some places are of a much lighter shade than others. The conjunctivæ have undergone very little change of colour. This woman has blue eyes, and lank hair; her nails have never become either black or yellow. She says she has suffered lately from attacks of intermittent fever. She was affected with amenorrhœa accompanied with derangement of the digestive functions, characterized by loss of appetite, difficulty and slowness of digestion, but without either abdominal pains, thirst, or redness of the tongue. The heart beats regularly, the breathing is natural, the sleep is disturbed. I tried in vain to bring about a return of the catamenia by the application of leeches to the genital organs, and by strengthening the constitution with the use, alternately, of the tepid and sulphureous water bath. This very unmanageable and passionate woman quitted the hospital in almost the same state in which she had entered it, and without any appreciable alteration in the morbid colour of the skin.

## EPHELIS.

Vocab. *Ephelis*, *Freckle*.

1065. Following the example of Lorry, and of Peter and Joseph Frank, I have made use of the word *ephelis* in its literal acceptance, so well indicated by Blanchardus and Castelli, employing it to designate the brown spots produced by the action of the rays of the sun on the skin. They are often few in number, broad, irregular and of a deep brown, (*Ephelis umbrosa*, J. P. Frank,) sometimes small, circular and very numerous, and of a deep yellow, approaching to lentigo in form and colour (*Ephelis lentigo*, P. Frank). They always appear in the spring or during the heats of summer, upon the face, neck, upper part of the thorax, and hands, particularly among children and individuals who have a very fine skin. Our gentlewomen make use of veils to prevent these spots. Some carry their solicitude so far as to wash their hands and face in a mixture of white of egg and water; others, to restore the colour of the skin when covered with freckles, to its natural colour, bathe it with cream, whey, a variety of distilled and aromatic waters, &c. These marks generally disappear on the approach of winter.

1066. Dr. J. Davy<sup>1</sup> has made several experiments to ascertain the mode in which this discoloration of the skin occurs upon exposure to the rays of the sun. In order to determine the nature of the change which takes place in this case, and in seeking to discover the uses of the change itself, he has ascertained that among Europeans, when any part of the surface of the skin is exposed for the first time to the burning sun of hot climates, slight erythematous inflammation takes place: the epidermis is subsequently detached in large scales, and is replaced by a new one of a very light brown hue, but which becomes much darker after several successive desquamations. A similar change is frequently known to follow the inflammation produced by a blister. This alteration in the colour of the skin, nevertheless, often happens without any previous perceptible inflammation; and then occurs after long exposure to a strong diffused light. The change of colour does not take place in the epidermis, but is attached to the surface of the dermis, upon which a quantity of brown colouring matter is deposited. This substance is chemically the same as the black pigmentary matter of the eye, and like it, resists a low red heat, without decomposition. The effect of the change of colour which the skin undergoes, is to protect it against the farther action of the burning rays of the sun. The results of Dr. Davy's experiments on this point are in accordance with the conclusions which Sir E. Home<sup>2</sup> has drawn from his inquiries on the same subject. When the skin has once acquired the brown colour, exposure to the rays of the sun may still occasion some slight smarting and a trifling increase in the temperature, but desquamation does not generally take place. From analogy, the name of *ephelis ignealis* is given to the brown or yellow spots which are seen on the

<sup>1</sup> Transact. of the Med. Chir. Soc. of Edin., v. iii. p. 89. Extract in Arch. gén. de méd., t. xviii. p. 89.

<sup>2</sup> Home (Everard). Sur la couleur noire du réseau muqueux de la peau des nègres, considérée comme servant à la préserver de l'action trop vive des rayons solaires. Extrait. Archiv. génér. de méd., t. i. pp. 90-92. Phil. Trans., 1821.

inner parts of the legs and thighs of females who are in the habit of warming them over pans of lighted charcoal.

## LENTIGO.

Vocab. Art. *Freckle, Lentigo.*

1067. *Lentigo*,<sup>1</sup> more generally known under the name of *freckle*, is characterized by the presence of yellowish, not prominent, and circular-shaped spots. These occur both scattered and in clusters, especially on the face, breast and arms. The spots are of a lighter or darker yellow hue, and as has been said, do not rise above the level of the skin. Appearing from the period of infancy, without any appreciable cause, these spots are generally seen on persons with very light, or reddish brown, or bright red hair; they sometimes continue to an advanced period of life, but usually decline towards the age of puberty. The epidermis does not present any inequality over the stained parts. These spots are not accompanied either with tingling sensations or itchiness, but they abstract powerfully from the whiteness and brilliancy of the skin, which no topical application will restore. They sometimes disappear at indefinite periods, in consequence of the modifications produced by age in the structure or condition of the skin. The spots of *lentigo* differ from those of *ephelis*, in their permanence; the latter appear on the face, hands and other exposed parts of the body during summer, and disappear or become paler in the winter; the stains of *lentigo*, again, are lasting. Farther, *ephelis*, appears indiscriminately in all children, and in almost all adults who are exposed to the heat of the sun, while the spots of *lentigo* are more particularly observed in persons whose hair is red or very light, whose eyes are of a pale blue, and whose skin exhales a very unpleasant odour.

1068. When pieces of skin covered with these pigmentary spots are put to macerate, the colouring matter almost always remains firmly adherent to the dermis, when the epidermis has been detached from it.

*Lentigo* is never made the subject of medical treatment. "Pene ineptiæ sunt, curare varos et lentículas et ephelidas; sed eripi tamen feminis cura cultûs sui non potest."—Celsus. *Dere medicâ*, lib. vi., sect. v.

## CHLOASMA. LIVER-SPOT.

Vocab. Art. *Pityriasis versicolor, Maculæ hepaticæ.*

1069. *Chloasma* is characterized by one or more accidental spots or patches, from the size of a millet seed to that of the palm of the hand; they are dry, generally without pruritus, and of a pale or brownish-yellow colour; they are almost always developed on the trunk, sometimes on the face and neck, but very rarely on the extremities.

1070. *Symptoms.* The colour of the spots of *chloasma* may, in some cases, be compared to the pale yellow of the withered leaves of certain trees, in others to the deep yellow of rhubarb or saffron; in other instances, but very rarely, these spots are of so deep a colour that they approach the description of stain which I shall afterwards treat of, under the name of *melasma*. The form and size of these spots are subject to great variety: some are several inches in diameter, whilst others are scarcely a few lines long. Others, still smaller, of the size of the papulæ of lichen *simplex*, are generally scattered over the anterior parts of the chest and abdomen, and are to be distinguished by their yellowish or greenish colour. In some individuals, these spots, at first single, multiply, enlarge and unite into larger or smaller clusters, so as to give the skin a very remarkable appearance. A certain number of these maculæ, very analogous to those of *ephelis*, do not rise above the surface of the skin which surrounds them, and are not the seat of any apparent exfoliation. Spots of *chloasma* are more particularly observed among persons whose skins are fine and delicate, and among pregnant women (the *Maculæ gravidarum* of certain authors). The stained parts are at other times slightly pro-

minent; their surface becomes the seat of an itchiness which is increased by heat and exercise, or the use of strong liquors. The epidermis afterwards cracks over the surface of the spots, and is detached in small furfuraceous lamellæ (*chloasma pseudo-porrigo*, Frank; *pityriasis versicolor*, Willan); and even when these spots do not appear at all squamous to the eye, the altered epidermis may often be detached by scratching them with the nail or rubbing them with a dry cloth, and the true skin left exposed, which then appears impregnated or overlaid with colouring matter, of a greenish-yellow. The epidermis scales off with particular ease after several sulphureous water baths have been taken. When patients leave these baths, the spots, instead of presenting the ordinary saffron or yellow appearance, are of a reddish colour which bears some analogy to that of lichen *simplex*. Sometimes, also, during summer, or at the beginning of spring, the yellow spots of *chloasma* extend, become itchy, and acquire, temporarily, a fiery tint. I have observed this change more particularly among women who had one or more spots of *chloasma* between the breasts.

The duration of the spots of *chloasma* is very variable; they are most frequently evolved without any known cause, and generally last for several years, if not treated appropriately. The skin of females is more frequently affected with them than that of men; they are rarely seen among children. Women who are affected with them often observe that the colour becomes deeper at the period of menstruation; in this case the spots appear and disappear without any visible desquamation of the cuticle taking place. Several pathologists have designated under the name of *chloasma gravidarum* or *chloasma amenorrhæica*, similar spots which appear during pregnancy or on the suppression of the catamenia.

1071. Pieces of integument, covered with the spots of *chloasma*, have been left to become putrid in the open air, and in maceration; the epidermis, when detached from the former, did not remove the colouring matter; it remained on the external surface of the dermis, under the appearance of a brownish, blackish or grayish layer, which was easily removed with the back of the scalpel. The colouring matter of the pieces subjected to maceration, was divided between the epidermis and dermis, on the surface of which it appeared in the form of a blackish or grayish liquid matter, stagnant in the small furrows, and disposed in layers of unequal thickness. On the surface of the dermis there was observed besides, a band of a blackish colour, deeply situated, which could not be detached with the scalpel without implicating the tissue of the true skin.

1072. *Causes.*—These spots (*maculæ hepaticæ*) often appear in individuals otherwise in perfect health. Patients suffering from chronic affections of the stomach and lungs are also liable to them. In spite of the vulgar opinion which attributes these spots to disease of the liver, it is notorious that they rarely accompany affections of this organ.

The mode in which these spots of *chloasma* are produced is almost unknown; although a marked analogy between the colour of particular spots, and those which follow the application of blisters, may lead us to suppose that the former, as well as the latter, are preceded by a morbid accumulation of blood in the discoloured parts.

1073. *Diagnosis.*—Hepatic spots cannot be confounded with any other morbid discoloration of the skin; *ephelis* differs from them in situation, colour, and above all, in its cause; *lentigo* in its form, its continuance, its red colour, and its commonly accompanying hair of a similar tint. *Nævi*, of the colour of milk coffee, are, in the particular of colour, singularly like some spots of *chloasma*, but differ from these in other respects, inasmuch as they are congenital, lasting, and their surface is never either furfuraceous or itchy, like that of the patches of *chloasma*.

1074. *Treatment.*—The spots of *chloasma*, which often appear in women a few days after conception, frequently disappear at the end of the first month of pregnancy, along with the troublesome symptoms which announced this state; but they have been known to continue during the whole period of utero-gestation, and even for some time after delivery. In this last case, and whenever these spots exist independently of all other affections, they must be treated by sulphureous water-baths, administered every other day, a remedy under which they almost always disappear in the course of a fortnight, or

<sup>1</sup> Forestus. Obs. chir. lib. v. ob. iv: De lentigine et panno faicei.

of a month at the longest. This means is greatly preferable to various other remedies which have been recommended, such as acid washes, the application to the parts affected of embrocations and liniments of camphor, borax, the lauro-cerasus, &c. I ought to remark that, after the administration of a sulphureous bath, the spots of chloasma often appear of a very deep red, which lasts during several hours. I have seen liver spots vanish after an attack of measles. When the cure has been effected by sulphureous baths, or any other means, it is not uncommon for chloasma to reappear the following year, particularly in the spring.

Chloasma is in general easily subdued by the use of sulphureous baths. Nevertheless, I have seen several cases of a variety of this affection, which is almost incurable, but which is happily of no real consequence. Almost the whole surface of the body was covered with large spots of a dirty yellow colour, neither itchy nor furfureaceous, some of which it would have been impossible to cover with the palms of both hands joined together. In these rare cases, small streaks only, or isolated points of healthy skin, were seen between the spots. Several of the patients thus affected, had been sent to various watering-places, but this without avail in so far as the affection of the skin was concerned, and almost always with temporary injury to their general health. These yellow discolorations of the skin resemble meladermia in their rebelliousness to treatment and their continuance.

When patches of chloasma exist at the same time with an affection of any of the internal organs, as of the intestines, the uterus, &c.; or, when they appear after the cure, or decline of the more active symptoms of these affections, many practitioners object to treating them by the sulphureous bath, lest any disease which should occur accidentally afterwards might be attributed to their cure. This alarm, however, though it may not always be prudent to oppose it, does not appear to be justified by any well-authenticated case.

#### Historical Notices and particular Cases.

\* 1075. Hippocrates has designated under the name of εφελιδες not only the spots which are produced by the heat of the sun, but those also which sometimes appear on the faces of pregnant women.<sup>1</sup> Sennertus<sup>2</sup> has given a very good description of liver spots, and has quoted and praised that of Solenander. At various later periods, these spots have been described by Lorry<sup>3</sup> under the name of *macula biliosa*; by Willan and Bateman, under that of *pityriasis versicolor*; by M. Alibert under that of *ephelides hepaticques*, and by P. Frank, under the title of chloasma. Some cases of this disease are to be found in the medical journals.<sup>4</sup>

CASE CLXVII.—*Liver spots on different parts of the body, cured by the use of sulphureous baths.* A girl, eighteen years of age, of a bilious and sanguine temperament, had observed, for the space of about a year, some brownish-yellow coloured spots on almost all parts of her body. When I saw them, these spots occupied more particularly the anterior and posterior parts of the trunk. These were of different forms and sizes, extending in some places to between four and five inches in diameter. The greatest number of them were accompanied with no morbid sensation. Others were itchy, and their surfaces appeared covered in parts with small furfureaceous squamæ. A careful examination of the thorax and abdomen detected no organic lesion in either of these cavities; the general health of the girl was good. The spots disappeared after the use of five and twenty sulphureous baths.

CASE CLXVIII.—*Spots of chloasma on the trunk and limbs.* D\*\*\*, five and twenty years of age, was attacked with chloasma in the month of February, 1824. The spots first showed themselves on the neck, and from that extended over the other regions of the body. On the 7th of May, 1826, the whole posterior part of the trunk was

covered with brownish-yellow spots, running into each other; they were all of the same colour except in some few places in front of the neck and chest, and especially between the mammæ where the skin appeared whitish, and from which desquamation had taken place. The spots were fewer in number on the belly, but increased again on the thighs where they were very deep in colour and confluent. There were none on the legs and very few on the upper extremities, except above the elbow where they were more numerous. The face was free from them, with the exception of two on the right side of the forehead. On all the parts affected, this young woman experienced great itchiness and a tingling sensation which were excessive when she was not in motion. Her general health was good and all the functions regular.

These spots disappeared in the course of six weeks after the use of thirty-three sulphureous baths, without any implication of the general health.

CASE CLXIX.—*Spots of chloasma on the trunk and scrotum.* M\*\*\*, forty years of age of a sanguine temperament, consulted me on the 11th of June, 1821, for chloasma which appeared in several parts of the body. On the skin of the neck and shoulders, and on the posterior and anterior parts of the trunk, there were many superficial spots of a brownish-yellow hue which did not change colour on pressure; they had a fimbriated appearance in some places, in others, by being disposed in small circular spots, they gave the skin a marbled appearance. Their edges were well defined, not shaded off into the surrounding skin, and so close together on the upper part of the trunk, that it was scarcely possible to distinguish the natural colour of the skin; they became fewer in number on the lower part, so that the hypogastrium and loins were almost entirely free from them. In the spaces between these spots the skin retained its natural colour. Any thing that accelerated the circulation, and produced an increase of heat or perspiration, was sure to create a violent itchiness in the spots of chloasma. The patient could not then be prevented from scratching himself violently, and the spots were soon afterwards affected with furfureaceous desquamation. The skin of the scrotum and of the upper and inner parts of the thighs was of a yellowish-brown hue, similar to that of the other spots, from which, indeed, it did not differ in outward appearance, save in being habitually affected with a pretty abundant furfureaceous desquamation.

During the heats of summer these spots became exceedingly itchy. During the past year, a great number of them had disappeared after some sulphureous water douches which the patient had taken at Aix. After the use of forty sulphureous baths they disappeared entirely without there being any necessity for having recourse to other forms of treatment.

#### MELASMA.

#### Vocab. Art. *Melasma, Pityriasis nigra.*

1076. Under the title of *melasma* I designate an accidental and temporary blackish discoloration of the skin, and particularly of the epidermis occurring in one or more parts of the body, and almost always followed by furfureaceous desquamation. This disease has been observed by Willan in children born in the Indies and brought to England. Lorry<sup>5</sup> and M. Alibert describe it as a peculiar species of discoloration of the skin, under the name of *ephelide scorbutique*. This morbid alteration in the colour of the skin, so frequently met with in those affected with pellagra, appeared among a certain number of individuals of both sexes and of all ages in the epidemic of Paris of 1828.

The variety of this affection observed by Willan in children (*pityriasis nigra*, Willan), began by a partial eruption of papulæ, and ended in slight furfureaceous desquamation from, and blackish discoloration of, the skin. This disease sometimes affects only the half of a limb, as the arm or the leg, sometimes only the fingers or the

toes. M. Alibert<sup>1</sup> relates three cases, one of which is a very remarkable instance of melasma: the skin of a beggar became as black as that of a chimney sweeper, and the surface in many parts rough and granular. A similar alteration of the skin has occasionally been observed in cases of pellagra (see Pellagra). In the epidemic of Paris, in 1828, the epidermis became thickened in a great number of cases, principally at the extremities of the fingers and toes, and the skin of these parts, as also that of the chest, and abdomen particularly, frequently assumed a blackish hue, as though it had been coloured with soot. This colour sometimes extended regularly over a larger or smaller portion of the body; or it appeared in the form of isolated patches, at different distances from each other. The epidermis thus discoloured, became dry and rough, and then cracked and was detached from the skin, which appeared of the natural colour beneath it, and was speedily covered afresh with healthy cuticle.<sup>2</sup>

There is a morbid discoloration of the skin observed in South America, which may be assimilated to melasma (see Pinta).

CASE CLXX.—*Melasma observed during the epidemic of Paris, in an individual in whom no symptoms of this epidemic had appeared.* Gerard, three and thirty years of age, a sawyer, entered the Hôpital Saint Antoine the 27th of September, 1828. Born of healthy parents, his father having been fair, his mother dark, this man was of ordinary complexion, the skin naturally rather brown, and the hair black. In the month of July last he experienced great lassitude, and complained of pains in his limbs, which were independent of the fatigues of his occupation. These pains were accompanied with dry cough and some oppression of chest. Leeches were applied to the epigastrium, and demulcent drinks prescribed. He also experienced great itchiness over the trunk and limbs. He was relieved by bleeding; but the oppression of chest not having entirely subsided, he entered the hospital. We were struck with the force and irregularity of the beat of the heart; the face was swollen. The patient was bled twice, after which the palpitation and puffiness of the face subsided.

On the day of his entrance, all were struck on uncovering the patient with the black hue of the skin of the belly and trunk; the patient seemed equally astonished himself, and assured us that the skin, though always naturally brown, was very different from the state in which it then appeared. This hue continued. On the 30th of September, no morbid discoloration had taken place on the skin of the face; the skin of the neck and of the anterior and posterior parts of the thorax, was brown and smooth like that of a mulatto. The anterior part of the abdomen presented a very peculiar appearance: the epidermis was detached in small plates about the size of a silver threepence; these plates were positively black both on their internal and external surface, but appeared much blacker on the skin than after they were detached; when examined between the eye and the light, they were of a grayish hue. On the parts from which the cuticular lamellæ were ready to be detached, the skin was already provided with a new epidermis, not nearly so black as the preceding one, and almost of the same colour as the skin of a mulatto. The skin of the scrotum and upper parts of the thighs, was as black as that of a negro, but was not smooth and shining as it is in blacks; desquamation was in fact going on in several places from its surface. After the coloured epidermis had fallen off, the skin assumed a brown hue. The patient left the hospital in a fortnight from the time of his entrance; he now suffered no inconvenience from palpitations, and after taking a few tepid baths the skin resumed its natural colour.

#### PIGMENTARY NÆVI.

1077. Under the title of *nævi*<sup>3</sup> are designated those congenital alterations of the colour or texture of the skin, which are generally permanent and confined to one part of the body. Although these

<sup>1</sup> Précis théor. et prat. sur les malad. de la peau, t. i. p. 400. Plate xxvii. bis of his folio work gives a faithful representation of this alteration.

<sup>2</sup> Kuhn. Epidémie régnante à Paris. Bull. des sc. méd. de Férussac, t. v. p. 252.

<sup>3</sup> Haller. Element. physiolog., 4to. t. viii. p. 129.—Jacquin (Ch.). Mémoire et observations sur les marques ou taches de naissance. (Journal général de médecine, de chirurgie, etc., tom. xliii. 8vo. Paris, 1812.)

nævi are of very various appearance, they may all be classed under three heads: the one comprises congenital anomalies of the rete mucosum, in which the colouring matter of the skin is contained; another vascular formations and hypertrophies; and a third various congenital tumours formed by the cutaneous and subcutaneous tissues hypertrophied. These two last species of nævi will be treated of hereafter.

1078. Congenital affections of the pigmentary membrane, which were generally spoken of by the ancients under the name of *spili*, present an endless variety in regard to number, form, size, colour, &c. Those yellowish congenital spots which in colour are so singularly like the patches of chloasma, but which differ from them in generally resisting the curative means to which they yield, may be designated under the name of *nævus chloasma*. A young woman, twenty-eight years of age, had a slightly oval-shaped spot, of a brownish-yellow colour, and nearly of the size of a five-shilling piece, on the right side of the fore part of the neck; this spot was exactly like those stains which I have designated under the name of *chloasma*. In conformity with the vulgar notion, this young woman attributed the existence of this spot to a longing which her mother had had during her pregnancy for *café au lait*. These congenital spots are also sometimes seen of a lighter or darker brown or black colour (*nævus niger*). A young man had on the inner and upper part of the right thigh, a black congenital spot, not prominent, of about two inches in diameter, the edges of which were irregular and as if scalloped; the hairs which grew on the surface of this spot, presented a slight enlargement towards their roots.

Gaultier<sup>4</sup> mentions congenital and bronzed spots of the skin. A man, forty years of age, calling himself Joseph Galart, born in Switzerland, attracted the attention of the curious, by exhibiting himself under the name of the *living angel*. He presented the following appearance: the skin of the whole posterior part of the trunk, from the nape of the neck to the loins, is of a bronze colour. This colour extends over the shoulders and the sides of the neck. This part is covered with hairs, of great fineness and growing very thick; the skin of the rest of the body is of the usual whiteness. Those parts are darkest which are most thickly covered with hair; on the back there is a space of an inch in diameter, which has preserved its whiteness, and where the hairs are fewer in number, darker at their bases, and surrounded by a very small black circle; the hair is thinner on the sides of the neck; there are a great many individual hairs surrounded by circles of colouring matter; but there are also many which present nothing of this coloured areola. In some places the general dark colour of the skin blends with the areola surrounding the roots of the hair, so that one uniform brown surface results. In many places the brown colour changes into black. The pupil of the eye is very black, the iris brown. This man is of a very unstable character, extremely undecided in all his undertakings; he has a lively but silly expression of countenance. A distinct smell of mice, with a mixture of a garlicky odour, is emitted from those parts where the excessive secretion of the colouring matter takes place. In these places the heat is also greater than natural. To conclude, I recollect having seen at the *Bureau Central des Hôpitaux*, a young man, whose eyelids, and adjacent parts of the cheeks, were of a bluish tint, similar to that which is produced on the skin by the explosion of gunpowder. Still more recently, I met, among the out-patients of the Hôpital de la Charité, with a man, on the outer side of whose legs there was a congenital spot, which at first sight might have been taken for an ecchymosis. A child was also brought thither to me, who had a grayish-black spot in the region of the loins, the colour of which resembled that which is produced by spreading a thin stratum of mercurial ointment upon the skin.

1079. *Pigmentary nævi* are sometimes covered with hair, the strength and colour of which are very different; it is, however, most generally brown and short. Some of these congenital pigmentary spots fade in intensity of colour after birth; others continue through life, without spreading either in breadth or in depth. These congenital alterations are removable with the knife, the use of caustics, and the repeated application of certain irritating solutions which inflame the skin; but

<sup>4</sup> Gaultier (G. A.). Recherches sur l'org. de la peau, etc., p. 66, 8vo. Paris, 809.

these various means leave cicatrices almost as disagreeable in appearance as the spots themselves.

## BLUE COLOUR OF THE SKIN.

1080. Billard<sup>1</sup> has published a very extraordinary case of *blue discoloration* of the skin, which ought probably to be assimilated with the *blue sweats* that have been described. "Victorine Rufland, sixteen years old, and of a good height for her years, presented on the neck, face, and upper part of the chest, a beautiful blue tint of the skin, principally spread over the forehead, the *alæ nasi*, and round about the mouth. When these parts were rubbed with a white towel, the blue colouring matter was detached from the integument, and stained the towel, leaving the skin white. This girl's lips were red; she was pretty stout; the pulse was regular and natural; the strength and appetite like those of a person in health. The only morbid symptom was a dry cough, but without mucous rattle, and without any deficiency of sound of the chest, and without alteration of the natural beat of the heart; the catamenia had never failed. She had been engaged as a laundress for the last two years; from the time she began this occupation, she had perceived a blueness round her eyes, which disappeared, however, on going into the air. This phenomenon reappeared, more particularly when the irons were heated by a very bright charcoal fire, or when she worked in a hot and confined place. This discoloration, however, made no progress until the month of May last, when the whole forehead and face became so blue, as to attract the attention of those who met the patient. The dry cough, of which I spoke, came on; the catamenia became more abundant than usual, and she was seized with spitting and afterwards with vomiting of blood: still the regularity of the catamenia was never interrupted. The patient was bled several times, and had a blister applied to the arm, but all without any improvement. When I first saw this girl, I looked upon her as affected with *cyanosis*, depending upon organic disease of the heart; but as the colouring matter was secreted on the surface of the skin, which was left colourless when it was wiped off, I soon came to the conclusion that the cutaneous secretion only was diseased. This diagnosis established, I now felt myself embarrassed as to the indications to be fulfilled. Still I ventured to advise medicines which, by their direct action on the skin, might perhaps bring about a favourable modification in its functions. I therefore prescribed six grains of sublimed sulphur, and a pint of decoction of sarsaparilla made with half an ounce of the root every day. Far from being useful, this course, which was continued for twelve days, only occasioned profuse perspiration, a material diminution in the quantity of urine excreted, and a considerable increase of the blue discoloration. The forehead, face, neck, breast and belly now became shaded with azure blue, which spread like clouds, and appeared deeper or paler according as the subcutaneous circulation was accelerated or retarded; when, for example, the patient should have blushed, the face became *blue* instead of *red*. The changes exhibited were positively like the sudden transitions from one shade to another, presented by the chameleon. It is proper to observe that the face and forepart of the trunk, the shoulders, the arms, and a portion of the thighs, were alone coloured; the posterior part of the trunk, the axillæ, and the calves of the legs were in their natural state. The linen of the patient was stained blue. The sclerotic coats of the eyes, the nails, the skin of the head, and the external ear preserved their usual colour. The mucous membrane of the mouth was a little pale, the tongue almost always loaded. No febrile symptoms appeared. I saw the patient again at the distance of a fortnight from the time of my first visit; the different parts of the body which I have described were then of a deep blue colour. The cough was more violent; there was, however, no fever; but for six days the urine had been scanty, and for the last three, the patient had not passed a single drop. She did not, however, experience any of the inconveniences that usually accompany a retention of urine, such as distension of the abdomen, pain in the hypogastric region, swelling of the legs, &c. From the absence of these symptoms, it was easy to

perceive that if the patient did not make water, it was only because there was none secreted; on the other hand, the blue colouring matter had become more abundant, and profuse perspirations took place each night. Thus the skin seemed to supply the place or to perform the function of the kidney. Spitting of blood had occurred some days previously, for which she had again been bled. The blood did not present any peculiarity of appearance. By means of a little oil, I obtained a considerable quantity of the blue colouring matter, which I had only been able to collect with great difficulty, and in small quantity by using plain water or vinegar and water. I sent it to M. Cadet, the distinguished chemist, who, from several experiments, concluded that this blue matter did not partake of the properties of the *cyanourine*, which M. Braconnet found in the blue urine of a patient, and that it was not composed of cyanogen, neither was it one of its compounds with iron.

Having found that an alkaline solution was the most innocent of all the reagents capable of neutralizing this colouring matter, I prescribed the bicarbonate of soda in an infusion of orange leaves, in doses of six grains a day, then of twelve, and finally of eighteen, progressively. At the end of twelve days, the skin of the trunk and limbs had become quite white; a light blue tint only remained round the eyes, about the *alæ nasi*, and over the forehead; the urine had become more copious, and was passed with greater ease, and the perspirations had diminished in quantity. During the following month the blue colour continued to diminish. In the whole of this time the patient had taken an ounce of bicarbonate of soda; the urine, which had previously been very acid, became in nowise alkaline; the perspiration was less acid than usual. This patient is at present in a very satisfactory state; the face is only slightly discoloured; but this colour increases with exposure to heat, any agitation of mind, fatigue of body, and towards the time that the catamenia appear. At this period, too, the cough increases, and she spits and vomits a certain quantity of blood, as in hæmatemesis. She has been bled in the arm; and the blood subjected to chemical analysis, presented no peculiar feature. The patient has nevertheless vomited blood, which contained a sufficiency of blue colouring matter to stain the sides of the vessel. She says, also, that in bleeding from the nose, she has seen blue drops among the drops of blood. Unfortunately, these matters were not preserved.

## YELLOW COLOUR OF THE SKIN.

1081. Morbid *yellowish* tints of the skin occur much more frequently than the preceding ones, and are almost always connected with serious diseases, of which, indeed, they generally constitute an unimportant symptom; it will be enough to mention these very briefly.

Icterus is the most common of these discolorations; although depending, in a great number of cases, on disease of the liver, and mechanical obstacles to the proper course of the bile, yet it sometimes exists without any apparent lesion of the biliary ducts, of the liver itself, or of any other organ which might affect the passage of the bile into the intestines (*icterus spasmodicus*, &c.). The discoloration in icterus varies from a pale lemon colour to a greenish-yellow, to a dark or brownish-yellow, and even to a green. This discoloration, more or less general, and always deeper in some parts than in others, appears at first on the conjunctivæ, the temples, the forehead, round the mouth, on the hands, breast, &c. The superior surface of the tongue seldom becomes yellow, but this tint is often observed on the inferior surface. The urine that is passed is of a deep yellow, and stains linen of a saffron hue. This yellow tint of the skin in icterus diminishes sensibly after death.

The kind of icterus to which new-born infants are subject<sup>1</sup> seems to differ essentially from common jaundice. Two or three days after birth, when the child is still very red, a yellowish shade is perceived over the skin, very light at first, but which increases by degrees. Instead of becoming white under the pressure of the finger, the skin assumes a yellow tint, and returns to the red colour when pressure is discontinued; at a later period the skin becomes very distinctly yellow.

<sup>1</sup> Billard [C.]. Mém. sur un cas particulier de cyanopathie cutanée ou coloration bleue de la peau, causée par une altération de la transpiration. [Arch. génér. de méd., t. xxvi. p. 453.]—Gazette méd. Paris, 1831, p. 399.

<sup>1</sup> Billard, op. cit., p. 643.

The *yellowish appearance* of the skin in the yellow fever, seems to depend, according to Desmoulins,<sup>1</sup> upon a kind of bloody effusion, or rather upon a very slight and diffuse ecchymosis of the skin and subcutaneous cellular tissue.

A *yellow tint* often appears in cases in which pus is absorbed into the system, even when the liver is not affected.

A similar *yellow tint* is sometimes seen in cases of pneumonia of a bad description.

The skin assumes a *straw-coloured tint* in intermitting fevers of long duration, and presents an earthy and yellowish hue in the cancerous diathesis.

#### ARTIFICIAL DISCOLORATIONS OF THE SKIN.

1082. Independently of the various morbid discolorations of the skin, which I have either just described or mentioned, there are others which are produced artificially, either by the direct introduction of certain colouring matters into the tissue of the skin (*tattooing, the black or blue discoloration occasioned by the explosion of gunpowder, &c.*), or by the introduction into the system of certain substances, which give the exterior of the body a peculiar adventitious colour (*the slate colour produced by the internal use of nitrate of silver*).

#### *Slate colour of the Skin produced by the internal use of Nitrate of Silver.*

1083. The nitrate of silver, which has now for a considerable number of years been employed internally in the treatment of various nervous diseases and more particularly of epilepsy, sometimes produces a slate colour of the skin, something similar to that of the mulatto, and one which occasionally becomes even nearly black.

1084. This alteration of the pigment appears to have been observed for the first time by Swediaur.

A Protestant clergyman, says he, of the neighbourhood of Hamburg, affected with obstruction of the liver, took, by the advice of an empiric, a solution of nitrate of silver. Having continued the use of this remedy for several months, the skin insensibly changed its colour, and became at last almost *entirely black*. This colour lasted for several years, and then began to diminish.<sup>2</sup> J. A. Albers, of Bremen, in 1801, prescribed nitrate of silver to a woman, thirty years of age, subject to epilepsy. This woman being much relieved by this remedy, continued to use it for three years and a half. Towards the end of the last year, being pregnant, the skin, particularly of the face, neck, and hands, became of a bluish colour; the sclerotic coats were also coloured in the same manner. The blue tint of the integuments was afterwards observed to increase on the approach of the menstrual periods; the colour of the blood was quite natural; the health of this woman was in no way affected; notwithstanding the application of different remedies, the skin continued to retain its deep blue colour.<sup>3</sup> Struck by the singularity of this phenomenon, Albers addressed himself to other practitioners, inquiring if they had observed any thing of the kind. Reimar, of Hamburg, wrote to tell him that he had seen two cases. Professor Rudolphi informed him that similar results had been observed by a physician in Griefeswalde. Doctor Schleiden, and Doctor Chauffepié, of Hamburg, sent the particulars of three new cases of the discoloration of the integuments in question. Doctor Roget, of London, having prescribed nitrate of silver to a young lady affected with epilepsy, and continued it for four or five months, perceived, some time after the use of the medicine had been discontinued, that the tongue and fauces had assumed a blackish-brown hue. At the end of some months a dusky-coloured circle appeared round the eyes, and the same tint spread successively over different parts of the body. This alteration of colour was permanent; it underwent no change at the time of menstruation.<sup>4</sup> Three similar cases have been detailed by M. Butini,<sup>5</sup> in his *Dissertation on the internal use of the preparations of*

*silver*. Professor Sementini has mentioned this change in the colour of the skin, in a work on the same subject. M. Planché,<sup>6</sup> in an analysis of this work, relates that in the year 1817, he saw a woman, seventy years of age, in Guy's Hospital, London, whose whole body was of a deep violet or livid colour, the effect of a course of nitrate of silver. I have myself observed this change in the colour of the skin in four persons subject to epilepsy who had been treated with the nitrate of silver.

C \* \* \*, formerly a soldier, twenty-nine years of age, entered the hospital of St. Louis, in the month of January, 1816, labouring under epilepsy. At this period the fits were violent and frequent. Since 1811, they had occurred in the most unequivocal form, after a shock which C \* \* \* had received at the battle of Wagram, where he was struck down senseless by a cannon ball, which tore away his knapsack from his back. It is very possible, however, that the origin of this disease might date from an earlier period, as the patient had for several years experienced a constant pain in the frontal and supra-orbital region, which he compared to the vibrations of the arm of a balance within his head. Shortly after his entrance into the hospital of St. Louis, nitrate of silver was prescribed for him. The dose, consisting of half a grain, at first, was progressively increased to eight grains a day. C \* \* \* took the shower bath at the same time, and the head was kept constantly bathed with cold water. The use of the nitrate of silver, interrupted from time to time, was continued for about three years. The fits became less frequent and not so violent, but did not entirely disappear. The digestion of the patient became exceedingly bad, and for a year there were unequivocal symptoms of gastro-intestinal inflammation. The tongue was constantly dry and loaded. Some months after he had commenced taking the nitrate of silver internally, C \* \* \* perceived that his skin had assumed a bronze hue. At the end of the course which it was considered necessary he should undergo, this morbid discoloration had increased to such an extent, that at first sight the patient was always taken for a mulatto. The coppery hue has always been deeper on the face than on any other part of the body. For several years it has gradually decreased, and the patient assures us that now (March 8th, 1827) the colour is not half so dark as it was in 1819 and 1820. It has remained deeper on the face and body than elsewhere, and the skin now presents a livid appearance similar to that of workers in copper. This hue is not so apparent on the legs and thighs, hands, and forearms. The conjunctiva is bright and of a very light coppery yellow; the mucous membranes of the lips and penis are sallow, the nails and hair have not experienced any change. Two or three small cicatrices have remained white, and have not participated in the general change of colour of the skin.

1085. I have seen two other persons affected with epilepsy who had been unsuccessfully treated with the nitrate of silver, whose skin also assumed this bronzed appearance. In one of them, R \* \* \*, this morbid discoloration was very dark, particularly on the face and hands; it was less so on the parts which are not constantly exposed to the light and air. This patient had several cicatrices which have acquired the same hue as the skin. The mucous membrane of the tongue, and the conjunctiva, are changed in the same manner as the integuments; the nails and hair have not undergone any alteration.

1086. M. Lelut has ascertained in two cases that the mucous membrane of the stomach and intestines presented a similar hue to that of the skin; he gives the following summary of his observations:<sup>7</sup>

1st. The discoloration has not extended to the osseous, the muscular nor the serous tissues, nor to the substance of the encephalon, of the liver, &c. The mucous membrane of the lungs seemed also to have escaped it. Perhaps some gray spots on the inner membrane of the aorta, were the effects of the medicine.

2d. The skin, and the mucous membrane of the digestive organs, were the only tissues which were evidently affected. The corion is the special seat of the discoloration; through the whole extent of the two integuments, this alone is uniformly discoloured. The epidermis and corpus mucosum, do not necessarily participate in this discoloration, as they were only affected in the hands and face; and as in the

sub-diaphragmatic portion of the mucous membrane of the digestive organs, there is neither epidermis nor corpus mucosum.

3d. The action of the air, and that of the light and heat of the sun, are not necessary conditions of this discoloration, as the mucous membrane of the digestive organs was bronzed through its whole extent. They seem, nevertheless, to favour the development of the preternatural hue, since it was much deeper on the face and hands than elsewhere, and as it was only over these parts that the two epidermic layers were affected.

4th. The colour which the internal use of nitrate of silver gives to the integuments, is influenced in its intensity, as well as the natural colour of the skin, by the state of the circulation, and the other vital actions; in fact, after these actions have ceased, it loses half its intensity.

1087. Mr. Brande<sup>1</sup> assures us that he found oxide of silver in the skin and other organs, in a case in which all the tissues were said to have acquired a livid hue.

1088. The change caused by the nitrate of silver in the colour of the skin, cannot be confounded with any other alteration in the pigimentary matter; it is even very distinct from the black discoloration produced on the integuments by the action of lunar caustic.

1089. The slate colour of the skin, produced by the continued action of nitrate of silver, has not as yet yielded to any of the means employed with a view to remove it. It generally fades in intensity after lasting for some years; but I do not know whether it ever entirely disappears. Perhaps stimulating baths might aid in removing the morbid discoloration in question. Mr. Badeley<sup>2</sup> found that the inflamed skin resumed its natural colour after the application of a blister. M. Lombard,<sup>3</sup> after making a number of experiments on the administration of nitrate of silver internally, in cases of epilepsy and other nervous diseases, thinks it advisable, when the state of the patient admits of the practice, to suspend the use of the remedy from time to time, in order to prevent the slaty discoloration of the integuments from taking place.

CASE CLXXI.—*Slate-colour of the skin and of the mucous membrane of the stomach and intestines, produced by nitrate of silver.*—Jacques-Auguste, twenty-eight years of age, subject to epilepsy, after having undergone a course of nitrate silver of about thirteen months' duration, observed, some time afterwards (in 1822), slate-coloured patches forming on different parts of his skin, and extending progressively over the whole of his body. Having been received into the Bicêtre, this man died there on the 18th of April, 1827. On opening the body, three cancerous tumours, with destruction of the cerebral convolutions in each of the lobes of the left hemisphere of the brain, were discovered as probable causes of death. A similar tumour was also found in the anterior lobe of the right cerebral hemisphere, and pleuro-pneumonia of both lungs. M. Lelut examined the integuments with much care, and ascertained the following facts: All the external integument was of a gray slate-colour, of moderate intensity. This hue, which was nearly the same in all parts of the skin, did not prevent the vascular colour of the cheeks from being distinguished. The edges of the lips, their internal surface, the inside of the cheeks, and both sides of the tongue, presented an exactly similar hue; the internal surface of the whole alimentary canal was of the same colour as the skin, and the upper opening of the gastro-pulmonary membrane. In the stomach this tint was extremely deep; it was not mixed with any violet-coloured marblings, depending on vascular patches or striæ; it was uniform over the whole extent of the viscera. In both the small and great intestines it was a little clearer, but still very appreciable; it was uniform as in the stomach, and slight traces only of vascular ramifications were discovered in the whole extent of the alimentary canal. Before being subjected to the action of boiling water, the epidermis generally, and the epithelium of the lips and tongue, were exactly similar to the same tissues in individuals whose skin has not been coloured with the nitrate of silver. The colour, both of the outer and inner tegument, resided in the corion, and did

not extend beyond it to the subcutaneous cellular membrane. After having been boiled in water, the cuticle and epithelium, both in their deeper and more superficial component parts (corpus mucosum vel reticulaire, and cuticle, properly so called), were perfectly colourless and white. The corion of the skin, and of the mucous membrane, alone preserved their slate-colour. The mucous membranes of the alimentary passages, freed from their epithelium, and the mucous layer supplied by the mucus they secrete, preserved the slate colour which they presented at first, after being boiled in water, another proof that the seat of this peculiar tint was the corion. The cellular and adipose cellular membrane, the muscles, tendons, aponeuroses, nerves, vessels, and bones, in different parts of the body, presented the same hue as corresponding parts examined in two individuals, one aged, the other young, who had never taken nitrate of silver. Maceration in simple cold water for several days made no difference in the depth of the slate tint of the pieces of skin thus treated. The cuticle of the skin, the epithelium of the tongue, and the mucous body were colourless; the peculiar tint in question resided entirely in the corion, both of the external and internal tegumentary envelop.

## ARTIFICIAL STAINING OF THE SKIN.

1090. Harrold informs us<sup>4</sup> that he had seen a man who became uniformly black by taking sulphur during a mercurial course; a kind of *Æthiops mineral* appeared to have formed on the surface of the body. Dr. Rigby also tells us<sup>5</sup> that he has known a patient, labouring under syphilis, complicated with scabies, who was ordered to rub in mercurial ointment, after having been treated with the unguentum sulphuris, become as black as an *Æthiop*. This phenomenon, which is easily imagined, disappeared very speedily after the disuse of the medicines named. I have myself seen a kind of black scurf formed on the surface of the skin of workmen employed in the manufacture of white lead, whom, having become affected with paralysis of the extremities, from the action of this poison, I had ordered to take the sulphureous water-bath.

M. Chevalier<sup>6</sup> was once consulted by a young woman as to the means of getting rid of a great number of black stains upon her face: he discovered that these were produced by a solution of nitrate of silver, designated *Eau de Perse*, which this damsel used to dye her hair.

1091. Various substances applied to the surface of the skin stain it of different colours. The females of our great cities especially, are, many of them, in the habit of using rouge, with a view to restore the brilliancy of the complexion, when wrinkles and the lapse of years begin to abate its colour and freshness. The women of Greenland rub their faces with white and yellow; those of Nova Zembla streak their foreheads and chins with blue; the Japanese dye their lips and eyebrows with the same colour; the old inhabitants of the Canaries painted their bodies red, green and yellow; the ancient Britons preferred blue for this purpose; the negroes of the kingdom of Juida (Guinea) paint their persons red [and the female savages of London and Paris still bedaub themselves with rose pink and pearl white].<sup>7</sup>

1092. The study of these strange practices, and the discussion of several other species of artificial maculation of the skin, are almost foreign to the object of this work. Paré informs us that in his day lazy mendicants used to rub their faces and persons with a mixture of wood soot and water, to simulate jaundice; the deception was readily detected by examining into the white of the eye and applying a wet towel to the skin. Many have also attempted to simulate icterus by staining their skin with a strong infusion of rhubarb, of the curcuma or chelidonium.<sup>8</sup>

1093. Motion, friction, and the action of the perspiration, speedily rub off or alter colouring matters applied to the skin; to fix them

permanently the art of tattooing has been invented; this custom exists extensively over the face of the globe. The colouring matter appears to be inserted into *linear incisions* of considerable depth in many cases; although in some of the tattooed heads preserved in our museums, the skin appears without cicatrices, but chiseled as if the lines had at least been retouched after the death of the individual.

1094. In Europe the practice of tattooing is unknown, save among our sailors, and the lazy soldiers confined to garrison duty. After having drawn with a pen and ink the letters or designs they mean to imprint upon their skin, these tracings are thickly pricked with needles, and colouring matter is then rubbed into the punctures. The only mischief that ever follows this practice is the occasional excitement of a kind of phlegmonous erysipelas.

1095. The stains thus produced by the insertion of indigo, curcuma, red lead, finely pulverized charcoal, &c., are indelible like those that follow burns with gunpowder. They cannot be removed by blisters, nor any other form of topical application, unless they act so energetically as to destroy the corion at the same time, in the substance of which the colouring matters which cause them are fixed.

1096. After having macerated several pieces of tattooed skin, I found that the epidermis was not coloured any more than that of the unchanged parts of the skin; that the colouring matter was deposited underneath it, and at various depths from the surface of the corion, as the needles had been forced more or less deeply; and finally that the tattooed corion was firmer and harder than that which was in its natural state.

## HYPERTROPHIÆ.

1097. The papillæ of the skin and the epidermis, the vascular rete, occasionally the entire substance of the skin, and even the subcutaneous tissues themselves, now and then occur of unusual thickness. This state may be either congenital or adventitious.

### *Hypertrophy of the Papillæ and Epidermis.*

1098. The papillæ of the skin occasionally present themselves of unusual dimensions, and the cuticle which covers them almost invariably then undergoes very remarkable modifications. I shall, by and by, detail a case of congenital extraordinary development of the papillæ, which, projecting like fringe, became covered with an almost cartilaginous epidermis. Ulcers on the legs, *chronic eczema*, *impetigo figurata*, and particularly blisters—(§ 311)—are occasionally accompanied or followed by an unusual development of the papillæ; these become particularly apparent when the part affected is plunged in water, and look mammillated and uneven, like the pile of coarse plush or velvet. The skin in these cases is habitually covered with scales, sometimes micaceous in appearance, generally brown and rough, and easily rubbed off. By maceration the cuticle can be removed entirely; this part is then found to consist of several laminae, the innermost of which adheres to the points that correspond to the hypertrophied papillæ. It occasionally becomes necessary to remove the callous and nipple-like granulations which the papillæ form in some cases, with the flat scissors.

Excessive development of the papillæ and epidermis is besides one of the principal characters of several other diseases.

1099. To this hypertrophy of the papillæ of the skin observed after blisters, must be assimilated the affection which Mr. Hawkins describes under the title of *warty tumours of cicatrices*,<sup>2</sup> which appear on the surface of old cicatrices succeeding wounds of very dissimilar kinds, and several years after the date of the original injuries. These growths make their appearance on the cicatrice in the shape of a small wart or warty tumour, covered with a thin epidermis, and dry in the

first instance, but which soon becomes moist and the seat of partial ulcers, like the warts of mucous membranes, and which finally secrete a thin, sharp, half-purulent looking matter. At this time there is no complaint made either of pain or inconvenience of any kind. In its second stage the tumour grows more rapidly, and the resemblance to a wart is lost to a certain extent; a more solid substance arises from the diseased integument, whilst around the original excrescence new warty formations go on making their appearance, which in their turn undergo changes similar to those that have been already mentioned. The excrescence is extremely vascular, and bleeds when touched; a probe can generally be pushed through its irregular tissue; sometimes, however, it is of such solidity as to resist the blunt end of the probe. This kind of excrescence is best removed with the knife.

## ICHTHYOSIS.

Vocab. *Ichthyosis*, *Fish-skin disease* [*Porcupine disease*].

1100. Ichthyosis is characterized by a morbid development of the papillæ and thickening of the epidermic lamellæ; these often assume the form of small irregular compartments, which have been compared to the scales of fish. The affection may be almost quite general, or it may be confined to a single region. (a)

1101. *Symptoms*.—When ichthyosis is general, it is always in those places in which the skin is naturally thick, and the epidermis rough, as around the great articulations, on the anterior and external parts of the lower extremities, in front of the patella, over the olecranon, &c., that the altered epidermis becomes thickest. Everywhere else the adventitious layer which it forms over the surface of the skin is much thinner; it is commonly entirely wanting on the prepuce, eyelids, groins, axillæ, &c.; in a word, in every place where the skin is soft and of great delicacy. This morbid development of the cuticle is also very rarely seen on the palms of the hands and soles of the feet, and when it does appear there, it is always to a less extent than in the regions mentioned as its principal seats.

At the period of birth, *congenital ichthyosis* is usually but little apparent. Yet in the anatomical collection of Berlin, there is a fetal monster preserved, the whole surface of whose body is covered with a thick layer of epidermis. The skin is also several lines in thickness; the cuticle presents numerous fissures, and forms a covering like a coat of mail to the body. This singular case has been particularly described by M. Steinhausen.<sup>3</sup>

The skin of those infants, who are by and by to become the subjects of ichthyosis, instead of being smooth and soft as usual, appears sallow, dry, and like shagreen. The affection is proclaimed with characters less equivocal during the course of the two first months of existence. The cuticle in some places becomes rough, sallow, of a grayish colour, and to the touch conveys a sensation similar to what is communicated by the skin of the aged in many cases. An alteration of the epidermis to this extent may continue during a whole lifetime without going farther; or it may increase with the progress of years until it becomes excessive.

Ichthyosis may occur several months after birth, with more decided characters. After having passed by different intermediate degrees of thickening, the epidermis at length appears divided into small irregular compartments, the appearance of which is certainly more analogous to that presented by the legs of fowls than to that of the scales of serpents, although Alibert has designated the variety of ichthyosis under review by the title of *ichthyose nacrée serpentine*.

When ichthyosis shows itself with characters still more decided, it appears upon the extremities, especially in the sense of their extension, under the guise of a thick epidermic layer, which has been likened by some pathologists to the bark of certain trees. In this, as in the two first varieties, the epidermis appears composed of numbers

(a) Ichthyosis is divided by Mr. E. Wilson into *I. simplex*; *I. cornea*; *I. spuria*.

of small compartments, very irregular in their shapes, not imbricated, not more than from two to three lines in diameter, generally broad in proportion as they are thin, and of a grayish or sallow hue. In some rare cases they are shining and in some sort opalescent; more frequently they are of a deep brown colour; the surface is then so rough that the hand passed over it experiences a sensation similar to that which is felt when a file, or shagreen, or the skin of certain fishes is handled (*Ichth. nacrée cyprine*, Alib.). These squamæ may be detached without causing any pain, if we except the largest, which always seem to adhere more strongly, and which, when removed, occasion at least an unpleasant sensation. In every case, when they are detached, whether by friction or in any other manner, they are speedily reproduced with the same characters as before.

1102. There is a fourth variety of ichthyosis, extremely rare, but very remarkable. Individuals have been seen whose skins were covered with numerous small and prominent appendages, which could not be taken away without pain, or the subsequent exudation of a reddish or sanguinolent fluid. These appendages are often whitish internally, though black on the surface. One of the most remarkable cases of this singular alteration of the skin, occurred in a man, a native of Suffolk, who exhibited himself about the year 1710, and was known under the name of the *porcupine man*. The whole surface of this individual's body, except the face, the palms of the hands, and the soles of the feet, was covered with small excrescences in the form of prickles. These appendages were of a reddish-brown colour, and so hard and elastic, that they rustled and made a noise when the hand was passed over the surface. They had appeared two months after birth, and fell off every winter to reappear with the summer. The man was, in other respects, in very good health; he had six children, all of whom were covered with excrescences like himself; the hand of one of these children has been figured by Edwards in his *Gleanings*;<sup>1</sup> the hand of the father may be found represented in the 59th volume of the Philosophical Transactions. (a)

This race of *porcupine men* has been mentioned by several writers, the accounts being taken from the well-known family of the name of Lambert. The whole of the males of this family have the body covered with spines. Two brothers, members of it, were examined by Geoffroy St. Hilaire, one aged twenty-two, the other fourteen. The body of the elder, except the head and palms of the soles, was entirely covered with spines; the younger was naked in several places, particularly over the breast; but a number of brown spots showed that with age he would probably become as completely covered as his brother. The spines on the back of the hand were extremely thick, and might have been compared, as far as the diameter was concerned, to the quills of the porcupine; those which surrounded the nipple bore a greater resemblance to squamæ; they formed long narrow laminæ, very numerous, closely set, and implanted vertically into the skin. This thickening of the epidermis and hair was the effect of a morbid disposition, which was transmitted hereditarily, but only from father to son; the daughters not being affected. Five generations could be reckoned which had been affected in the manner described.<sup>2</sup>

Local and accidental ichthyosis constitutes a fifth variety very distinct from the preceding species, which, in its mode of development, bears the greatest analogy to that of corns; of this nature is the ichthyosis evolved on the anterior and lower part of the thighs in shoemakers, in those places upon which the last rests, whilst they are going on with their work, and especially when they are driving nails into the soles of shoes; of this nature is the scabrous formation which occurs on the elbows of paper stainers, on the surface of the outer ankle in tailors, &c. I have also observed a morbid development of the papillæ of the tongue, in a man in all respects in very good health, which I regarded as precisely similar in its nature to local ichthyosis of the skin.

It is not uncommon for the skin, in subjects affected with ichthyosis, to cast off the adventitious epidermic formations, characteristic

of the different varieties of the general disease, during the summer season; these are, however, constantly reproduced on the approach of autumn. This kind of desquamation has also been observed at other seasons. The skin, divested of its squamæ, shows no signs of inflammation; whether the epidermis have been removed by the influence of the seasons, or by the action of the vapour bath, or any other external application, its colour is natural, only the shallow furrows which occur on its surface are more remarkable than usual. The cutaneous exhalation and follicular secretion appear to be entirely suppressed, or, at least, are inappreciable.

Ichthyosis is not accompanied with pruritus, nor with any other morbid sensation. Neither does it seem to have any kind of unfavourable influence on the general constitution; I have met with several individuals labouring under the first and third varieties of the disease, who enjoyed the most perfect health, and were very robust. In these individuals it is probable that the pulmonary exhalation and urinary secretion supplied the place of the defective cutaneous perspiration; which, however, is sometimes seen to be very copious in the palms of the hands and soles of the feet.

Individuals labouring under ichthyosis are liable to be attacked with acute inflammation of the skin. I have given the case of a young man, twenty-three years of age, affected with congenital ichthyosis who died of small-pox.<sup>3</sup> The porcupine man, seen by Baker, also contracted small-pox; his skin was temporarily freed from the squamæ, but these reappeared before long. I have also seen ichthyosis modified by the occurrence of an internal disease; during its course the squamæ became thinner, the surface less dry and rough, &c., but the ichthyosis recovered all its original characters as soon as the disease which had accidentally complicated it, had subsided.

1103. *Anatomical observations.*—I have tried the effect of maceration upon portions of the skin of individuals who had laboured under ichthyosis. The small compartments of which the epidermic layer consists, and which give the malady its principal external characters, are readily detached under the form of a grayish or blackish membrane, impregnated with pigmentary matter in the porcupine species, little or not at all coloured in the other varieties of the affection. These small compartments do not overlap each other like the scales of a fish; the title ichthyosis, taken in its literal signification, would lead to an erroneous anatomical idea. Tilesius made a few experiments on the nature of the thick black superficial epidermic layer, which was detached in squamæ from the bodies of the brothers Lambert. Buniva has since assured us that the squamæ were nothing more than gelatin, become hard and solid from its combination with a certain quantity of phosphate and carbonate of lime. M. Delvaux has discovered that it also contains a little carbonate of iron and traces of silica; consequently that the squamæ of ichthyosis supplied the same chemical principles as the nails, the hair and the epidermic productions generally. I have myself demonstrated experimentally that this substance possessed physically and chemically the same properties as the epidermis. Dr. M. Good,<sup>4</sup> who designates it improperly by the title of *incrustation*, supposes it to be formed by cutaneous secretions containing an excess of calcareous matter. Under the first epidermic layer in ichthyosis, which is commonly coloured by pigmentary matter, a second is found of a dirty white or grayish hue.

The lines or furrows which the corion presents on its outer surface are much more decided in ichthyosis than in the standard condition. The papillary eminences, which are also much more remarkable than on the healthy skin are sometimes extremely large; it is indeed to the hypertrophy of these that Tilesius ascribes the production of the epidermic spines in the porcupine men. I have ascertained the occurrence of this hypertrophy in the four first varieties of ichthyosis. This excess of development of the epidermic layers recalls an analogous circumstance already observed in a great number of simple cutaneous warty productions.

Tilesius informs us, that in the brothers Lambert, the cutaneous follicles were obstructed, and full of a thick substance. These organs were but little apparent, and in many places imperceptible, in the great majority of the subjects affected with ichthyosis, whom I have examined. The hair and hair bulbs were found remarkably enlarged in a particular case, the history of which is given by Dr. Martin. To conclude, the

<sup>4</sup> Study of Medicine, vol. iv. p. 591.

corion has always appeared to me to be thicker, harder and more dense than it is in the natural state.

In the small number of cases in which opportunities have been found for examining the bodies of individuals affected with ichthyosis, who have died of some accidental intercurrent disease, a variety of organic changes, differing both in kind and situation have been observed, which appeared in nowise connected either with the development or the existence of this affection of the skin.

1104. *Causes.*—General ichthyosis is by no means a very rare disease, at least in France. I have myself seen above forty cases of the kind. It is known to be transmitted through several successive generations. The history of the Lambert family, which has been given by Geoffroy St. Hilaire, Tilesius and Buniva, affords a remarkable instance of the affection being only transmitted to the males. Ichthyosis is seldom developed accidentally long after the period of birth. The whole of the male children of the same father and mother, who were themselves free from such an affection, have been seen labouring under ichthyosis. Such was the case of the brothers, Brayer, born in the department of Cantal. One of them, John, who became a patient at the Hôpital de la Charité, in 1827, assured me that his brother, thirty-seven years of age, was like himself affected with ichthyosis, although neither his father nor his mother had ever been the subjects of a similar affection, of which his three sisters also presented no indication.

Some pathologists have ascribed the development of ichthyosis to moral affections of the mother during pregnancy; this cause, however, is very problematical. I was once consulted on account of three little boys affected with congenital ichthyosis, born of healthy and well-formed parents; and the mother assured me that she had never been better than during her three pregnancies, in none of which had she suffered any thing like mental disquietude or alarm. Neither climate, nor mode of life, nor temperature appears to exercise a marked influence on the production of this disease. It does not appear to be endemic in Hayti, in Paraguay, nor among the inhabitants of the sea coasts or banks of rivers who live much upon fish, as it has been stated to be on insufficient authority.

Women are known to be much more rarely affected with ichthyosis than men.

1105. *Diagnosis.*—Ichthyosis bears but a remote and slight resemblance to the squamous inflammations. Willan and Bateman, and several other pathologists, certainly did wrong in uniting these affections into a single group. Ichthyosis almost invariably makes its appearance in the course of the first months of existence, and continues during the whole of after life. It is not accompanied either with morbid heat or pruritus, or, in a word, with any other symptom observed in inflammation of the skin. (a) In lepra, psoriasis and pityriasis, the production of squamæ is constantly preceded by redness of the skin, which can be readily made apparent by divesting the integument of the epidermic scales and furfuræ deposited on its surface. In confluent and inveterate lichens, the skin may become rough, brownish, and covered with an infinity of minute scales somewhat similar in appearance to those of slight and partial ichthyosis; but this state is accompanied with pruritus of the most insupportable description, and is preceded by an eruption of papulæ. The simultaneous existence, or the ulterior evolution of papulæ on some neighbouring point of the skin already covered with furfuræ, will always suffice to dissipate any doubt which might be entertained of the true nature of these obscure cases. Local ichthyosis is no less distinct from the squamous and furfuraceous states which the skin presents around old ulcers, or after chronic and long-standing eczemas.

We know that from the second to the fifth, and sometimes the tenth day after birth, the skin of the new-born infant throws off its epidermis. (b) This *epidermic exfoliation*, which has been particu-

larly studied by Billard,<sup>1</sup> can never be confounded with ichthyosis; for independently of other circumstances, it does not continue longer than a limited period. The skin of the aged is also occasionally affected with an epidermic exfoliation, which differs from the slightest known form of ichthyosis in the absence of all thickening of the cuticle about the knees and elbows, a condition the existence of which is invariable in the latter affection.

It were useless here to particularize the numerous characters which distinguish ichthyosis from all kinds of horny productions of the skin, and from pellagra; these having been either already mentioned, or being about to be noticed. But I think it necessary to solicit attention to a mistake which must be readily fallen into, seeing that two excellent observers have committed it. Bateman has given a figure in his atlas under the title of *ichthyosis of the face*,<sup>2</sup> of a case which is certainly one of *ceruminous or sebaceous deposit* from diseased action of the follicles; and Dr. A. T. Thomson has detailed a case of the same description under the same erroneous title.<sup>3</sup> In this affection of the follicles, however, which I was the first to notice particularly, the part of the integument affected becomes at first, as it were, unctuous or oily; the secretion of the sebaceous follicles then increases; the fluid thrown out upon the surface acquires additional consistency, and finally forms a kind of *squamous crust or layer* of greater or smaller extent. Soft at first, and adhering but slightly, it by and by acquires hardness, and then cannot be removed without occasioning very considerable pain. The skin under this sebaceous deposit is of a vivid red; the orifices of the follicles appear dilated, and sometimes distended with concrete sebaceous matter. (c)

1106. *Prognosis and treatment.*—*Congenital* ichthyosis often disappears for a time in consequence of acute inflammation of the skin. *Local or accidental* ichthyosis is often successfully treated by means of flying blisters, or topical stimulants. In two cases, in which this chronic alteration of the skin was limited to the legs, Mr. Plumbe succeeded in curing the affection by strapping the affected parts tightly with adhesive plaster, and applying a long roller kept constantly moistened with cold water. The straps were removed every fourth or fifth day, and brought away with them the accidental epidermic lamina with which they were in contact. The skin under this treatment gradually recovered its natural texture and appearance.<sup>4</sup>

Patients have been recommended to pick off the squamæ with their nails whilst they were seated in a warm bath, or to get rid of them by rubbing the surface with a flannel cloth or coarse towel after coming out of a simple or sulphureous tepid water bath (Bateman). I have always found that though the hardened cuticle could be readily removed in this way, it was constantly reproduced after the lapse of a few days. Dr. A. T. Thomson has made the same remark.

In *general* ichthyosis emollient applications continued for a long time, gentle frictions, mucilaginous and soothing fomentations, tepid baths frequently repeated, or alternated with the watery vapour or the alkaline bath, used with such discretion as to cause no disturbance in the performance of the principal functions, are usefully employed in clearing the skin from the squamæ that cover it, and in keeping it in a state as near as possible to that which characterizes the healthy integument.

Bateman tried, but fruitlessly, the effect of plasters of different kinds, and a great variety of stimulating lotions and topical applications in *general* ichthyosis. Mr. Coulson<sup>5</sup> appears to have been more successful:—W. Scott, aged eight years, was brought to him on the 13th of July, 1832, having laboured under ichthyosis for several years, the arms and legs being the parts principally affected, but the skin of the breast and back being also brown, dirty looking and

(c) One might be led to infer from this confident critique on Drs. Bateman and Thomson, that ichthyosis of the face is hardly ever met with. This would be a great mistake. I see from time to time a case of congenital origin in which the whole face is implicated.

(a) On this assertion Mr. Plumbe (p. 318, *op. cit.*) remarks—“There is always—always irritation—present, showing itself in some form or other.”

(b) A thick layer (*smegma*) of deadened epidermis, or rather consisting of sebaceous matter and soft and flexible lamellæ, invests the body of the infant at birth. This is soon detached, in zones and patches, at different times within a few days from birth.

<sup>4</sup> Plumbe on the Diseases of the Skin, p. 334.

<sup>5</sup> Coulson, in Med. Gaz., vol. x. p. 718.

rugous. No internal medicines were employed, but the parts principally affected were bathed twice a day with a wash of the corrosive sublimate. The skin, although improved in appearance, soon became stiff and tense, and at the end of a week, a liniment consisting of half an ounce of the nitrate of mercury, and an ounce of olive oil, with which the parts were anointed thrice a day, was substituted for the sublimate wash. Under this liniment the scales, as they are denominated, soon disappeared, but the brown colour of the skin still continued.

I have not succeeded in curing a single case of *hereditary ichthyosis* of some extent. Happily this congenital affection of the skin is unaccompanied by every thing like important symptoms, and is in itself, indeed, of no consequence. It is not true that individuals affected with it die early from pulmonary consumption, or are worn out by colliquative diarrhœa.

Willan recommended *tar* as an excellent medicine in ichthyosis. He prescribed this substance in doses of from half an ounce to an ounce daily during several months, and assures us that by this means he succeeded not only in freeing the skin from its thickened epidermic covering, but imparted such pliancy and softness to the membrane, as prevented the recurrence of the affection. Bateman also gives the case of a lady who took, for a considerable time, from two drachms to half an ounce of pitch daily, and tells us that not only did this remedy produce the best effects on the state of the skin, but that her general health improved immensely under its use.

Bateman further informs us, that a young girl who laboured under a slight squamous affection, particularly of the scalp, the shoulders and the arms, got well under the use of the *arsenical solution*. In two other cases, however, the same preparation was tried without advantage.

Under the objectionable title of *Greek leprosy*, Turner describes a case of ichthyosis which was advantageously modified by the exhibition of antimonial, mercurial, and several other medicines.<sup>1</sup>

I must also add that Dr. Elliotson, having been consulted on behalf of two brothers labouring under ichthyosis, was so fortunate as to cure one of them by means of *oleaginous applications*, and the administration of pitch internally. He prescribed, he informs us, a warm bath every day, and desired the patient to anoint himself on coming out of it with oil, treating him like an ancient Roman; twice a day, besides, the whole of the body was rubbed with sweet oil. Pitch was also prescribed internally at the same time, at first in quantities of ten grains a-day, the dose being gradually increased until at last *ten scruples* were taken three times every day. The patient who had laboured under ichthyosis for four years, soon derived the most marked benefit from the treatment; the skin became less rugous, and on the 13th of January,—the patient was admitted into the hospital on the 2d of December,—he was perfectly well, the skin being as supple as that of a young female, and softer than the doctor's own. On his discharge he had a plentiful supply of oil and pitch. From the beginning the patient had been clothed in flannel, and advised never to wipe the surface of his body after having anointed himself with oil. On the contrary he was directed, during the whole period of his stay in the hospital, to wear the same flannel shirt, drawers and stockings, so that his skin was kept constantly impregnated with oil. The pitch had no appreciable effect on the organs of digestion; the motions were the same as they had been before its administration; neither was there any pitch mixed with the evacuations, which had no smell of this substance. The chief difficulty experienced was to induce the patient to swallow so many pills; but he got into the way at last of taking down twenty at a time. A good plan, Dr. Elliotson informs us, of taking pitch pills is to make the patient chew a piece of biscuit till it becomes a soft pulp, with which a number of pills being mixed, the whole is swallowed readily.

Dr. Elliotson was further informed by a gentleman, that a lady of his acquaintance, who had laboured under ichthyosis, and was attended by Dr. Willan, had taken an ounce of pitch daily with the same success as the patient whose case has just been quoted. Dr. E. also knew of another case, treated by Willan, which got well under the use of pitch taken in the same doses.<sup>2</sup>

Willan and Bateman do not tell us, whether the cures they effected were accomplished rapidly; had they been so, these authors would

probably have mentioned the circumstance. The doses of pitch prescribed by Dr. Elliotson were much larger than those ordered by Willan. The warm bath seemed to have had little or no share in the cure of Dr. Elliotson's patient. Having rubbed off the thickened cuticle of his legs, he complained that the baths caused these parts to smart, and they were given up after ten days' trial. It is very possible that the use of the oil hastened the cure. This point deserves to be made the subject of further inquiries.

Several trials which I have myself made, particularly of pitch internally, have not been followed by the beneficial results obtained by the practitioners quoted; whether it was that the cases were more severe, that the pitch was not prescribed in doses large enough, or continued for a sufficient length of time, I know not. I have nevertheless ordered half an ounce daily for more than a month.

Dr. A. T. Thomson reports his having cured a woman attacked with an affection of the skin of the face, which he entitles *ichthyosis*, by the use of a decoction of the roots of the *rumex acutus*; but in reading over the account of this case, I am satisfied that the patient was not affected with true ichthyosis, but with a disease of the sebaceous follicles.<sup>(a)</sup>

#### Historical Notices and particular Cases.

1107. Panaroli,<sup>3</sup> Van der Weil,<sup>4</sup> Mare. Donatus,<sup>5</sup> Schenckius,<sup>6</sup> Willan,<sup>7</sup> Alibert,<sup>8</sup> Janin de St. Just,<sup>9</sup> Ansiaux,<sup>10</sup> Chiappa,<sup>11</sup> &c., have given the details of numerous cases from which information may be acquired in regard to the several varieties of ichthyosis. Among the

(a) The eruption always returned a short time after the decoction was discontinued; and hence, believing the return to depend on habit, Dr. Thomson blistered the face with cantharides plaster, immediately after the eruption was again cleaned off, and the cure became permanent. (Thomson's Bateman, p. 81.) Subsequently (in *Cyclop. Pract. Med.*), Dr. T. recommends the *rumex obtusifolius*.

Mr. E. Wilson (*op. cit.*) sums up briefly the treatment as follows:—“The indications to be fulfilled in the treatment of ichthyosis are two-fold; firstly, the removal of the abnormal production; and secondly, the prevention of its reproduction. The first of these indications may be effected, without much difficulty, by employing the well-known powers of soda in the dissolution of albumen. Warm baths containing the subcarbonate of soda will speedily soften and then dissolve the hardened epidermis. The second indication calls for the use of measures which are calculated to modify the state of the system. For this purpose, alteratives should be used, both externally and internally, with the intention of exciting a different action in the cutaneous textures. Some stimulating application, such as a liniment, or ointment of croton oil, in the proportion of a drachm to the ounce, should be rubbed into the skin, with a view to excite and keep up the capillary activity; while the liquor potassæ, the hydriodate of potash, or, as a last resource, the liquor arsenicalis, should be administered internally. (a) Willan, Bateman, and Elliotson, have recommended the use of pitch, taken internally, in doses of an ounce, daily; creosote is an elegant substitute for this remedy. Ichthyosis cornea may be treated with local stimulants, in addition to the constitutional management. The nitrate of silver, in solution, may be used beneficially in this form. The spurious form of the disease, particularly when it affects the lower extremities, requires the use of well-adjusted bandages. These, with some slight stimulant, will frequently remove the disposition to recurrence of the epidermic formation.”

(a) Plumbe assures us that both pitch and arsenic have failed in his hands.

most serious cases on record, however, are undoubtedly those of the brothers Lambert, of which Tilesius<sup>1</sup> and Buniva<sup>2</sup> have each published very accurate details. Dr. Martin<sup>3</sup> has lately described a very remarkable variety of ichthyosis in which the skin was covered with strong hairs like the bristles of a boar. Follet<sup>4</sup> and Joulhia<sup>5</sup> have also described two varieties of ichthyosis in their inaugural dissertations.

CASE CLXXII.—*Ichthyosis over part of the legs and feet; erysipelas of the left leg; death from perforation of the heart.* Lanautte, aged seventy-seven, entered the hôpital de la Charité, on the 23d of March, 1832, on account of an œdematous erysipelas of the left leg. For the last two years, this old man has suffered habitually with swelled legs towards evening, and for a year past has complained of pains in his limbs, which he attributes to the dampness of the room in which he lives. In 1825, he wounded his right leg, which did not get well till it had been eight months under treatment. At this present date, 24th April, 1832, the patient is in the following state.

The left leg is affected with ichthyosis, and with an œdematous erysipelas, and is covered with several phlyctenæ. The ichthyosis only extends over the lower third of the outer and posterior part of the legs, and a portion of the dorsum of the foot. It is characterized by small epidermic lamellæ, from one to two lines in diameter, and from half a line to a line in thickness, rising above the level of the healthy skin towards the circumference of the patch, of an irregular quadrilateral shape, slightly adherent to the skin, and separated from one another by slight furrows.

The erysipelas is characterized by a great increase in the heat of the skin, and a violet-red colour of its surface: the inflammation reaches as high as the knee on the inside, not higher than the level of its upper third on the outside. The colour is so deep in some places that it seems to be produced by a deposition of blood within the substance of the skin; for it cannot be made to disappear with pressure. Several bullæ or phlyctenæ are scattered over the parts most violently affected. Some of these of considerable size are isolated; others smaller are crowded and confluent. Several superficial sores are also observed on different parts of the limb, probably consequent on excoriated phlyctenæ. The surface of these presents different appearances according to their date. The subcutaneous cellular membrane is œdematous; the skin pits on pressure, and preserves the print of the finger.

The right leg is unaffected with inflammation. On the dorsum of the great toe, however, there is an erythematous spot. The lower part of this leg is affected with ichthyosis like the left.

There is an ecchymosed spot on the back of the left hand. The patient is besides affected with inguinal reducible hernia. He is exhausted with diarrhœa and complains greatly of thirst; the tongue is covered with thick mucus. The pulse is febrile in its beat. (*Bandage to the legs; simple dressings; eight leeches to the inferior and inner part of the left thigh; mucilaginous drink.*)

April 25th. The puffing and redness of the left leg have declined; but the patient is in a state of collapse, and is comatose. He died next day. *Sectio cadaveris.* The integument of the left leg presents the same violet-red colour it possessed during life. The skin of the lower third of the outer aspects of both legs, and that of the dorsal surface of the feet, is covered with a grayish epidermic layer, three or four times thicker than the healthy cuticle, divided into an infinity of small compartments, mostly of a quadrilateral shape, under which the layer of epidermis was discovered which was continuous with that of the healthy skin towards the circumference of the altered patch. The dermis of this patch was thicker, denser, and presented deeper furrows or lines than those of the healthy skin. The nails of the feet were long and thick. The subcutaneous cellular tissue of the inflamed leg was loaded with serum, and felt firmer under the scalpel than healthy cellular substance. The vena saphena was not inflamed; the

subcutaneous bursa mucosa of the left knee was red, injected, and contained a little yellow purulent matter. *Head.* The brain was healthy; there were about three spoonfuls of serum in each ventricle. *Thorax.* The lungs were loaded with blood posteriorly, and presented a number of blackish marblings anteriorly. The pericardium contained about six ounces of sanguinolent serum, or rather of fluid serous blood. At the base of the heart near the left auricle a fibrinous clot was discovered, the broad extremity of which was free, and floating in the cavity of the pericardium, whilst the other was impacted in the tissue of the auricle. This coagulum having been detached by means of a jet of water, we discovered a small opening in the auricle, into which a grooved director could be readily passed; the instrument penetrated a kind of sub-pericardial pouch filled with clots of blood. After washing away this blood, we found two small openings into the left ventricle near the attachment of the mitral valve which was ossified; the blood seemed, therefore, to have made its way from the left ventricle into the substance of the auricle, and from this into the pericardium. The substance of the heart was ecchymosed, and infiltrated with blood around the seat of the effusion. The substance of the heart elsewhere was of a tawny yellow colour, and tore with ease. There were also various other morbid appearances about the heart. *Abdomen.* The lower part of the œsophagus was slightly injected. The liver was altered, as was the spleen also. The kidneys appeared simply injected. The urinary bladder presented a remarkable alteration; a great number of fine filaments arose from the inner surface of this organ, and floated free within its cavity, so that the part, especially when laid in water, bore a pretty strong resemblance to one of those large powder puffs which were formerly in use for powdering the hair. The preparation is preserved in the collection of the École de Médecine. I very lately met with a second instance of the same organic alteration; the filaments, however, were less numerous, and not so long as in the case I have just mentioned; they were also intermingled with vesicles from one to two lines in diameter, adhering to the inner surface of the bladder, and consisting of a single extremely thin and pellucid envelop, containing a watery and colourless fluid.

CASE CLXXIII.—*General ichthyosis. Palliative treatment.* A wagoner, thirty years of age, had been affected with ichthyosis from his infancy. The affection was especially remarkable on the lower extremities, particularly in the sense of extension, and in the neighbourhood of the knees. In these situations the skin was covered with small thickened squamæ, of a blackish colour, and so rough that the appearance presented was altogether very similar to that of the bark of a tree. The trunk and superior extremities were covered with a cuticle which was evidently much thicker and drier than in the healthy state, and which was detached in the form of furfuraceous squamæ. This alteration did not extend to the skin of the face. The principal functions were performed with perfect regularity. The patient was directed to take the vapour and simple tepid water bath alternately. The squamæ disseminated over the surface of the body became, under this treatment, thinner and fewer. This palliative treatment had already been successful on two different occasions.

#### VERRUCÆ. WARTS.

Vocab. *Verruca, Wart.*

1108. Warts are small elevations produced by hypertrophy of the papillæ, and occasionally of the whole of the different component layers of the skin. (a) There are two species of warts:

1st. Some, commonly evolved upon the hands, (*verruca vulgaris*), are small eminences, from a line, or less, to two lines in diameter, rising to the height of from half a line to a line above the general level of the skin, rough, and almost insensible on their surface. When one of these warts is cut vertically across in the dead body, the epidermic laminae of the skin form a covering of various thickness over the exterior of the wart; the corion itself rises to the sur-

(a) Meynier of Orleans advances the opinion that warts in man are *gymnosporanges*.

<sup>5</sup> Joulhia. Diss. sur l'ichthyose nacrée. Paris, 1819.

face of the wart in the shape of a little tuft, enveloped by the cuticle which dives down between each of the papillary eminences. Small blood-vessels, in the form of red striae, accompany these prolongations of the corion; to conclude, small blackish points are frequently observed in the substance of warts.

1109. 2dly. Instead of small isolated eminences, *warty bands* are occasionally observed on the surface of the skin. These are commonly reddish, or of the colour of the skin, and are formed by small prolongations of the dermis, and of the papillæ, which arise from the particular part of the skin affected under the form of a kind of coarse plush or shag. It is frequently difficult to decide whether these are syphilitic or not (§ 922). M. Rennes<sup>1</sup> met, in the person of a conscript, with a very remarkable instance of this variety of wart; a band of agglomerated warts, from eight lines to an inch in breadth, extended from the upper and anterior part of the right side of the breast, underneath the clavicle, along the arm and forearm of the same side, till it reached the carpus, where it increased considerably in breadth, and finally overspread the whole palm of the hand.

1110. Warts occur at all ages; but they are certainly more frequent in childhood and youth than in old age. M. Marc saw a woman whose face and fingers became covered with warts, after an apoplectic attack. Habitual irritation seems to provoke their development on the hands; they are therefore most commonly seen among individuals who handle hard substances, who are negligent of proper cleanliness, and whose hands are exposed to great variations of temperature. Turner was of opinion that they were more common than usual among persons who milked, and had the charge of cows. Some individuals appear to have a kind of predisposition to warts, which return after they have been destroyed, in spite of every regard to cleanliness. It has been said that the blood which flows from a wounded wart is liable to cause the formation of others on the parts it touches. M. Cruveilhier informs us that M. Brunel showed him a band of warts upon the back of the hand, assuring him that they had sprung up in the line of the stream of blood which had followed the removal of one of these productions. I have tried repeatedly to inoculate warts in this manner, but the operation has never succeeded.

1111. Common warts must not be confounded with several small appendages of the skin which have been denominated pediculated warts, nor with those small *lenticular* hypertrophies of the corion without thickening of the cuticle, which are occasionally met with on the skin of the back of the hands, and which have also been designated under the name of warts.

Warts differ from syphilitic excrescences; the latter, preceded or accompanied by various symptoms of syphilitic infection, are situated especially on the genital organs, on the chin and face generally, and frequently disappear under the influence of the preparations of mercury, the deuto-chloride of gold and soda, &c. Vascular excrescences are of various shades of red, and pour out an infinitely larger quantity of blood, when punctured or excised, than warts. Cancerous tubercles of the nose and face differ from warts in the characters already particularly pointed out (§ 751). Chimney-sweeper's cancer, however, begins with a species of wart, (§ 761,) and many cases of warts on different parts of the body degenerating into cancer are mentioned.<sup>2</sup>

1112. Warts often disappear spontaneously; they are easily removed as well as destroyed; but in either case are apt to be reproduced. Some warts may be tied with a fine silk thread or horse-hair; when their bases are very broad they may be removed with a knife or flat curved scissors; or they may be destroyed by means of caustic applications. When warts are excised they ought to be bathed in warm soapy water for half an hour; they are then to be removed by very thin layers at a time until the blood begins to spring, when their surface is to be rubbed over with nitrate of silver. When active caustic substances are employed to destroy warts, such as the nitric acid, they must first be surrounded with a piece of diachylon plaster, to preserve the healthy skin from the action of the escharotic.

1113. We have been recommended to rub warts with a piece of moistened sal-ammoniac twice a-day; and this salt, though it acts slowly, destroys almost all warts that are not of extraordinary hard-

ness, without exciting either inflammation or pain. The acrid juices of the chilionium majus, of the euphorbia, juniperus sabina, ficus indica, &c., have been celebrated for removing warts in the same manner.

All these topical applications, however, destroy warts less speedily, and less certainly than nitric acid. Lorry tells us,<sup>3</sup> that in the early part of his life, he saw a practitioner order asses' milk to a crop of warts of the face, and that this application removed them, to his great amazement. The same author informs us, that an unstimulating regimen, the tepid bath, and a milk diet should be prescribed for those young people who, without any assignable cause, are affected with great numbers of warts upon the face and other regions of the body. (a)

#### Historical Notices and particular Cases.

1114. The description of warts left us by the older writers, are by no means free from obscurity.<sup>4</sup> The acrochordon appears to correspond to our pediculated warts; the myrmecia to the common *sessile* wart, and the thymus to excrescences.

Warts have not engaged any great share of the attention of medical men.<sup>5</sup>

#### VERRUCOUS NÆVUS.

1115. Dr. A. T. Thomson<sup>6</sup> has given two instances of *warty nævus*. One of these, which is figured in his Atlas, occurred in a young man, twenty-five years of age, in the enjoyment of good health, the skin of the right side of whose breast, from the nipple to the clavicle, over an extent of about eight inches, that of the axilla of the same side, and that of the inner aspect of the arm and forearm, presented a band, nearly two inches in breadth, of congenital papillary eminences, which had grown with extreme rapidity during the last four months. These papilliform eminences, simple or ramified, elastic, of a reddish colour, fungoid, and with narrow bases, were so much crowded together that they stuck out quite straight from the skin. The majority were four lines in length, and nearly three-quarters of a line in diameter. When they were cut they bled profusely. They were habitually moistened with a colourless exudation of so unpleasant an odour, that this alone had induced the young man to seek for medical assistance. When divided, the cuticle was dense and cartilaginous-looking, and was without difficulty detached from a kind of internal vascular nucleus. The appearance of this papillary nævus, however, was not alike in the different regions which it occupied: on the chest the papillæ, larger and redder, were traversed by furrows parallel to the clavicle, at the bottoms of which the white skin could be seen. Along the arm the excrescences looked like longitudinal spines. On the inner and lower part of the forearm, the nævus extended into the palm of the hand, and even along the inner part of the ring and little finger. In these latter situations the appearance of the formation was notably altered; the skin, indeed, only looked somewhat thickened, and the cuticle indurated. Each of the papillæ was separately cauterized with concentrated nitric acid; they were all thrown off in the course of about six weeks, and the young man got completely rid of his infirmity.

(a) "Warty formations on the skin are not unfrequently of a malignant kind, in the aged; and are most commonly situated on the face. The wart is of an angry and irritable character, and soon degenerates into the cancerous ulcer, surrounded by more or less of the carcinomatous deposit. The remedy is, free removal by excision, if possible, before open degeneracy has been fully established. All warts of the face, indeed, should be removed, at whatever age, and however simple their nature may seem to be; they all being most prone, if not certain, to degenerate in advancing years."—*Miller's Principles of Surgery*.

The other case is related more briefly. It occurred in a child eighteen months old. Here the papillary nævus occupied the right side of the lip and chin. Mr. Okes took away nearly the half of the lip, and a portion of the cheek affected, and by bringing the edges of the wound together, and retaining them in contact by means of a suture, a cicatrice was obtained which caused very little deformity.<sup>1</sup>

To these *warty nævi* we must assimilate a very remarkable case of congenital warts met with by M. Ollivier d'Angers in a fœtus at the full time.<sup>2</sup>

#### HORN PRODUCTIONS.

1116. The anomalous horny productions, often conoidal and prominent (*horns*), sometimes flattened (*horny laminae*), and of various sizes, occasionally observed on the surface of the skin, are formed of a substance very similar to that of the nails and epidermis.

1117. Horny productions are most commonly developed on the head, and on those districts of skin which are most plentifully supplied with sebaceous follicles. The greater number of horny productions result from an affection of one of these follicles. Sir Astley Cooper has given engravings of two cases of these appendages, developed in the cavity of a distended follicle.<sup>3</sup> The simultaneous development of follicular tumours and of these horny appendages has even been observed.

1118. Horny productions, secreted on the inner surface of the follicle, soft at first, soon become hard and tough; they then rise above the level of the skin, and grow both in length and in thickness; they have occasionally been seen several inches long.

During the early periods of their formation, and when they are still of small size, these horny productions are surrounded by a membrane which makes them appear encysted. By and by this membrane only envelops the base of the formation. Horny productions do not extend more deeply than the follicles, within the interiors of which they appear, as it were, to be set. They are consequently always movable, and participate in the motions which the skin receives from the subcutaneous muscles. The cyst, or kind of cyst, in the cavity of which they are implanted, is sometimes the seat of chronic inflammation, which occasionally ends in ulceration.

1119. Horny productions are also frequently evolved on parts attacked with chronic inflammation. M. Julius Cloquet met with a large horny production on the forehead, which made its appearance after a burn. Professor Dubois had an old woman under his care in the Hospice de Perfectionnement, upon whose forehead there was a conoidal horn six inches and a half high by about seven inches in diameter at the base. There is a drawing of this patient in the collection of the Faculté de Médecine. A contusion or wound of the skin had preceded the growth of this horn. The patient complained of habitual headache, the intensity of which was constantly on the increase. The apex of the horn was solid; its base was of a clearer colour, and much inferior consistency. Circular striæ indicated the successive deposits of the matter of which it consisted, and formed inequalities similar to those which are observed on the horns of certain ruminating animals. The cuticle was arranged around the base of the horn, as it is around the root of the nails; it extended beyond the corion to a greater extent, however, namely, by several lines. Portions of the horny production thrown upon lighted coals burned with a smell similar to that which horn diffuses when burned. This production had pushed the integuments of the forehead aside, and especially downwards, to such an extent that the eyelids were habitually closed. The head of the woman diffused a fetid odour.

1120. In a patient of the name of Aumont, who died in the Hôpi-

<sup>1</sup> Home, in Phil. Trans., v. 81, p. 95.

<sup>2</sup> On the front of the thorax and abdomen, shoulders, arms, &c., of this fœtus there were an immense number of warts, of a grayish-white colour, several of which were of the size of a lentil, and all pediculated in a greater or less degree. The larger were cleft to a considerable depth. They passed through the cuticle without being covered by it, springing from the substance of the corion and subjacent cellular membrane. Some of these warts presented the yellowish hue of epheles. The viscera of this fœtus appeared to be quite healthy. (Archiv. gén. de méd., t. xxxv. p. 74.)

<sup>3</sup> Cooper and Travers' Surgical Essays, vol. ii.

tal de la Charité of a disease of the heart, I observed a squamous and pearly-looking production developed on the cicatrice of a gunshot wound of the leg, which he had received in 1806, when in the military service. The cicatrice was covered with scattered pearly squamæ, bearing a strong resemblance to the scales of a carp, which they also equaled in size. Detached by means of warm water, or the tepid bath, these squamæ were soon reproduced. Examined after death, the corion presented an arrangement similar to that of the skin which covers the legs and feet of fowls.<sup>4</sup>

1121. Horny productions may appear on every region of the body. Of 71 cases of the kind in which M. Villeneuve was consulted, thirty-seven occurred in women, thirty-six in men, and three in infants. In nine of these cases the horns were situated on the head;<sup>5</sup> in fourteen on the forehead,<sup>6</sup> and in twelve on the thigh;<sup>7</sup> in the other cases they were situated three times on the temples;<sup>8</sup> five times on the nose;<sup>9</sup> twice on the cheek;<sup>10</sup> once on the jaw; four times on the chest;<sup>11</sup> four times on the back;<sup>12</sup> three times on the penis and glans;<sup>13</sup> four times on the ischium;<sup>14</sup> twice on the knee;<sup>15</sup> twice on the ham;<sup>16</sup> once on the leg, twice on the foot, and once on the hand.<sup>17</sup> They have also been seen on the back of the hand,<sup>18</sup> and above the ear.<sup>19</sup>

1122. The cases of horny degeneration of the skin of different parts of the body, and of monstrosity of the integument observed by Malpighi,<sup>20</sup> \* \* \* \* Ash,<sup>21</sup> Locke,<sup>22</sup> and Musæus,<sup>23</sup> appear to form a separate group, and to depend on a kind of general disposition, different from the morbid processes, of a purely local character, which eliminate horny productions.<sup>24</sup> (a)

(a) "The so-called horns (§ 514) sometimes met with on the head, and developed from the interior of a hair follicle, are nothing more than concretions of inspissated and altered sebaceous substance, modeled in shape by the interior and aperture of the follicle, and partially covered by the attenuated integument, which originally inclosed the sebaceous matter. I have seen productions of this kind so hard from desiccation as to resist the edge of the knife.

"The following is a case in illustration of the sebaceous horn:— Louise Marino, an Italian peasant, fifty-four years of age, perceived, in the month of January, a small tubercle, of about the size of a millet-seed, imbedded in the integument of the root of her nose. The tubercle was attended with a trifling degree of pain and pruritus, but continued to grow with considerable rapidity. On the thirtieth of October of the same year, it had reached the length of an inch, was of a grayish-brown colour, had the diameter of a writing-quill, was grooved along its under surface, and curved like the beak of a bird

<sup>4</sup> This case is surely one of accidental ichthyosis. It seems out of place here.—Tr. Caldani. Mem. di Verona, t. xvi. p. 137.—Schenck. Obs. med. lib. is Cornuti, p. 13.

<sup>23</sup> Morgagni met with a horn on the prepuce, which followed the degeneration of a wart. (Epist. lxx. art. 2.)

1123. Besides the horny productions developed in the cavities of the sebaceous follicles, similar formations are occasionally seen succeeding a variety of wart. Rose Davène, aged sixty-four, of healthy constitution, and the mother of seven children, consulted me at the Bureau Central des Hôpitaux on the 31st of August, on account of a yellowish-coloured horny production, more than two inches in length, the base of which was fixed upon an inflamed patch of the skin, covering the inner surface of the thigh. In the situation which this production now occupied, two small spots (*boutons*) had appeared about six years ago, which had suppurated. On the seat of these a wart made its appearance, and by and by became covered with a horny top, which she had removed with a ligature; but it soon grew again, and was now of the length mentioned. It was only troublesome in walking; the glands of the groin were healthy. I recommended it to be removed, but do not know whether this was done or not.

1124. Voigtel, Conradi, J. F. Meckel, Otto and others, have published many interesting facts connected with the history of *manifold horny productions*. In the collection of the Ecole de Médecine at Paris, the hands and feet of an old woman, presented by Beclard, are preserved, which are covered with horny lamellæ of different sizes. The backs of these parts are covered with horny productions of less length than those of the palms and soles. From the latter arise five or six excrescences, as thick as the finger, and from eight to ten inches in length.

These productions are extremely friable. They demonstrate the analogy of the substance of proper horn to the epidermis. The mode of connection of these multiple horny productions with the skin, is less known than that of the single horns of which particular mention is made above (§§ 1117-1118).

1125. The causes of horny productions are extremely obscure; they appear most generally to follow some chronic irritation of the papillæ.

1126. The form, colour, and especially the consistence and structure of these productions, and the smell they exhale in burning, distinguish them sufficiently from the hard, dry, and pyramidal-shaped incrustations, which occasionally cover syphilitic, scrofulous and cancerous ulcers. These horns are still more distinct from fungous tumours of the dura mater, from nodes of the bones, &c., with which they have been said occasionally to have been confounded. Bony appendages or spiculæ of the femur, humerus, &c., similar to those mentioned by Cabrolus, Vicq d'Azyr and others, can never be mistaken for horny productions of the skin, even though they projected to a considerable distance after piercing the skin.

1127. I only know of one case which goes to prove that the spontaneous fall of horny productions may be followed by a permanent cure.<sup>3</sup>

of prey. It adhered firmly, by means of a narrow base, to the skin and subjacent areolar tissue. Dr. Portal removed it by incision; the areolar tissue at its base, the periosteum and bone, were perfectly sound."—Wilson (*op. cit.*).

Mr. Wilson has recently, in vol. xxvii. of the *Medico-Chirurgical Transactions*, contributed a paper,<sup>2</sup> setting forth the mode of production of horn from the skin and giving some statistics of the subject. He remarks:—"The sebaceous substance is secreted from the blood, through the urgency of the cells which contain the epithelial lining of the gland, as is the case probably with all the secretions of the body; but there is this difference between the sebaceous and other secretions, namely, that the former is semi-solid, while the rest are fluid; the solidity or density of the sebaceous matter being due to the great number of empty and more or less distended cells which compose the mass."

Mr. Wilson has collected ninety cases, of which fifty-four were females and thirty-nine males, the sex of the remainder not mentioned. Forty-eight were seated on the head, four on the face, four on the nose, eleven on the thigh, three on the leg and foot, six on the back, five on the glans penis, and nine on the trunk of the body. Old age seems to be a predisposing cause of this affection.

When it is held necessary to remove these horny productions, on account of the inconvenience or deformity they occasion, the knife is always to be preferred to every form of caustic application. After including the base of the formation within a circular or elliptical incision, it is necessary to dissect away, or to destroy, by means of escharotics, the follicular pouch, the warty excrescence, &c., from which they spring. When this precaution is neglected, or when these productions are simply cut across at their bases, or removed with a ligature, they are very apt to grow again.

Little has yet been done in trying to subdue the particular disposition manifested by certain individuals to have horny growths developed upon the surface of their bodies. Fabricius Hildanus<sup>4</sup> tells us that a young female, having made use of evacuates, emmenagogues and the sulphureo-aluminous thermal waters of Neuham, was cured for a time of these horny productions with which her skin was covered. The combined action of simple tepid, of alkaline, and of vapour baths, would probably prove advantageous, if these appendages were found to adhere but slightly to the skin.

#### *Historical Notices and particular Cases.*

1128. In alluding to a horny production springing from the surface of a wart, Morgagni remarks, with justice, that this fact confirms the observations of Malpighi on the part which the papillæ play in the formation of natural horns: "Quid (ait) aliud denique sunt verrucæ nisi productæ morbosæque cutis papillæ?"

Home and Cooper have studied the horny productions developed in the sebaceous follicles. I have already referred to several cases of horny productions, arising from extensive surfaces of the skin, usually after these had been affected with chronic inflammation. Dauxais<sup>5</sup> and Westrumb<sup>6</sup> have quoted an immense number of cases, in which accidental horns were evolved in men and among the lower animals.

#### CORN.

##### *Vocab. Tylosis.*

1129. Corns are accidental circumscribed epidermic indurations, of a round shape and hard consistence, which are commonly evolved on the upper surface, or on the lateral aspects of the toes, occasionally also on the soles of the feet, especially towards the anterior extremities of the metatarsal bones. Corns compress and irritate, and sometimes inflame and even pierce the subjacent skin; they have also been known to cause inflammation in the joints situated underneath them.

1130. *Causes.*—The injurious pressure of tight, short, or ill-made shoes immediately upon the skin, or of the toes upon one another, are the most frequent causes of corns.

1131. Corns are generally shaped like the head of a nail; the cuticle of which they consist is so much thickened, that layer after layer of it may be removed with a knife. In the middle of the yellowish hardened epidermis, a small point, of a white colour, may be perceived, which penetrates more deeply than the other parts of the induration. The slightest pressure over this white point occasions severe pain. This nucleus is sometimes surrounded by a slight ecchymoses, situated in the corion.

Corns of the lateral aspects of the toes are usually situated under the projections formed by the articular heads of the phalanges, upon which, of course, pressure acts more powerfully as well as more continually. They are almost always moist; their centre is depressed, and presents a slight cavity of a grayish tint, that forms a marked contrast with the pearly white which the constant moisture of the feet gives to the thickened cuticular rim that surrounds the corn.

1132. *Bunions, callosities and indurations* are names given to thick-

<sup>2</sup> Account of a Horn developed from the Human Skin; with observations in the Pathology of Certain Diseases of the Sebaceous Glands.

<sup>3</sup> A case detailed by Roots, quoted by Westrumb.

enings of the cuticle covering the palms of the hands, soles of the feet and joints of the toes. They do not differ from corns, save in being without the central white cone, observed in these last, which, from penetrating deeply, has procured them the title of *clavi pedum*. Pressmen, in printing offices, are liable to indurations of the nature of bunions on certain parts of the palms of their hands, and to painful chaps which are produced by the alkaline leys used for cleaning type. Hard cuticular indurations frequently occur around the heels, on the inner sides of the great toes, on the inferior surface of all the others, and especially over the digital extremity of the first metatarsal bone.

1133. When pieces of integument, affected with corns, are macerated for some time, the thickened epidermic layers are seen to have depressed and altered the corion beneath them. The central nucleus, firmer and more horny than any other part, is almost always distinct.

M. Blandin<sup>1</sup> believes that corns are always formed by a kind of hypertrophy of the superficial lamina cornea seu albida of the skin, and that the thickening of the cuticle observed at the same time is entirely accessory.

1134. Corns may be prevented by wearing easy shoes. These are essential to persons who by their avocations are required to walk a great deal. These individuals ought also to rub their toes with a little tallow, as well as to grease the ends of their stockings, and those points which are in contact with the projecting parts of the foot.

The acute pain produced by corns may be appeased for some time at least, by cutting away the exuberant parts of these productions with a sharp knife. The eye of the corn may sometimes be picked out with the nails after soaking the foot in warm water, or softening the induration by the application of a soft cataplasm, or a piece of diachylon plaster, &c. Two or three operations of this kind, at the distance of a fortnight or three weeks from one another, occasionally suffice to remove the evil entirely. A blunt needle, fixed into a handle, is an excellent instrument for working out these central nuclei. The part should afterwards be anointed with a little mutton suet and covered with a bit of soap or diachylon plaster.

Plasters of soap, of mucilage, of gum ammoniacum, of galbanum, various unguents, the leaves of the house-leek, the pith of the rush used by coopers, cotton, fine linen, &c., applied around the toes, will all be found useful in treating corns of the feet, provided the sufferer at the same time reforms his boots and shoes in the essential point of size. It is not without great advantage either, that the central nuclei of corns are preserved from pressure, by being covered with a piece of thickish soft leather spread on one side with diachylon and pierced in its centre with a hole of a size corresponding to that of the nucleus to be defended. Sir A. Carlisle proposes the above means of dressing, continued during about six weeks, as a simple and very effectual plan of cure.

Corns have also been destroyed by being rubbed with caustic potash, nitrate of silver, muriate of antimony, nitric acid, &c. These agents are attended with many inconveniences in inexperienced hands, and excision appears to be preferable.

#### Historical Notices.

1135. Corns were described very long ago.<sup>2</sup> Rousselot,<sup>3</sup> Lion,<sup>4</sup> and Carlisle,<sup>5</sup> have studied them particularly in modern times.

#### HYPERTROPHY OF THE VASCULAR ELEMENTS OF THE SKIN.

1136. The vascular tissue of the skin occasionally acquires preternatural enlargement. In one case the superficial veins become extremely apparent, ramifying in large branches in situations where none are usually seen (*Phlebectasia*); in another instance, but much more rarely, the skin presents small red spots, formed by extremely

delicate and almost capillary arborizations, *angiectasia capillaris* in a third set of cases, violet or purple covered stains appear upon the skin (*mother marks*) or bloody tumours, the centre or a considerable portion of the surface of which exhibits no vascular ramifications, at least when viewed with the naked eye, but whose circumference generally presents a remarkable vascular net-work, or numerous branches of dilated veins.

1137. *Phlebectasia*, or simple dilatation of the veins, has been most frequently observed on the nose, in consequence of rosacea of long standing, or of a preternatural enlargement of this part, somewhat analogous to Arabian elephantiasis in its nature. The veins occasionally acquire a very considerable size, and form very strongly marked bluish lines on either side of the nose. I have observed this dilatation of the veins in individuals of mature age without any other alteration of the nose.

In those individuals who are affected with enlarged veins of the legs, the skin of the instep and inferior inner part of the leg often presents bluish arborizations, produced by some dilated venous twigs. One of the consequences of ascites, and of pregnancy, is occasionally a dilatation of the superficial veins of the skin as well as an enlargement of the principal trunks of the lower extremities.

1138. Under the name of *capillary angiectasia*, I would designate those vascular spots or patches of various magnitudes, ramified on the surface, not prominent, and of a reddish or rose colour, different from the violet tint of the spots occasioned by dilatation of the veins. This variety of blood-mark may be congenital or accidental.

1139. Under the title of *nævus araneus* certain small congenital, reddish, arborescent spots, of the size of a sixpenny piece or less, have been described; these disappear on pressure; and very seldom occur singly, being frequently scattered over the whole of a limb or region of the body. These marks differ from certain other congenital spots which are occasionally observed on the forehead, the eyelids, &c., the uniform red tint of which has caused them to be compared to a ripe cherry. This last species of spot is frequently prominent.

1140. There is a kind of red arborescent spot, of which I have met with but one instance, that bears a great analogy to the *nævus araneus*.

A woman, thirty years of age, of good constitution, who had long been an inhabitant of New Orleans, came to consult me on account of some spots of the description alluded to, which had made their appearance on one foot and on both legs about nine years previously, some months later on the hands and thighs, and very recently on the abdomen. At first sight I took the spots she showed me for *spider nævi*; but the woman assured me that they were accidental, and that they increased every year in the spring season. The smallest of them could be covered with the head of a large pin; the largest did not quite equal a sixpence in size; the whole were covered with vascular ramifications; but were without heat, unaffected with pruritus, and the seat of no desquamation of the cuticle. Neither the father nor mother of this person was affected with similar spots. She had been married at an early age, and had had nine children, five of whom had died in infancy. For the last four or five years the menstrual discharge had been scanty, and she was a good deal troubled with leucorrhœa, but she enjoyed habitual good health notwithstanding this. In the hope of discussing the marks in question, the anti-scorbutic syrup, with the addition of bichloride of mercury, the Barèges baths, and baths with the addition of sulphate of iron, had been made use of, but unsuccessfully. I recommended a trial of astringent baths, and local styptic applications with no better success.

In the Hôpital de la Charité, I once saw a woman, on the back of whose foot and lower part of whose leg there was a *reddish blotch*, which disappeared under pressure, and returned immediately, and was evidently connected with an extraordinary development of the minute blood-vessels of the skin. This woman had no varices of the legs, and felt neither unusual heat nor itching nor smarting in the part affected. She had been aware of the existence of the red mark for a great many years.

1141. Under the title of *nævi flammei* or *port-wine marks*, flat stains, marks or blotches of various shades of colour have long been designated. These are sometimes of the shade of port-wine or claret, and sometimes of the stain produced on the skin by the raspberry or black

current. They all become deeper in colour under the influence of those causes which accelerate the circulation, such as violent exercise, hot rooms, the use of strong liquors or stimulating food, affections of the mind, and in women the approach of the menstrual period. The portion of skin affected with this kind of nævus is little or not at all thickened or swelled. The surface of the spot is in one case smooth, in another more or less uneven and sometimes even shagreened and mammillated. The blood-vessels distributed to these congenital marks are occasionally of considerable size. Alibert has described and figured a case of nævus *flammeus* under the name of *ecchymome congenital*.

These nævi *flammei* occasionally extend from the skin to the neighbouring mucous membranes: in a man of the name of Petit Jean, who was received into the Hôpital de la Pitié, on the 16th of November, 1826, on account of pulmonary catarrh, one of these nævi was observed occupying the left half of the upper lip, and spreading from thence over the mucous membrane of the same side of the mouth. The temporal, malar and palpebral regions of the left side were also beset with irregularly circumscribed congenital spots, of the colour of wine lees, the skin between them being healthy. These spots did not rise above the level of the skin, did not disappear under pressure, and were unaffected with any unpleasant sensation. When the patient grazed any of these spots with the razor in shaving, he had always great difficulty in arresting the hemorrhage. Under the lower eyelid there were two small red vascular tumours about two lines apart, as large as grape-stones, soft, and capable of being flattened, and made to diminish in size with pressure. These two little tumours had arisen about two years previously after slight wounds. The skin around their bases was redder, and more evidently raised than it was about any of the larger spots.

Nævi *flammei* are occasionally only observed on one side of the body, as in the above instance. I have, however, seen a more remarkable one in the person of a man twenty-four years of age, the whole of the right side of whose body, including the right arm and leg, was covered with thickly set and in some places confluent spots of a vinous red colour. The colour of these spots did not become paler with pressure; but was evidently deepened under the influence of bodily exercise, exposure to an elevated temperature, &c. The subcutaneous veins of the right side generally were extremely large; the mucous membrane of the right side of the mouth was also occupied by several spots of a ruddy violet colour. The gums of this side looked swollen and more vascular than usual.

1142. These *cutaneous* vascular nævi left to themselves may long continue stationary. When they happen to become inflamed, they are apt to ulcerate; and the sores that result are never healed but with great difficulty. E \* \* D \* \* was born with an extensive vascular nævus of the right forearm and hand. It did not rise sensibly above the level of the healthy skin that surrounded it. It was of a violet colour, and deepest upon the hand. Five weeks after birth this nævus was affected with inflammation in several places, which all gave way and became open ulcers. These spread gradually, became united, and at length occupied the whole surface of the preternatural formation. The extensive ulcer that now resulted discharged considerable quantities of blood and purulent matter, and only began to heal in different places, towards the age of five months. The hand and forearm not having been kept upon a horizontal split, as cicatrization advanced, were gradually drawn towards one another, and the cicatrice finally assumed the appearance of a thick hard band of the same nature as those that follow burns, extending from the breast along the anterior margin of the axilla, down the inner aspect of the arm and forearm, turning over the outer edge of which last, it gained the back of the hand, where it divided into several branches spreading downwards to the backs of the fingers, and upwards to the posterior and outer surface of the forearm, &c. The hand is consequently fixed in a state of extreme extension upon the forearm; this remains in a semiflexed position on the arm, and the arm itself cannot be brought into complete abduction.

M. Sabatier once showed me a child at the breast affected with a cutaneous vascular nævus, situated on the inner aspect of the left thigh, ulcerated in several points, and presenting numbers of small cicatrices in others.

1143. Under the name of *vascular growth* of the skin I would indicate a rare and little known affection, characterized by small red persistent vascular elevations, scattered and isolated, or clustered together, scarcely rising above the level of the integument in the first instance, but subsequently attaining one or more lines in length, and then forming true *excrecences*.

1144. These vascular growths, the etiology of which is extremely obscure, are commonly evolved on the face. Few in number and isolated at first, they occasionally become confluent in consequence of several successive eruptions. They often continue stationary during a long course of years; but in some cases they become extremely numerous in a short space of time, without any appreciable cause. When these vascular growths are dispersed over the skin, this tissue generally preserves its natural colour in the spaces between them; but it acquires a reddish tint similar to that of nævus *flammeus* when they are very numerous and much crowded together. Pricked with a pin the vascular growths in question pour out a drop of blood; cut into, the hemorrhage that follows is rather considerable.

1145. When these vascular excrecences are situated on the extremities, they are seldom numerous; and as they occasion neither inconvenience nor visible deformity, individuals affected with this slight alteration of the skin do not generally resort to medical assistance; but when they occur in great numbers on the face, there are few who do not seek advice on account of the deformity which then ensues; for the affection not only shows no disposition to improve, but on the contrary gets continually worse.

1146. Styptic lotions, successfully employed against syphilitic excrecences, are unavailing in the description of the case at present under review. Vascular excrecences, as they scarcely rise above the level of the skin and have uniformly broad bases, cannot be attacked with the ligature. Excision and cauterization to be of any service must interest the whole thickness of the skin, in which case puckered cicatrices and a great deal of deformity ensue. Convinced by experience of the inutility of these surgical measures, I tried the effect of the bichloride of gold and soda, the action of which is so powerful in cases of syphilitic excrecences, whose organization appears every way as perfect as that of the vascular growths we are considering, but without any success.

CASE CLXXIV.—*Vascular elevations and excrecences of the skin.* Booklage, a German by birth, twenty-seven years of age, and of a lymphatic temperament, entered the Hôpital de la Charité on the 16th of March, 1827, on account of a slight gastro-intestinal inflammatory affection, which gave way in the course of a few days to antiphlogistic treatment.

This man also laboured under an extremely rare affection of the skin of the face, characterized by small vascular elevations and excrecences. The patient is not aware that this affection arose under the influence of any particular cause; he only remembers having been told by his parents that it was not born with him, but made its appearance about the third year of his age. The excrecences, scattered at first pretty evenly over the face, by coalescing in a greater degree in one place than another, now form three principal bands. They are red, and appear completely vascular; they shrink and become pale under pressure, but instantly return to their former size and colour, when the finger is removed. The smallest of them, of the size of a pin's head, scarcely rises above the level of the skin, and is of a pale rose-colour; the largest are globular in form, three or four lines in diameter; but several are filiform, especially such as are situated about the alæ of the nose. Several of the excrecences grow from the free edges of the lips, but there are none on their inner surface nor around the orifice of the nostrils. On the gums of the upper jaw there are a number of small elevations and excrecences of the same colour as the general lining membrane of the mouth; the prominent angles of the gums that lie between the several teeth are loose and movable. The forehead, ears, and eyelids are free from excrecences; the base of the nose is covered with them; they become gradually fewer and fewer in number towards the root, where there are none. The skin of this member is red, as in cutaneous vascular nævi generally. There are no vascular excrecences on the neck, but three small cutaneous appendages, two lines in length, are there perceived. On the back there are several appendages of the same description; and both

on the upper and lower extremities there are a few small tubercles of the form and magnitude of a split pea scattered about.

On the 2d of April, I touched five or six excrescences situated close to the left side of the nose, with sulphuric acid, and a cluster of eight or ten others, situated on the chin, with nitric acid. Neither of these applications was complained of as extremely painful.

The excrescences thus treated were detached spontaneously on the 18th; the cicatrice was even, not at all conspicuous, and nearly of the colour of the skin. I therefore determined immediately to touch the whole of a warty-looking band, which ran transversely between the chin and the under lip, with the nitric acid. This application destroyed the excrescences, but it interested the skin through its whole substance. The patient had for some time rubbed in the bichloride of gold and soda under the tongue, in quantities successively of a twentieth, a tenth, a fifth, a quarter, and a third of a grain, but without any evident influence whatever.

CASE CLXXV.—*Vascular tumours and excrescences of the face.* I was consulted for an affection similar to the last which had made its appearance in the spring of the year 1816, in a young man then in the twelfth year of his age, of a sanguine temperament and well formed. The red and enduring globular elevations which characterized the affection, had appeared at first on the chin, and about the furrow which runs between the *alæ nasi* and the face, and on the cheeks, especially on that of the right side. From the year 1817 to 1826, these growths had scarcely been observed to increase either in number or in size. At the latter date, they were red, grew pale upon pressure, and bled profusely when one of them happened to be touched by the razor in shaving; pressure was the only means of arresting the hemorrhage.

Alcoholic and acid washes had been fruitlessly employed with a view of discussing these excrescences. I proposed to destroy them by the use of the potential cautery, but the patient having expressed great repugnance to this measure, I did not urge it; the disease was trifling in extent.

1147. Cutaneous vascular *nævi* frequently occur under the form of red grains or small ovoidal tumours, pediculated, or with bases which blend insensibly with the skin that surrounds them. This variety of *nævus* appears at first in the guise of one or several spots of a rosy or red colour of varying intensity of shade, which children bring into the world with them. These spots are generally of trifling extent, and often bear a great resemblance to flea bites. They frequently continue stationary for several years, and only begin to enlarge in some cases about the age of puberty, or during an attack of dysmenorrhœa in females; more generally, however, they extend both in breadth and depth from the very first, acquire a darker colour, and are gradually changed into red, uneven and irregularly circumscribed tumours, compressible and elastic, less tense when the individual affected with them is in a state of repose than when he cries or moves actively, indolent, without inflammation, and generally exhibiting nothing like pulsation, unless when they happen to lie over large arteries. These vascular tumours have been especially observed upon the forehead, about the root of the nose, on the eyelids, lips, lobe of the ear, labia majora, shoulder, and over the sternum. They commonly grow less rapidly than the vascular tumours of the same description accidentally evolved after birth.

1148. Subcutaneous vascular *nævi* occur more frequently on the face than on other regions. The size of these tumours is diminished by pressure, and increases under efforts, exercise, crying, &c.; but they do not pulsate, like aneurism, by anastomosis.

1149. Congenital cutaneous and subcutaneous vascular tumours are characterized by a preternatural development of a point of the vascular network of the skin or subcutaneous cellular tissue. Two species are admitted; *erectile* tumours, and *varicose* tumours.

1st. Those vascular tumours which consist of *erectile tissue* (Dupuytren), whether evolved as a consequence of a bruise or blow, or independently of any assignable cause, are of a reddish or brownish colour, and generally granular on the surface. Their base is commonly broad, implanted in the skin and subcutaneous cellular tissue, and even penetrating between the muscles; they communicate a peculiar jar to the hand applied to them, as if the obscure rushing of a fluid were felt, and dilate and contract synchronously with the diastole and systole of the heart.

This pulsation is generally particularly obvious at their bases. Soft to the touch, when nothing irritates them, very slight stimuli cause them to increase remarkably, and to become extremely firm; when wounded, the hemorrhage is always profuse, and stopped with difficulty. These vascular tumours never disappear spontaneously; they tend, on the contrary, constantly to increase, to spread into new parts, and to disorganize these in their own peculiar manner. Having attained a great degree of development, these erectile tumours have been known to give way on the surface, to form the bases of enormous fungiform growths, and to give rise to hemorrhage so incessantly repeated and so profuse, as to cause the speedy death of the individual affected.

Vascular tumours, consisting of erectile tissue, generally begin in the subcutaneous cellular substance of the lips, eyelids,<sup>1</sup> inner aspects of the arms and thighs, of the breasts, lobes of the ears, palms of the hands,<sup>2</sup> cheeks, &c., appearing at first in the shape of small, movable, indolent, and elastic red tumours, the progress of which is usually slow, if it be not accelerated by violent efforts, convulsions, and so on. The skin is for the most part only consecutively affected; the disease finally gains the characters that have been indicated.

Tumours of this description form well-defined masses of various sizes, covered occasionally with a thin fibrous envelop, presenting internally the appearance of a cellular or spongy cavity, consisting, in fact, of an inextricable plexus of mingled arteries and veins, communicating by innumerable anastomoses like the capillary vessels, but of much larger size than these. The veins are readily injected from any of the surrounding branches; injection penetrates with greater difficulty into the arteries. When these tumours only implicate the skin and subcutaneous cellular membrane, the neighbouring muscles are simply pushed aside without being altered in their structure. But the muscles very generally participate in the morbid change of structure. The large vessels running in the vicinity of such tumours are generally free from alteration. (a)

(a) *Nævus, or vascular or erectile tumour*, is so well and tersely described by Mr. Miller (*Principles of Surgery*), that I must introduce his remarks in this place.

"The term denotes a diseased formation, in which the vascular tissue bears the most prominent part. There are varieties of such adventitious structure. 1. The capillaries of a portion of integument may be equably and permanently dilated; producing discoloration, and but slight elevation of the affected part. Bleeding is copious from any breach of its surface, by ulcer, or by wound. This is one form of *nævus*, or congenital mark; an affection of no danger, and but little inconvenience; which may be looked upon as rather a deformity than a disease. 2. The structure may consist chiefly of dilated veins; not over-distended, and mere passive tubes, as in varix; but retentive of tone, and energy of function; fed by arterial branches, of somewhat corresponding size and activity; yet the latter tissue holding but a comparatively subordinate part in the development of the tumour. This morbid structure is not found in the substance of the true skin, like the preceding, but in the subjacent cellular tissue; of various size and prominence; causing a doughy elastic swelling, of a livid hue—the venous structure appearing with tolerable distinctness through the superimposed integument. If breach of surface take place, the hemorrhage is profuse, and chiefly of the venous character; capable of being arrested by pressure, without much difficulty. If an incision pervade the mass to any considerable extent, arterial branches are found spouting with much activity; still the main stream is dark and venous. Or the tumour may be submucous; as exemplified by one kind of hæmorrhoid, situated partly within and partly without the verge of the anus.

"3. The third form of swelling is composed chiefly of dilated and active arteries; supplied with large tortuous veins, placed in the vicinity; the principal mass consisting of the changed arterial tissue; the veins not properly constituting any part of this, but being rather the mere conduits whereby the arterial contents are conveyed back into the general circulation. Also, in the neighbourhood, are to be

2d. On the palms of the hands particularly, but also on other regions of the body, we occasionally observe soft bluish-coloured tumours, formed by a plexus of dilated veins. These vascular tumours diminish under the influence of cold, the application of ice, and compression. They are much rarer than the species which has just been described.

1150. *Causes*.—The causes of vascular nœvi, and the mode in which they are formed, are little known. The vulgar opinion which attributes these alterations of the tissue of the skin, &c., to the influence of moral affections of the mother, reckons but few supporters in the present day. Chaussier has made the remark that nœvi were more frequent among those infants whose mothers were subject to chronic inflammation of the skin.

The etiology of all the other varieties of accidental sanguineous blotches, excrescences, and tumours, is also extremely obscure.

1151. *Diagnosis*.—Vascular marks, excrescences, and tumours, have external characters so striking, that they are not liable to be confounded with any other form of cutaneous affection. Cutaneous and subcutaneous vascular tumours differ from vascular nœvi in regard

found the feeding arteries; originally twigs, now enlarged to trunks; pulsating strongly, and obviously carrying on a plentiful and active supply. The mass may be subcutaneous; constituting the true aneurism by anastomosis or erectile tumour; varying in bulk and tension, according as the circulation is sluggish or excited; compressible; elastic to the touch, and indicating its tubular structure on being pinched or rubbed when in the flaccid state; of a reddish hue; in some parts tending to liver, but not continuously so, as in the preceding form of tumour. Or it may be submucous; constituting the most frequent form of internal hæmorrhoid. The structure is analogous to the normal erectile tissue; but with this difference, that whereas in the normal, there are periods of complete repose and collapse, tension and fulness occurring but occasionally by local determination—in the morbid, there are never utter flaccidity and repose. The tumour is more full and tense at one time than at another; yet at all times is full and active; evincing an undulatory movement, if not actual pulsation. Strictly speaking, there is no aneurism here; but rather a simple exaggeration of arterial tissue and function; no degeneration of coats, but simply dilatation; and yet not dilatation alone, but corresponding increase of function as well. The morbid formation may supervene at any period of life; but most frequently it is congenital; and, growing faster than the normal structures around, claims our attention at an early age. The most common situations are, beneath the integuments of the face, head, and neck; not unfrequently it forms on the hands and feet. The tumour pulsates synchronously with the heart's action; but much less distinctly, and with less expansion, than the true aneurism; it may be considerably diminished by equable and sustained pressure, resuming its wonted bulk on removal of the pressure; a bruit is heard, dull and rough, and sometimes associated with a vibratory thrill. At first the skin is free; ultimately it becomes involved in the morbid structure, and incorporated with the general mass. Sometimes the growth is slow; sometimes, and more frequently, rapid. In all cases, bulk is temporarily increased by mental excitement, muscular exertion, and whatever suddenly and much excites the circulation. The tumour having become superficial by involvement of the skin, ulceration is likely to occur; and hæmorrhage follows, profuse, and not easily restrained; demanding active interference, otherwise, by repetition or continuance, it may exhaust the patient. Or the ulceration may have a salutary result; if surrounded and preceded by fibrinous exudation, the vascular structure may be consolidated, no bleeding taking place, even from an acute and wide ulcer; and this consolidation advancing as the ulcer spreads, so as invariably to precede and surround the breach, the adventitious structure may be altogether got rid of, partly by obliteration, partly by ulcerative loss of substance. Sometimes hæmorrhage is vicarious in the female adult, taking the place of the menstrual discharge; the tumour becomes tense and full at the return of each period; a small fissure, or sore, forms in the skin, and from this the blood slowly distils; such bleeding is seldom dangerous, or even excessive, and is not to be suddenly arrested, without means having been duly taken to secure return of the normal discharge."

to the circumstances in which they are evolved. Tumours of erectile tissue do not, like varicose tumours, exhibit any dilated veins in their circumference. Vascular tumours, uneven on the surface, clastic, and of fungiform consistency, even at their base, are easily distinguished from abscesses of every description. It is, however, occasionally difficult to ascertain the extent of these tumours, for they frequently send prolongations deeply among the muscles, which are not indicated externally. Professor Boyer has related two remarkable instances of this anatomical disposition.

1152. *Prognosis*.—Vascular stains and excrescences are never affections of much consequence in themselves. The case is very different in regard to congenital or accidental vascular tumours of the skin, especially to those consisting of erectile tissue. Left to themselves, they seldom continue stationary; and when they have attained dimensions at all considerable, they can only be remedied by operations often of doubtful success, and sometimes extremely dangerous.

1153. *Treatment*.—Compression, cold, and styptic applications, cauterization, artificial inflammation, the ligature used variously to the tumour itself or to the principal vessel that supplies it, and excision with the knife, have all been proposed for the cure of vascular tumours.

After a careful review of almost all the cases of vascular or erectile tumours published up to the present time, and a comparison of the histories of these with the circumstances attending a great many others which he himself had seen both in England and in France, Mr. Tarral, in an excellent paper published in the *Archives générales de Médecine*, has given a summary of the different modes of treatment which have been proposed in these affections, the advantages or disadvantages of each, and the peculiar circumstances in which they are severally applicable.<sup>1</sup>

*Compression* acts slowly, and cannot be had recourse to with advantage, or any likelihood of its proving successful save when the tumours lie over hard parts, which may be made to serve as points of support. Compression, to be decidedly useful, must also be applied with sufficient force to the whole extent and even to the parts beyond the circumference of the tumour.<sup>2</sup> The combined action of *cold*, *compression*, and *styptic applications*, as recommended by Mr. Abernethy, is not generally deserving of much confidence.<sup>3</sup>

The *ligature* was employed with success by M. A. Petit<sup>4</sup> for pediculated vascular tumours. John Bell and White<sup>5</sup> have recommended a needle armed with a double thread of strong silk to be passed deeply under and across the whole mass of the tumour, and one half of it to be included within each of the threads. This plan of treatment is painful, and less certain in its effects than *excision*,<sup>6</sup> which is the method usually adopted for the removal of vascular tumours of erectile tissue. It is also the kind of operation which, numerically considered, has been attended with the greatest amount of success, although, truth to say, it has occasionally been followed by alarming and even fatal hæmorrhage.

1154. Certain species of nœvi have been named as best attacked with the actual, or with the potential cautery. Quick lime has been recommended by one,<sup>7</sup> caustic potash by another (Græfe), and nitrate of silver by a third. Mr. Tarral has given a great number of cases which show incontestably, that simple cauterization of the more superficial parts of these tumours, may be had recourse to with frequent success; that by this means the smaller of them often disappear, apparently from the direct action of the escharotic thus applied, and that even the larger may by this means have their vessels obliterated and their vitality so much altered as to shrink and gradually to vanish. When the tumours are large, repeated cauterization is practised; the operation causes little pain. Wardrop,<sup>8</sup> who was the first to propose

and to practice this mode of using caustic in bloody nævus, tells us, that he had never known the application followed by hemorrhage, and further, that its employment had been uniformly successful.

With a view of exciting inflammation in these tumours, we have been inclined to inoculate vaccine matter upon their surfaces.<sup>1</sup> Several cases are also quoted of cures performed by means of the ointment of tartrate of antimony,<sup>2</sup> rubbed into them; and this plan has the advantage over the former of being applicable to those who have already had cow-pox and small-pox.

Mr. Lawrence has proposed to pass a seton through large tumours of erectile tissue.<sup>3</sup> And Mr. Lloyd<sup>4</sup> has spoken of injecting them with a fluid containing from three to six drops of nitric acid to a drachm of water, care being taken to compress the circumference of the tumour, during the operation. Dr. Marshall Hall<sup>5</sup> has recommended a cataract needle with cutting edges to be plunged into these tumours, and their substance to be traversed in eight or ten different directions without withdrawing the instrument or perforating the skin anew.

Of all these modes of treating vascular tumours, the plan of Mr. Wardrop appears to me the best.

More than one excellent surgeon has further proposed and even practised the ligature of the principal arterial trunk whose branches are distributed to these tumours.<sup>6</sup> This operation has been imagined with especial reference to erectile tumours evolved in the orbit, and those situations in which they are inaccessible by any of the other means already enumerated, as well as to such as, from their immense extent, and the importance of the parts among which they penetrate, cannot properly be attacked with caustic, the ligature or the knife. It has also occasionally been performed as a preliminary to the removal of these tumours, and as a means of controlling hemorrhage, and sometimes only as a palliative, and to prolong for a time the life of the patient hourly threatened by the progress of the disease. (a)

(a) Of the different modes of treating nævi described in the text, that by ligature is preferable in most cases in which an operation is deemed necessary. I have, myself, repeatedly succeeded in removing these congenital tumours by applying tartar emetic plaster over them, and keeping it on sufficiently long to cause free pustulation and ulceration.

If the caustic, potassa fusa, for example, be used to produce ulceration, it ought to be rubbed lightly, so as not to produce a large eschar, the separation of which would likely be followed by hemorrhage.

The method by excision is spoken of in the text, in terms of more decided approbation than surgeons generally use when speaking of it. Mr. Miller will, we believe, be found to express the prevailing opinion on this point, when he says: "Excision, so applicable to tumours in general, is inexpedient; the extent and activity of the component vascular tissue render that mode of removal in the highest degree perilous. To cut into the texture of such a tumour, when large and pulsating, would be madness; the gush of blood might prove almost instantly fatal. To cut even wide of the diseased texture, is not always a matter of safety; unless the knife move cautiously, and the forceps and ligature follow nimbly after, the loss of blood will still be dangerous. The mode of removal by excision, therefore, must be limited to those tumours which are small—not larger than a prune—of no unusual activity, not fed by large and numerous arterial trunks, so situated as to admit of the incisions being made wide of the diseased structure, and also in a locality favourable for the use of the ordinary means of restraining hemorrhage. In all other cases, the ligature is preferable."

The operation by ligature is thus briefly described by Mr. Miller. "A needle is passed beneath the mass, carrying a stout ligature; the needle is withdrawn, and the ligature left; its noose having been cut,

### Historical Notices.

1155. Vascular spots, and tumours of erectile tissue were observed at a very early period. But it is only since the writings of John Louis Petit threw light on their true nature, that really important researches have been instituted with regard to their structure and their treatment. For further information on this subject, I beg to refer to the works of the celebrated surgeons of our day, to those particularly quoted below,<sup>1</sup> and to the excellent paper of Mr. Tarral, already mentioned.

### CHELOID TUMOUR.

Vocab. Art. *Cancroid, and Keloid tumour.*

1156. Under the name of *Keloïde* or *Cancroïde* is described a species of oval or cylindrical-shaped tumour of a permanent character, reddish colour, sometimes with a smooth, but often presenting a wrinkled surface, of a hard and firm consistence, without pulsation or rushing in the interior, slightly prominent, spreading in flat patches, or sending off from the circumference cylindrical or ovoidal prolongations, which have been likened to the claws of a crab.

1157. *Symptoms.*—The appearance of this description of tumour is not the same at its commencement as it is at a subsequent period of its growth. There arises at first on some point of the healthy skin, and still more frequently on the cicatrice of a phlyzacious pustule, of a wound, a burn, &c., a reddish point, of the form and dimensions of a grain of barley. This point is occasionally affected with pruritus of a pretty severe description. Several of these points have been seen arising simultaneously on different parts of the skin which had been irritated by the previous development of phlyzacious pustules. I have, for instance, seen them occurring on the face after confluent small-pox, and in the course of a few months acquiring all the characters proper to the cheloid tumour in its radiated or completely developed form.

When the cheloid tumour is examined with care in the first stages of its growth, and when it does not yet exceed a small hazelnut or

each portion is tied separately on either aspect, so as to include the whole of the morbid tissue; pulling with as tight a strain as the ligature will bear, in order at once to kill the included part, and save both time and pain. If the swelling be circumscribed and prominent, this mode of deligation will be found very suitable; if diffuse, a second needle and ligature may be passed at right angles to the first, and managed in a similar way; the tumour then being secured by four nooses instead of two. Or, if too flat and spread for even this, two hare-lip pins are passed beneath the base, at right angles to each other, and left permanently there, each extremity of each needle protruding somewhat beyond the integument; then a stout ligature is thrown around the whole mass and drawn tightly, secured beneath the protruding ends of the needles; in this way, the noose is made to embrace the whole of the diseased formation. In whichever way deligation is employed, it is often necessary, in the case of large tumours, to make a fresh application within a few days after the first, in order to expedite the sphacelation. But in all cases in which the integument is uninvolved, the use of knife and ligature may be happily combined; the former being employed, in the first place, to reflect the integument in flaps, and thus to expose the diseased structure naked and defenceless to the needle and ligature. In this way, strangulation is effected much more effectually; the part is killed at once, and soon sloughs away. The flaps are then reposed; and, in consequence, not only is the process of cure by granulation abbreviated, but loss of substance saved, and consequently less cicatrix and deformity occasioned:—a point of some considerable importance, when it is remembered that the ordinary sites of the tumour are on the head, face, and neck. Sometimes the morbid structure is so diffuse, as to render inclusion of the whole, by one deligation, impracticable. In that case, it may be taken away in detachments; the operation being repeated at different parts, successively.<sup>2</sup>

<sup>1</sup> Dupuytren. Clinique Chirurg. de l'Hotel-Dieu, t. iv. p. 1. Paris, 1834.—Dupuytren. Vide méd. opér. de Sabatier, édit. Sanson, t. iii. p. 245. Paris, 1832.—Roux. Dict. de méd. Art. Tumeur.—Tarral. Mém. cit.—Lawrence. Lecture (Lond. Med. Gaz., t. vi. p. 228).

the barrel of a quill in size, according as its shape is ovoid or cylindrical, its surface is found covered with numerous transverse wrinkles. Generally indolent, these formations are commonly unaffected with morbid heat, or pain, and it is very seldom, indeed, that they are the seat of any thing like painful shooting sensations.

Several months, and sometimes many years after their first appearance, these tumours extend in length and acquire something of the form of a finger (*Keloïde cylindracée*, Alibert). The wrinkles of the surface become at the same time more conspicuous; the tumour preserves its hardness unimpaired, and now looks like a kind of tuberosity, flattened at one of its extremities, whilst it appears withered and shrunk at the other. In this state the cheloid tumour is not affected with pulsation; neither does it communicate any thing like a jarring sensation to the hand applied to it, like vascular erectile formations; yet its size is affected by various accidental circumstances; it swells, for instance, under the stimulus of increased temperature, of violent exercise, of the approach of the menstrual period, &c. Cheloid tumours occasionally exhibit very small blood vessels on their surface, and almost always send off arms or radii from their circumference, which give them a very characteristic appearance.

1158. Instead of extending in length only, the small reddish and resisting tumours in which cheloid formations commence, sometimes enlarge in all directions, and acquire a quadrilateral rounded or oval form (*Keloïde ovulaire*, Alibert). The hard and prominent circumference rises unevenly, and the centre appears depressed. The boundaries of the tumour, now distinctly marked, are evident to the eye by the reddish colour of the new formation. This variety of cheloid tumour sends off prolongations from several points of its circumference in the form of cones, which are lost in the substance of the skin at the distance of several lines from the bounding line of the tumour.

When the disease, thus far advanced, is left to itself, after an interval, generally of several months, its central part, or different points of its circumference, appear to become the seat of some new action which causes them to turn soft, to shrivel and wrinkle, and finally to assume the appearance of bands similar to those of the cicatrices that follow burns in the third degree of severity. The progress of the peculiar tumours under consideration is otherwise so slow, the inconveniences they occasion are in general so trifling, that I have known patients refuse to submit to the curative means proposed for their relief.

1159. *Causes*.—I am not aware that cheloid tumours have been observed among children previously to the period of the second dentition. The majority of the cases which have been published, and those I have myself seen, occurred among adults and the aged. Some slight circumscribed local inflammation, a scratch, the alteration of the skin consequent upon small-pox, a burn, &c., seem to prove the usual existing causes of these tumours. Their formation, however, appears to depend further on some peculiar state of the constitution. Although they have been met with in individuals of every variety of temperament, they nevertheless appear to be most frequent among persons of lymphatic constitution.

This kind of formation is rare. I have not met with more than five cases of it in the course of my practice. In three of these the tumour arose over the sternum without assignable cause; in another it occurred on the buttock of an adult upon the cicatrice of an extensive burn which he had received when but a few months old. In the last case I encountered, there were two tumours, one on either cheek; these supervened after small-pox. From the cases recorded by other observers,<sup>1</sup> women appear to be at least as liable to the disease as men. Accident, however, has shown me four men, and only one woman affected with it.

1160. *Diagnosis*.—There is no difficulty in recognizing the cheloid tumour when it has attained any considerable size, whether it appears under the form of a broad, reddish cylindrical crest or ridge, or that of a flattened tumour, sending off prolongations from its circumference, bearing some analogy to the claws of a crab. But the distinguishing features of the small reddish tumours by which these

varieties of the tumour begin in common with syphilitic, scrofulous and cancerous tubercles, and sanguineous nævi, are not so decided as to be at all times readily at once appreciable. Still the cheloid formation, independently of any inference deducible from the most frequent seat of its development, the sternal region, presents characters enough to distinguish it from any other form of cutaneous affection. It is, for instance, harder than the scrofulous cutaneous tubercle even from its first appearance; its wrinkled surface is in obvious contrast with the smoothness and polish of the syphilitic tubercle; cancerous tubercles are usually affected with acute lancinating pains, which never occur in the early stages at least of the cheloid tumour; syphilitic, scrofulous and cancerous tubercles almost always end in ulceration, without, for a time at least, spreading superficially. The cheloid tumour extends, but does not ulcerate. Scrofulous tubercles are moreover peculiar to certain constitutions, and are very frequently accompanied with ulcers, cicatrices and other alterations of a strumous nature. Syphilitic tubercles appear under the form of an eruption; the cheloid is very frequently solitary, and it is much more slowly evolved. Vascular nævi and erectile tumours often present pulsations which are never observed in the cheloid tumour; these are besides soft, compressible, and disappear in a great measure under pressure, whereas the cheloid formation is hard and becomes pale, indeed, under the finger, but does not shrink or diminish sensibly in size.

1161. *Prognosis and treatment*.—Cheloid formations do not seem to have any deleterious influence on the general health. The reddish tubercles by which they begin have a constant disposition to extend; but they only increase with extreme slowness and occasionally continue during life altogether stationary. They have even been seen, after attaining a certain size, to shrink and to disappear either in part or wholly, becoming changed into a kind of cicatrice.

I have made but a very few attempts to cure tumours of the description under review. When they are situated over parts such as the sternum, which afford bases for instituting pressure of sufficient amount and permanence, this means appears to me preferable to any other. In one case, in which I recently tried this plan of treatment, the tumour had already decreased considerably, when the patient, feeling little solicitude about the ulterior progress of the affection, demanded his discharge from the hospital.

The excision and cauterization of cheloid tumours in the small number of instances in which one or other of these procedures has been instituted, have been followed by returns of the disease. They are therefore generally left to themselves: the symptoms that accompany them are nowise urgent, and the measures that have hitherto been tried for their cure have proved any thing but uniformly successful.

#### *Historical Notices and particular Cases.*

1162. The cheloid tumour was mentioned by Retz under the strange name of *fatty teller* (*dartre de graisse*).<sup>2</sup> To Alibert we are beholden for the first accurate description of the disease.<sup>3</sup>

CASE CLXXVI.—*Cheloid tumour of the right buttock developed after a burn*. Mousselet, forty-four years of age, presented himself among the out-patients at the Hôpital de la Charité, on the 18th of May, 1834. This man has from his infancy had a tumour upon the right buttock, which he attributes to the effects of a burn. The tumour is of the size of a child's hand, and is shaped very like a crab. In its centre it is formed of bands of a bluish-white colour, which terminate superiorly and inferiorly in prolongations of a very decided reddish cast;

<sup>2</sup> This disease is very extraordinary: I have only met with three cases of it. The epidermis is not affected; it is only of a deep red colour, and is raised by a collection of solid matter, which here occurs in lumps of the size of an apricot, and there in rays the length of the finger, and as thick as macaroni; or the substance appears under the form of flattened and extensive wens, much raised and as broad as one or both hands. These wen-like patches are singularly interlaced with bands of the same substance, of different thicknesses, resembling broad cicatrices, and form several folds and counterfolds as if there were sundry cicatrices placed one on the top or by the side of the other. Retz. Des mal. de la peau, et de celles de l'esprit, p. 55. Paris, 1790.

<sup>3</sup> Alibert. Précis théorique et pratique sur les maladies de la peau, 2 vols. 8vo. Paris, 1810. Art. Cancroïdes, t. i. p. 417. Atlas, pl. 28–28 bis.—Alibert. Monographie des Dermatoses, t. i. Art. Kéloïde. Vallerand de Lafosse, Revue Méd., Oct., 1829.

<sup>1</sup> Alibert, in his Monographie des dermatoses, mentions eight cases of cheloid tumour, six of which occurred among women, two in men. One of these tumours was evolved on the face; a second on the neck; the rest occupied the sternal region.

five of these prolongations are sent off from its upper part in the form of a fork; one of them ends in a small mass of a redder colour, harder consistence, and greater prominence than the rest. The prolongations were lost insensibly in the substance of the skin. The most prominent of them was marked with very distinct transverse striae.

The father of this man is affected with a tumour over the sternum, and his brother has a number of congenital marks upon his breast. He complains of no pain in the tumour, but occasionally of a kind of smarting or pricking sensation. The tumour is evolved on the cicatrice of a burn which is still very apparent in one place. The object of this man's visit to the hospital was not on account of the tumour described, but of a fall which he had had some weeks before. He was bled. He is the father of four children, none of whom are affected with cheloid tumours.

CASE CLXXVII.—*Cheloid tumour, depressed in its centre.* A woman, aged sixty-five, presented herself among the out-patients at the Hôpital de la Charité, in the course of the year 1831, having a cheloid tumour on the fore part of the chest. She says, that at the age of thirty-five years she received a puncture over the middle of the sternum with the point of a knife; that a *spot*, the size of a pea and the seat of troublesome pruritus from time to time, followed this wound. Ten years after the cessation of the menstrual discharge, this pruritus became still more urgent, and the spot began to enlarge. At the present time, twenty-eight years since the receipt of the puncture of the skin covering the sternum, upon the median line and about the level of the third rib, a transverse tumour is perceived, of a whitish colour in its centre, like the cicatrice of a burn, about a quarter of an inch in diameter perpendicularly, by about three inches in diameter transversely. From this central cylindrical production, three red rays or arms, rising about a line above the level of the surrounding integuments, and five lines in length, are sent off with remarkable symmetry, which bear no slight resemblance to the disposition and form of the claws of a river crab.

According to the patient's account, the centre of this cheloid production, now white, and somewhat wrinkled like an old cicatrice, was formerly as red as the radii detached from the tumour. The red colour disappears on pressure. The tumour is painful and itchy.

#### HYPERTROPHY OF THE CORION.

1163. Hypertrophy of the corion or dermis sometimes shows itself externally in the shape of small lenticular tubercles, the colour and consistence of which are very nearly the same as those of the skin that surrounds them. These tubercles are scarcely ever seen among children, but they are not rare among adults and individuals of mature years. They occur most commonly on the upper lip, and on the *alæ nasi*. They are occasionally congenital, and are then frequently surmounted by one or several strong and bristly hairs. They never terminate either in resolution or suppuration, and when they increase in size it is only in the slowest and most gradual manner.

1164. It often happens as one of the consequences of obesity, that the skin in the vicinity of old ulcers, and as an effect of elephantiasis *Arabica*, that the integuments covering the parts affected experience a real hypertrophy, and acquire a mammillated or tuberculated appearance (vide *Elephantiasis Arabum*).

1165. Hypertrophy of the corion and subcutaneous cellular substance may be limited to a single region of the body. This species of structural change occurs more frequently in the nose than in any other part.<sup>1</sup> The affection takes place very slowly and gradually, and most commonly without any evident cause. It generally attacks individuals of mature years. Women appear to be its subjects very rarely. It occurs under three principal forms; in one case the lobes of both *alæ nasi* are affected with hypertrophy simultaneously, accompanied with a notable development of the vascular rete of the skin,

which assumes a vinous red colour; in another instance one or more small tumours of the form and dimensions of the indurations of rosacea, appear upon the *alæ nasi*; in a third instance these two forms of hypertrophy occur combined.

Hypertrophy of the *alæ nasi* extends by degrees towards the root of the organ. The small tumours or indurations that make their appearance on their surface may continue long stationary, and never exceed a small hazelnut in size, or they may attain dimensions much more considerable. Not only do they then deform the features, but they impede the free entrance of the air into the nostrils, and even of food into the mouth. The tumour has a knotty uneven surface externally, and is of a deep red or purple colour, traversed by an infinity of fine tortuous vessels. The various nodules composing the general hypertrophy are often separated from each other by deep fissures. When the affection is of very long standing, the integument of the cheeks sometimes acquires a colour and an appearance similar to that of the enlargement of the nose. The sebaceous follicles are very much developed, and the secretion from them sensibly increased. As the disease advances the enlargement extends in length, hanging down upon the upper lip and over the mouth in one or several lobulated masses. In the aged, the hypertrophied nose occasionally ulcerates superficially in one or several points of its surface.

1166. The hypertrophy now described, although accompanied with a considerable morbid increase of the vascular rete of the skin and subcutaneous cellular membrane, differs in point of structure from the sanguineous erectile tumour. When wounded with a cutting instrument these enlargements bleed profusely, indeed, but their lamellar, hard and dense tissue, which is one of the principal elements in their composition, differs entirely from the open, spongy substance which constitutes the erectile tumour. Both in its external appearance and organization, this alteration of the skin of the nose has still less resemblance to cancer.

1167. Topical blood-letting is an efficient means of checking the progress of this affection. A woman of the name of Bertin, thirty-four years of age, became an out-patient at the Hôpital de la Charité in the month of April, 1827. The point and left side of the nose were enlarged and of a vinous red colour. The redness and swelling disappeared on pressure, and were not accompanied with either heat or pain or itchiness. The affection had commenced with a slight pain in the *alæ nasi* towards the middle of October last, having neither been preceded nor accompanied with any symptom of an inflammatory nature. The red tint of the part affected was most vivid in the morning, at the moment of waking; it declined slightly by and by. It had been temporarily increased by the application of a plaster which had been recommended to the patient, of the composition of which she knows nothing. Several applications of a number of leeches to the orifices of the nostrils subdued the swelling and the redness of the parts materially.

1168. The local abstraction of blood is unavailing when the upper part of the nose has been swollen and injected for several years. Affections of this description, indeed, as they constitute simple deformities rather than troublesome maladies, are not often made the subject of any special treatment. A man, named Mocton, fifty-three years of age, of a sanguine temperament, is the subject of this kind of vascular and incurable hypertrophy of the root of the nose. It is now, April, 1827, nearly five and twenty years since the lobes of the nose began to swell and to present a ruddy violet colour. The size of the base is nearly the double of what it ought to be, and is of a violet hue, which becomes redder under the influence of increased temperature or after indulgence in strong liquors of any kind, a circumstance, however, which does not prevent Mocton from yielding to temptation at very frequent intervals. Cold, on the contrary, renders the tint deeper. The orifices of the cutaneous follicles are extremely open. The nose is unaffected with rosacea.

1169. Patients often seek medical aid, the base of whose nose is surmounted with many cellular and vascular tumours. Civadier, Hey, Dalrymple, and several other surgeons, have removed such tumours with success. Imbert Delonnes<sup>2</sup> removed a tumour of this description, which weighed two pounds, and hung down as low as

the breast of the patient. When such tumours are only attached to the nose by a narrow pedicle, which, however, is not commonly the case, they may be removed with a ligature.<sup>1</sup>

1170. Hypertrophy of the skin of the extremities is even more frequently met with than that of the nose. I once examined the arm of a woman, with M. Reynaud, who had had the right breast removed on account of a cancerous affection of the mammary gland. Subsequently to the operation, the lymphatic glands of the axilla had enlarged, and become scirrhus; the right arm then became œdematous, and the skin of the forearm, hard, grayish, and tuberculated on the surface; it bore a very considerable resemblance to the skin of the leg of the elephant. There was a large ulcer on the back of the hand, at the bottom of which the extensor tendons could be seen; the discharge from this sore had been copious and fetid. Towards the upper and inner part of the arm there was a kind of excrescence which projected nearly half an inch. The surface of this growth was smooth and reddish; a part, into which an incision had been made, was of a dull white; it was traversed by a number of small vessels; its general characters were in all respects those of encephaloid formations, especially of that variety which is often found in the stomach. There were two other tumours of a similar kind, of smaller size, near this principal one. A careful dissection of the skin of the forearm exposed the following particulars: a great number of lobules or nipple-like eminences arose from its surface. The smallest might be regarded as simple papillæ very slightly developed, others were of the size of a large pea, or even of the extremity of the little finger. Those of considerable magnitude were uneven on the surface; secondary mammillary eminences rose from, and gave them something of a mulberry appearance. In the spaces between them there existed a number of orifices, apparently belonging to the cutaneous follicles. An epidermic formation, of a dirty gray colour, and of very considerable thickness, covered them; the outer layers of this rather resembled a kind of scurf deposited irregularly than a proper membrane, and were rubbed off with the greatest ease. When thus removed, the adhering surface exhibited a multitude of elevations, which appeared to bury themselves by their bases, within the spaces between the mammillæ and in the follicular orifices, and represented in exaggerated intaglio and relief the different particulars of the external surface of the skin.

Under this layer there existed another of a dull white, covering the papillæ and nipple-like eminences in a more uniform manner, and adhering to them more intimately; after maceration for a few days, however, this inner layer could be detached with the same facility as the outer one, when it appeared under the guise of a second epidermic lamina, its outer surface being of a dull white; its inner aspect, on the contrary, appearing slightly sprinkled with black, apparently contained in a thin mucous-looking layer, entangling a little dark colouring matter. In some places this remained deposited on the papillæ and nipple-like projections under the form of a layer which was readily removed by scraping.

The numerous elevations which beset the surface of the skin immediately underneath it, now appeared so much the more conspicuous, as the thickened cuticular layers were removed, these having penetrated the spaces between them, and tended to conceal the extent of their relief. The papillæ then appeared under a variety of aspects, according to their size; the smallest consisting of slight simple projections, somewhat flattened, and presenting a faint tinge of black upon their summit, similar to papillæ generally, when slightly enlarged, but forming, especially when seen under water, a kind of nap or pile, extremely similar to that which is observed on the mucous membrane at the commencement of the small intestines, when it is examined under the same circumstances. There were others which did not differ from these, save in being a little less prominent; others again, of a larger size, radiated from a kind of central foot-stalk; to conclude, there were nipple-like projections of small size, and patches of flattened laminae standing side by side, like the leaves of a book, and by their general reunion, composing mammillæ of various magnitudes. The epidermic laminae, of which I have made mention first, did not penetrate between the layers of these composite mammillæ; they merely covered them generally. Divested of their common

covering, and floating in water, as I said before, these elevations bore a strong, though, of course, an exaggerated, resemblance to the foliaceous and ramified villi of the small intestines, when examined with a magnifier under water.

The skin cut through perpendicularly, presented some differences of appearance before and after maceration. Before maceration, the corion, considerably increased in thickness, formed a deep layer, to specify the exact limits of which was easy. Its surface was plain in some places, as the direction of the line, which showed its termination, indicated. In others it was sinuous, and the corion appeared to enter as a constituent part into the composition of the papillæ and mammillary eminences.

Under the corion there was a layer of considerable thickness which in some points was not very distinct, but which in others was easily distinguished by its slightly bluish cast of colour. This layer entered as an element into the organization of the elevations of the skin, and even formed its basis. It was infiltrated with a very considerable quantity of serum, and in the points corresponding to the elevations, and particularly to the larger of these, it was traversed perpendicularly by ramifications of arteries and veins, which expanded on the surface of the papillæ and mammillary eminences. Some of these eminences were of a vivid red, not only on their surface but to a certain depth also. This appearance was destroyed by maceration. When the serous infiltration had flowed out, the corion was seen penetrating into the whole of the elevations.

In this case of hypertrophy of the skin, as well as in many others which I have examined, the inner surface of the skin had nothing of the muscular appearance which Oslander<sup>2</sup> informs us he detected in the skin of the abdomen of several women who had died in child-bed. The corion, the papillary body, the albid and epidermic layers were truly hypertrophied, but the follicles of the skin did not appear to have participated in this anormal development.

#### HYPERTROPHY OF THE SUBCUTANEOUS CELLULAR, AND ADIPOSE TISSUES.

1171. I have met oftener than once with individuals affected with accidental as well as congenital tumours, frequently pyriform and pediculated, varying in their dimensions from the size of an olive to that of a large pear, and consisting of *cellular substance*<sup>3</sup> which the skin, in a perfect state of health, or furnished with a larger number of blood-vessels than usual, covered externally. A man, fifty-one years of age, who died of dropsy in the Hôpital St. Antoine, had a great number of congenital tumours of the above description on different parts of his body. Their size varied between that of a pea and that of a hen's egg. The smallest of these tumours were pediculated; the largest were globular, soft and flaccid. There were several on the face, and some on the extremities; but they were most numerous on the trunk. On incising the smallest of these tumours vertically, the cut was smooth, cellular, without any appearance of vessels; but several were seen in the tumours of a somewhat larger size; and they were so conspicuous in the largest of all that the cut surface became covered with blood; the tumours were also of a livid colour, and by compressing them, numbers of veins swelled up and became extremely conspicuous in their interior. These tumours contained no fat, and their white appearance or bluish cast in those places where they were traversed by veins, distinguished them sufficiently from fatty growths. Of a soft consistency, not creaking under the knife when cut, nor presenting those lines of a dull white, and those bluish veins so uniformly met with in scirrhus tissue, the tumours under consideration were evidently not of this nature. Over the surface of this man's body there were, further, a considerable number of congenital patches, some of a milk-coffee colour, others of the hue of wine lees.

I have since seen a case exactly similar to the above among the

<sup>2</sup> Comment. Gœtting., recent. vol. iv. 1820.

<sup>3</sup> The skin, says Beclard, is sometimes raised by quantities of tumours of different sizes formed of an accidental tissue of a white fibrous aspect, much more compact than the cellular, but softer than the ligamentous. This same formation is also frequently found in polypi, and especially in the submucous tumours of the vagina and vulva. Elem. d'Anat. génér., p. 294, 8vo. Paris, 1823.

<sup>1</sup> Ephem. Nat. Cur. dec. iii. ann. viii. et viiii. Obs. clxxxiv.

patients of my colleague, M. Rullier. Dagorn<sup>1</sup> has given the details of a very remarkable instance of the occurrence of these tumours in a girl eighteen years and a half old, upon whose body there were eight of them, the largest weighing forty-six pounds. After the removal of this mass, it was found to consist of cellular substance, the cells being very much dilated, and filled with transparent serum intermingled with minute yellowish-coloured fatty flocculi. An artery and vein were observed to divide and subdivide in the *interior of the tumour*. The skin which covered it appeared thinner than natural.

1172. P. F. Walter<sup>2</sup> has figured and published a very extraordinary case of *nævus in the form of a tumour*, which differs, among other particulars, from that detailed by Dagorn, in the skin which covered it having been beset with hair, and in having contained a large quantity of adipose substance.

1173. Hypertrophy of the subcutaneous adipose tissues gives rise occasionally to a single, soft, slightly mammillated tumour, generally of a flattened form, unaffected with pulsations and without change of colour of the skin (*loupe graisseuse*); tumours of this description, however, are not always single; they occasionally occur in considerable numbers under the skin of the upper parts of the extremities, which then appear covered with inequalities. I have met with several instances of tumours of this kind occurring without assignable cause in individuals who were by no means very stout. Tumours of this kind have been seen to form in the palm of the hand,<sup>3</sup> the skin of which then experienced a remarkable alteration, analogous to that of a variety of ichthyosis. Lorenz Ruff, fifty-three years of age, had been affected from his infancy with hard knubby protuberances on his hands and feet which had become extremely troublesome from the time he began to labour with his hands. These tumours had increased imperceptibly, and, especially within the last three years, had acquired an enormous size. This man was in other respects strong and healthy, and had never been unwell, save with small-pox and dysentery. The hands and fingers, which were remarkable for their size, were covered on their palmar aspects with large excrescences. The nails looked like talons or spurs. Similar growths occurred on the inner side of the sole of the right foot, from the heel to the great toe; there were also several on the left foot. The tumours were of a grayish-white colour, of the consistence of soft horn, conveying to the touch a sensation similar to that imparted by a mass of warts of different sizes. The larger were surmounted by smaller ones; here they formed isolated clusters; there they were connected by parts projecting in a less degree. Their surface, although dry, was sensible to the slightest touch, and bled with extreme facility; it remained acutely sensitive for several days, when a few of the cuticular squamæ with which it was covered, happened to be rubbed off. Pressure and a blow caused pain. Walking was painful, particularly upon a dry, and hard road; and the patient could not continue it for more than an hour continuously, resting at frequent intervals, in which time he got no farther than another would have accomplished in a quarter of an hour. He required a long time to dress and undress, and the pain he then experienced was extreme. In rainy and windy weather he suffered from intolerable burning and prickling sensations in the diseased parts. The motions of the fingers were greatly impeded; they could not be bent, but the motions in abduction and adduction remained.

Several coloured engravings made from oil paintings add to the accuracy of these details. To the above case Behrends has assimilated that of a girl ten years and a half old, whose fingers were covered at their extremities with horny substances of a yellowish-brown colour, as thick as the finger, and from three-quarters of an inch to an inch and a half in length. The skin upon which they grew was red and painful. This case is related by Ab. Haskel.<sup>4</sup>

## DEGENERATIONS.

1174. The degenerations of the skin include fibrous, cartilaginous, and osseous transformations, melanosis, tubercles and cancer (§ 750).

### FIBROUS DEGENERATIONS.

1175. Under the name of *special tumours of the skin*, M. Velpeau has published a very remarkable case which appears to belong to the class of fibrous degenerations of the skin and subcutaneous cellular membrane; although indeed the spontaneous disappearance of several of these tumours by a process of internal suppuration is not altogether favourable to this opinion.

CASE CLXXVIII.—*Indolent tumours formed at the expense of the skin upon different regions of the body*.<sup>5</sup> On the 14th of July, a man, thirty-five years of age and well formed, presented himself for advice, on account of about a dozen tumours of a particular description formed at the expense of the dermis, and disseminated over different parts of the body—the face, neck, breast, crista ili, the thigh, the flank, &c. It is now above thirty years since the first of these tumours made its appearance. Many others have been evolved at different times, and have been discussed by the use of various topical applications. These tumours are slightly flattened and elongated; they are generally about the size of the point of the thumb; they appear to be covered by the cuticle; their surface is rough and uneven; their colour is very similar to that of the skin at large; they may be squeezed pretty strongly without the patient complaining of pain; in a word, all their external characters proclaim them to be of a fibrous nature.

There is one, however, which differs from the rest in several particulars. This is situated on the outer aspect of the right lumbar region. It is shaped like a mushroom or fungus, very much compressed, being one inch in thickness and above four inches in breadth. Its pedicle, which is extremely short, is three inches in circumference. The skin on the inner or under surface of the tumour is natural in colour, &c.; that which covers its outer aspect is, on the contrary, of a redish gray tint, soft, fungous in appearance, and discharging a little watery fluid of a bitter-sweet and very disagreeable odour. During the last three months, and since it has been exuding this fluid, it has been readily made to bleed, and the pressure of the body when the patient lies down makes it painful; it is in fact on this account that the patient has been induced to seek for medical assistance.

The tumour in question was removed in presence of M. Roux, by M. Berard, on the 11th of July. The operation was followed by no particular consequences, except that the whole of the other tumours which existed in different parts of the body softened and disappeared entirely, whilst the wound was cicatrizing. The whole became the seat of small abscesses before disappearing; and the patient informed us that the same thing had happened with the same circumstances several times before. This fact appeared to us the more worthy of remark, from the tissue composing the one which had been removed not being of a nature that usually falls into suppuration. It evidently consists of a degeneration of the outer laminae of the skin, which are nearly of the hardness of scirrhus, but differing from this in its want of homogeneousness, in the granular aspect of its cut surface, and in several other particulars. Words would convey but an imperfect idea of its structure, and we know of no object to which it can be compared. Let us only say that it could not be assimilated to the scirrhus, the fungous, nor to those degenerations that are simply fibrous; neither did it resemble any species of cancerous degeneration; nor, in fine, was it precisely similar to any of the kinds of morbid tissue described by pathologists. It appeared as if constituted by the dermis very much expanded (*rarifié*) in two thirds of its thickness, and intimately blended with an infinity of granules of a concrete cheesy matter. In our opinion, it forms a new, perfectly distinct, and yet undescribed variety of morbid production.

With the above case I connect provisionally the following one,

<sup>5</sup> Velpeau. *Arch. gén. de méd.*, t. xii. p. 511.

which in the first edition of this work, I had associated with my account of the *molluscum* of Bateman.<sup>1</sup>

CASE CLXXIX.—*Small, solid, flattened tumours of the face, trunk, and extremities.* A locksmith, fifty years of age, of a sanguine temperament, married, the father of a healthy family, and never having had syphilis, exhibited (in the year 1824) all the appearances of *molluscum*. The disease had begun on the forehead by a small tumour rather larger than a shilling, and gradually extended till its base was more than an inch in diameter, projecting so much as to annoy the patient when he put on his hat. He had had this tumour tied; but whether the ligature had not acted to a sufficient depth, or had been inadequately applied, the tumour reappeared, and several others of the same characters were evolved on different parts of the body.

The skin, at the expense of which these tumours were formed, was soft and movable over the subjacent parts. The tumours were not painful when handled. They were hard, and generally red, but became paler and somewhat shriveled under the action of cold. The right cheek was beset by about a dozen of broad, flattened, whitish tumours, separated by narrow intervals, and projecting from the surface of the skin, in a manner similar to the wheals of urticaria. On the neck, several lenticular tumours were perceived. Several were also observed on the forepart of the chest and abdomen, particularly on the right side. The left side of the trunk, and the left arm, presented but a very small number of these tumours. The right upper extremity, on the contrary, was beset with a great number of them, of an oval or irregular shape, hard consistence, deep red colour, and very much raised above the level of the skin. The lower extremities, especially the legs, were covered with similar excrescences. Their bases here were broader, they were also more closely set, and appeared to form slightly mammillated bands. The principal functions of the body were perfectly regular. He was put upon a course of laxatives and baths for about two months, but without success.

## MELANOSIS.

1176. Melanosis may appear deposited in *grains* within the substance of the skin, or may form true tumours in its substance or upon its surface. Deposits of the same description almost always take place at the same time, in one or more of the internal organs.

1177. The skin is occasionally beset with a considerable quantity of small spherical tumours, many of which are of the size, of the colour, and have even the lustre of black currants or juniper berries. They are black throughout, and, when cut through, present a great resemblance to the parenchyma of the truffle. According to Breschet, these small tumours appear occasionally to spring from the tissue of Malpighi. When melanosis shows itself in this way on the skin, a matter, similar in all respects, is generally deposited in several other organs and tissues of the body. A. Gautier, cook, aged fifty-nine, of fair constitution, entered the Hôpital St. Louis, Aug. 27th, 1816, on account of a disease which had appeared about two months previously, after violent grief. The complaint had begun with such feelings of general lassitude that the patient could not stand; she felt at the same time benumbed over her whole body, and a few days afterwards, she was obliged to betake herself to her bed. She soon lost her appetite, got no sleep, and was then attacked with diarrhoea and vomiting. A number of small tumours now appeared in the substance of the skin on different parts of the body. On her entrance into the hospital, Gautier was in the following state: a great number of tumours, of the form, and particularly of the colour of *black currants*, were scattered over the anterior part of the thorax. The spaces between several of them in this situation were dotted with minute red points, very similar to flea-bites. Over the breasts, the little black tumours were so much crowded that they formed a broad patch. Several of the same tumours of a larger size were also seen upon the abdomen; some of them were here two inches in circumference. The arms and thighs were also the seat of several, especially on their inner aspects; the forearms and legs were unaffected. The patient was in an extreme

state of debility; her appetite was gone; she vomited the small quantity of food she swallowed; she got no sleep; her bowels were relaxed; the breathing was laborious; she was tormented with frequent cough; the pulse was extremely soft and very compressible. The symptoms went on increasing in severity for some days, and were speedily aggravated by the occurrence of general œdema, which, by giving a white look to the skin, caused the black colour of the tumours to appear even stronger than before. The patient died on the 25th of September.

*Sectio cadaveris.*—The black tumours with which the skin was covered when cut into, presented a homogeneous substance of a black colour, of different degrees of intensity, and varying consistency, being in one of considerable hardness, in another almost pulpy. This substance, which was always enveloped in a cyst of cellular substance, had all the characters of the production which has been described under the name of melanosis. Tumours of the same description were found in the subcutaneous cellular tissue almost of every part examined; they were not, however, nearly so numerous in the extremities as on the trunk, and especially within the abdominal parietes; they were also less regularly rounded and softer than in this situation. The cellular substance which surrounds the blood-vessels, nerves, and lymphatic glands, was literally loaded with them. They there formed by their agglomeration masses of the size of the fist. The nerves were still healthy, but the vessels were so intimately blended with the black depositions, that they could not be separated from them without being torn. In the substance of the thyroid gland melanotic tumours, perfectly distinct from the lobules of the gland, were detected. The lungs, the general colour of which was rosy, contained a few of these tumours of small size; towards their base, and below the bronchial glands, many more were discovered, but of much larger size; the bronchial glands themselves were not black. In the mediastinum, and under the costal pleura, melanic tumours were also found, the size of which varied from that of a filbert to that of a walnut. These tumours were accumulated in great numbers in the epiploa and mesentery; the duplicatures of these membranes were, so to speak, crammed with them. They were here smaller than common, the largest of them not exceeding a cherry-stone in size. Several were met with around the whole of the organs contained in the cavity of the abdomen, none of which appeared diseased, except the liver, which was greasy, and the gall-bladder, which contained five or six of the melanic tumours in its parietes. The heart and the brain were healthy; the bones were not more brittle than usual.<sup>2</sup>

1178. Simple or compound melanic tumours constitute a third very remarkable kind of organic alteration. M. Ollivier d'Angers and I once dissected a melanic tumour which had been evolved on the sole of the foot in an adult; it was of a brownish colour, very similar to that of the truffle, nearly two inches in length, and rose about a line above the level of the skin that surrounded it. In dissecting this tumour, we found that it was formed at the expense of the skin, which was altered, and impregnated with black matter. On the outer surface of this tumour several small white patches were discovered, three, four or five lines in diameter, which were nothing more than isolated pieces of epidermis. Viewed on its inner side, by which it was in relation with the subcutaneous cellular membrane, the skin presented a pretty uniform, bistry tint; the line of demarcation between the healthy and diseased skin is very distinct. The tumour was formed by the skin, become thicker and softer than natural, fungiform and black. No vessels, no scirrhous tissue, no cerebriform matter could be detected in this tissue, and the matter which coloured the altered skin adhered to it so intimately that it could not be squeezed out of it by pressure. The subcutaneous cellular tissue, the bones and the structures that covered them, were perfectly healthy; the skin alone was affected, and no other melanic alterations were discovered in the whole of the body.

1179. Under the name of *anthracine cancer*, M. Jurine has described a kind of tumour of a more complicated structure, and composed of the accidental tissues proper to cancer and of melanosis united.

Melanic tumours rarely inflame. Messrs. Breschet<sup>3</sup> and Ferrus

<sup>1</sup> Under the title of *molluscum*, Bateman describes globular sessile or pedunculated tubercles, containing ætheromatous matter; this is an affection of which I shall speak when I come to discuss the diseases of the follicles.

<sup>2</sup> Laennec. *Auscult. Méd.*, 2ème édit., t. ii. p. 38.

<sup>3</sup> Breschet (G.). *Considérations sur une altération organique appelé dégénère.*

have, however, met with *ulcerated* melanosis, several inches in extent, and situated in the right groin, in an old woman at the Salpêtrière. This sore discharged a kind of blackish fluid which stained paper and linen in the same manner as bistre, rather than proper pus.

1180. It is always advisable to remove melanic tumours as speedily as possible, whether they be simple or compound, provided they be few in number and are developed upon a region of the body where they are exposed to be bruised or otherwise injured by pressure, &c., which always hastens their progress and causes them to increase in size. In any other cases the operation may be indefinitely deferred. When melanosis appears on the skin under the form of an eruption, it is always the evidence of a diathesis against which no effectual remedy has yet been discovered.

#### *Historical Notices and particular Cases.*

1181. M. Alibert has published a very remarkable case of cutaneous melanic tubercles with deposition of melanic matter in the epiploa, the mesentery, &c.<sup>1</sup> M. Breschet has seen a melanic ulcer of the skin. M. Cruveilhier has published a remarkable instance of melanic tumour on the back and on the palm of the hand. Drs. Cullen and Carswell<sup>2</sup> have reprinted this case, and have given several others of the disease. Mr. Fawcington<sup>3</sup> has detailed a case of melanic diathesis in which the skin itself was affected. Before any of these cases were made public, however, Dupuytren and Laennec had both directed attention to melanosis, and given a complete exposition of its characters. It was next studied in a general manner by M. Breschet, who pointed out the particulars of its diagnosis from accidental formations; by Noack,<sup>4</sup> whose learned dissertation deserves to be particularly consulted; by MM. Leblanc and Trousseau,<sup>5</sup> who have made many researches on the horse, and who consider melanosis as an accidental or new tissue; by Albers,<sup>6</sup> who has published a curious case of abdominal tumour composed of fat, melanic matter, and blood. I have, in a preceding part of this work, (§ 756,) given several cases which show that certain melanic tumours bear a strong analogy to cancer in many particulars.

CASE CLXXX.—*Melanic tumour of the forehead; melanic grains of the skin of the abdomen, &c.; death.* M \* \* \*, forty-nine years of age, tall, and of a spare habit, very excitable, possessing distinguished talents, passionately fond of music, and whose life had been very stormy, had not menstruated for a year, when Dr. Caballenas, her ordinary medical attendant, called me into consultation in the course of the month of August, 1834. Ten years ago a small blackish tumour had been removed from the right breast of this lady. The wound had been cauterized with arsenical paste, and a course of decoction of sarsaparilla administered. In 1832, a small blackish tumour, similar to the former one, and which appeared on the right side of the forehead, was also removed with the knife; but shortly after the operation, the cicatrice became possessed by a tumour of the same description as that which had been taken away, surpassing it in size in the course of a few months. Several other blackish points at the same time made their appearance, scattered over the face and the rest of the body, and since this time additional crops have been evolved. The lady had for some time complained of pain about the region of the liver; œdema had once occurred in the lower extremities, and since the invasion of cholera, she had been affected with diarrhœa and constipation alternately. During the whole of the winter of 1833-1834, this lady gave herself up with the greatest ardour to study, sitting up late, living on stimulating diet, taking coffee largely, and even using

scence noire, mélanose, etc., 8vo. Paris, 1821.—Lécat also speaks vaguely of an ulcer which poured out a black matter. *Traité de la couleur de la peau humaine*, 8vo. (Amsterdam, 1767, p. 50.) Cruveilhier, *Anat. Pathol.*, has figured an ulcerated melanic tumour.

spirituous liquors all the while. This affected her general health, and in the spring of 1834, she was obliged to alter her whole plan of life; she also took gelatinous and alkaline baths. The pain about the liver now returned; she became affected with cough, and for several days striæ of blood were observed in the expectoration. Some days afterwards she was attacked with hæmoptysis, the quantity of blood lost being estimated at three ounces. She was bled to six ounces from the arm. The hæmoptysis did not recur, but the cough, the oppression of breathing, night sweats and diarrhœa, which had preceded it, continued. In the middle of August, the oppression of the chest was excessive and constant; a mucous rattle was heard especially in the posterior parts of the chest; the pulse was hard and frequent. Six ounces of blood taken from a vein presented a buffy coat a line in thickness. The oppression went on increasing; the pain in the liver gained in intensity, the patient became drowsy, and died on the 1st of September.

The body was examined twenty-four hours after death. The emaciation was extreme. The melanic tumour of the forehead, divided lengthwise, presented the same colour as a truffle; several small tubercles, situated within the substance of the skin, or in the subcutaneous cellular substance of the trunk and extremities, were composed of pure matter of melanosis.

In the substance of the vastus externus muscle of the thigh, there was a melanic tumour the size of a child's finger. The head was not opened. On the exterior surface of both lungs, especially of the right one, there were a considerable number of melanic tubercles. In the interior of both lungs a few small encephaloid masses were discovered as large as a hazelnut. In the right lung there was one tumour, the size of a chestnut, formed of encephaloid and melanic matter combined, several other smaller tumours in this and the opposite lung presented the same amalgamation. There was further a quantity of tubercular matter deposited in the summits of both lungs, and that of the right lung presented more than one small cavity. We also discovered several small deposits of pure or mingled cerebriform matter in the substance of the heart. *Abdomen.*—Similar alterations of structure were found in the liver, in the tissue of which there were numerous masses of pure encephalic matter, or of this mixed with melanosis; the largest of these did not exceed an olive in dimensions. A considerable number of melanic granules were scattered among the epiploa, the ovaries, and the kidneys. The supra-renal capsules exhibited a small collection of pulaceous melanic matter. The spleen, stomach, uterus, and bladder were healthy.

#### TUBERCULAR MATTER.

1182. I have never observed a deposit of tubercular matter within the substance of the skin, but the following passage of Laennec deserves to be quoted: "It is nearly twenty years ago," says he, "that in examining several vertebræ, in which tubercular matter had been deposited, I grazed the forefinger of my left hand with the teeth of the saw. I paid no attention to the circumstance at the time. But next day the scratch was surrounded with an erythematous blush, and there was slowly formed a small rounded, compressed tumour, which, by the end of a week, had acquired the dimensions of a cherry stone, appearing to be situated within the substance of the skin. At this time the skin gave way in the point where it had been touched by the saw, and exposed a small firm yellowish body, precisely similar to a tubercle of an ochrey-yellow colour. I touched the part with deliquescent hydrochlorate of antimony. This caused very little pain, and in a few minutes after the caustic had penetrated the whole of the tumour, I detached it with a slight degree of pressure. The action of the caustic had softened it to such a degree as to make it look exactly like a softened tubercle, of friable consistence. The place from which it had been turned out resembled a kind of cyst, the parietes of which were of a pearl-gray colour, translucent, and without redness. I applied the caustic again. The wound soon cicatrized, and I never felt any ill effects from this accident."

With this case I shall connect an abstract of one related by Dr.

<sup>7</sup> Laennec. *Traité de l'auscultation médiate et des maladies des poumons et du cœur*, 2d edit., t. 1, p. 649.

Crampton;<sup>1</sup> John Byrne, aged fifty-six, came into the hospital complaining of rheumatism. He was soon found to be phthisical. The skin of this man's body and limbs was covered with broad brownish or olive-coloured patches of different dimensions; the skin in the spaces between these was pale and sallow. A number of tubercles of the same hue as the spots, were seen scattered among them. Several of these tubercles were about half an inch in breadth, and an inch in length, and soft to the touch; others of the size of a split pea, resembled papulæ, and others, of a pyramidal shape, were connected with the skin by slender but strong pedicles. These last felt as hard as cartilage. On the surface of the broad soft tubercles, small, hard, and prominent nuclei could be detected both with the eye and the finger. Byrne had enjoyed good health till the year before he came into the hospital. Yet it is five years past since the alteration of the skin described, first made its appearance; to this, however, the patient had paid little attention, as he suffered no inconvenience from it. He was filthy in his person, and given to drinking spirits. He entered the hospital in February, and died in August, of phthisis.

On examining the body after death, the brown blotches had disappeared, or rather, they were lost in the general dark hue of the integuments. The tubercles of the skin had undergone no change. Those of a round or oval shape were composed of a caseous or gelatinous-looking substance, penetrated the corion, and extended amidst the subjacent cellular substance. This stuff was dissolved by the water in which pieces of the skin were put to macerate. The pyramidal tubercles again did not penetrate the corion; they were composed of a white and very consistent fibro-cartilaginous looking substance, without any appearance of blood-vessels. Some of these cartilaginous tubercles contained a glairy matter. The broader and softer tubercles bore a considerable resemblance to subcutaneous scrofulous tubercles; but they had neither the redness, nor were they affected with the slight pain which so commonly accompanies deposits of the above description. The round and oval tubercles were of the consistence of cheese.

The lungs contained tubercles in different states; the upper lobes exhibited several cavities and softened tubercles. At the bottom of the lungs the tubercles were small and hard. The heart was very small. The liver small, hard, and of a deep colour, presented the tubercula diffusa of Dr. Farre. The spleen was also tubercular. The mucous membrane of the intestinal canal was red, and exhibited several slight ulcers, having the characters of those found in the bodies of individuals who die consumptive.

This instance of complex degeneration of the skin, into which tubercular matter appears to have entered largely, is very remarkable.

### SPECIAL DISEASES OF THE SEBACEOUS FOLLICLES.

1183. The sebaceous follicles of the skin are liable to a variety of affections. They sometimes appear under the form of small pearly elevations, in consequence of having undergone a truly fibrous or cellular transformation, occasioned by inflammation of the skin (after *impetigo*, the application of *blisters*, &c.). Their secretion maybe increased in a very remarkable manner; their secretion altered in a greater or less degree, may be pent up within their cavities, and give rise to *grubs* or *worms* in the skin, and to *follicular swellings*, or *tumours*; they have also been seen to become morbidly developed over tumours regarded as cancerous,<sup>2</sup> and under various other circumstances.

#### INCREASE OF THE SEBACEOUS SECRETION OF THE SKIN—[STEARRHŒA].

1184. The skin is known to pour out an oily or unctuous matter, which Mr. Cruikshank procured in the form of plates, by wearing a

woolen waistcoat night and day next his skin for a month, during the hottest season of the year. This substance, rubbed upon paper, stained it like grease; it burned with a white flame and left a residuum of charcoal. I designate the morbid increase of this secretion by the title of *sebaceous flux*.

*Symptoms.*—Although this affection may occur in any part of the body, it is most frequently seen upon the nose, the eyebrows, and the hairy scalp, situations in which the natural secretion of the sebaceous follicles is always most abundant. It is generally confined to one of these regions, but in some rare cases it has been seen extending to almost the whole surface of the body. There are at all events two very different degrees of the affection. In the one, the finger passed over the surface of the affected skin, feels it unctuous and soft; and when the parts are covered with hair, the oleaginous matter, in concreting, forms a kind of brownish incrustation, which I have frequently observed in the eyebrows, and at the roots of the hair of the head. Even in those parts where the sebaceous matter is poured out in greatest profusion, the skin does not appear either red or sensibly altered; the orifices of the follicles are not even more apparent than usual. Patients, however, frequently complain of a kind of tingling, and sometimes of positive pain in the part affected; although I have also met with patients, especially young women, who assured me that they suffered no other inconvenience than the necessity of wiping their nose, forehead, or eyebrows very frequently when these were the parts affected, in order to prevent the accumulation of the unctuous matter, the appearance of which was extremely unpleasant. The loss of the hair of the parts affected is a very frequent accompaniment of this first degree of the morbid increase of the sebaceous secretion.

Another and rarer form of this affection [*ichthyosis sebacea*] appears with the following characters, most commonly on the face. The skin of the cheeks, nose, or eyebrows, appears covered with a kind of yellowish scurf, nearly of the colour and consistence of the cerumen of the ears. The skin looks thickened and unctuous around this deposit, which in some points is moist and oily, and in others of the consistence of yellow wax. The surface of the deposit is traversed in different directions by shallow lines which mark it out into a multitude of little compartments; when several of these are detached accidentally, or are removed with the assistance of the douche of watery vapour, softening cataplasms, &c., the skin is exposed, usually of a brighter red than it is naturally, and almost always, as it were, riddled by a multitude of small holes, which are nothing else than the orifices of the follicles dilated, and many of them still filled with sebaceous matter. Some hours afterwards, the skin thus cleansed, will be found to have become unctuous; and it is always, before long, covered with a fresh coating of scurf that acquires the same appearance as the first.

Patients, under these circumstances, almost always experience painful shootings in the parts of the skin affected, and these I have had described to me as so violent, that I should sometimes have been inclined to hold the statements as exaggerated, had I not had their accuracy confirmed by numerous observations of a similar kind. (a)

(a) Respecting the anatomical lesions in this disease, Mr. E. Wilson says:—"In an instance of this affection which fell under my observation about ten years since, I had the opportunity of examining the skin after the death of the patient from visceral disease. In this case, the scales were remarkable for their thickness; after being well washed, they were grayish in colour upon the surface, but white beneath, and evidently consisted of concreted sebaceous substance. On removing a portion of the epidermis by maceration, the ducts of the sebaceous glands and hair follicles were found distended with inspissated white secretion, and had a very beautiful and brilliant appearance, projecting like cones of pearl from the under surface of the membrane. The dermis presented a number of small deep pits, corresponding with these dilated ducts. The mouths of the distended excretory ducts opened upon the surface of the epidermis, some immediately beneath, and in the middle of the scales, and others by their borders. In the former situation, they could be seen as small

<sup>1</sup> Crampton (J.). Case of tubercular affection of the skin.—Trans. of the Association of Fellows and Licentiates, etc., in Ireland, vol. v.

<sup>2</sup> Weber (L. H.). Obs. sur l'épiderme, les follicules cutanés, l'accroissement du

volume de ces derniers organes dans les tumeurs cancéreuses et les poils chez l'homme. (Journ. complém. des sc. méd., t. xxix. p. 138.)

Morbid increase of the sebaceous secretion very rarely ends spontaneously; I have, however, met with instances of spontaneous cure among young females in whom the affection had appeared with the mildest characters possible. In every case, even when treated with the greatest care and skill, this affection is very obstinate, and always lasts for a very long time,—many months, and sometimes even several years. It is also very apt to recur upon parts which have already been its seat.

1186. *Causes*.—I am not aware whether any proper flux of sebaceous matter has ever been observed among infants. Adults, and individuals arrived at maturity of years, are the general subjects of the affection. Women are more frequently attacked with it than men. It is rather a rare disease. Several individuals who have laboured under it, have, as I know, suffered from rheumatism; others experience pains which appear to be of a rheumatic nature, in parts in the neighbourhood of the seat of the flux. I have never observed the affection occurring at the same time as rosacea, nor succeeding it. The affection is not contagious.

1187. *Diagnosis*.—The morbid secretion of the sebaceous follicles that merely keeps the skin oily without drying or concreting on its surface, cannot be confounded with any other affection. But when the sebaceous exudation forms a yellowish checkered layer over the surface of the skin, the appearance of which is intermediate between that of squamæ and of incrustations, it is very possible, without minute attention, to mistake this affection of the sebaceous follicles for ichthyosis,<sup>1</sup> with eczema fallen into the squamous state, with pityriasis and chloasma. With regard to ichthyosis, it is enough to remember that it is almost always a congenital affection, generally extending in various degrees to almost the whole surface of the body, but always occurring in extremes lightness upon the face, without redness or pain of the skin, which is not unctuous to the touch, and in which the orifices of the sebaceous follicles are never conspicuous. Eczema, in the squamous state, (§ 348,) is always preceded by a serous exudation

white points through the scale, and still more evidently when the epidermis was separated by maceration.

“From the careful examination of this case, of which a preparation is now before me, and of other cases which I have subsequently observed, I have been led to the conclusion, that the scales, in this disorder, increase in thickness in two ways, first, by additions to the free surface, by means of the secretion poured out in the linear furrows of the skin, and, consequently, between the scales; and secondly, by additions successively made to the attached surface by the effusion of inspissated secretion beneath them. In the preparation before me, the growth of the scales by both of these processes is distinctly evident.”

<sup>1</sup> The two following cases related by Bateman and Thomson as examples of ichthyosis of the face, appear to me to be instances of sebaceous concretion upon the surface of the skin. One of them is remarkable in a therapeutical point of view, and should encourage practitioners in similar cases to persevere with the decoct. of *rumex acutus* and the application of blisters over the parts affected. Bateman, after stating that the face is rarely the seat of ichthyosis, tells us that he nevertheless met with one young lady whose face was affected with this disease. A large patch covered both cheeks and met on the upper lip under the nose. A drawing is given of the appearance in pl. xviii. of Bateman's Atlas. Dr. Thomson met with a similar case which he showed to Bateman. The patient was about fifteen years of age when the affection made its appearance (1810). The first symptom was a scurfy appearance of the cheeks; this was easily removed by the use of soap and water; two years later (1812) this scurf increased in quantity and began to adhere more firmly. By and by it was so considerable that the patient consulted D. J. Gregory, of Edinburgh. By the use of stimulating applications the skin was cleansed in ten days; but the improvement was merely transitory; the affection reappeared. Chalybeates, aloes, mercury to the extent of salivation, hot sea-water baths, the forcible removal of the incrustation by shaving or scraping, the action of an ointment composed of subcarbonate of soda, spirit of turpentine, sugar and basilicon, a wash of corrosive sublimate, and various other means were tried, but fruitlessly, to cleanse the skin during a succession of three or four years. It was at this time that the patient went to London for advice. The eruption now extended over both cheeks and met under the nose; it was of a dirty olive-brown colour, and disfigured the face greatly, which was naturally handsome. The skin of the affected regions was as hard and rough as shagreen. Under Dr. Bateman's care the patient took pitch pills, external and internal remedies, without any advantage, during six months. She then came under Dr. Thomson's care, who, after trying a great number of remedies, was so happy as to see the disease yield to a decoction of the root of the *rumex acutus* taken internally. The disease returned on leaving off this medicine several times, but always yielded to it. Suspecting that the constant return of the disease was owing to a vicious action of the skin become habitual, Dr. Thomson applied a blister to the part, immediately after which the affection vanished to recur no more. (Bateman. A Pract. Synopsis, &c., 7th edit. p. 80, 8vo. Lond., 1829.)

which has raised or impregnated the cuticle, whilst sebaceous deposits are spread over the outer surface of this membrane. The *furfuræ* of pityriasis *rubra* cannot be confounded with the laminated incrustations of a sebaceous deposit. Chloasma, in point of colour, bears a stronger resemblance to the sebaceous deposit under review than any other form of cutaneous affection, especially when the sebaceous layer is extremely thin, dry and partially detached; still they are distinguished by very numerous points of dissimilarity (§ 1070).

1188. From this sebaceous concretion on the skin of adults it is necessary to distinguish the whitish unctuous and cheesy deposit occasionally observed on the bodies of new-born infants. This is known to be most abundant on the groins and axillæ, behind the ears, on the scalp, wherever, in short, the sebaceous follicles are most numerous; but the deposit in this case is natural and unaccompanied with pain. We have been recommended to leave this deposit of new-born infants undisturbed, and especially to respect the kind of cap which it forms by drying a few days after birth over the surface of the scalp. The propriety of such a caution appears to me so much the more questionable as all infants are not born with this kind of covering, and as I have never observed any ill effects follow its removal, when the infants were well protected against cold and damp. The scurf of the scalp left to itself increases in thickness, becomes matted with the hair as it grows, dries, splits, and is subsequently partially detached in scales or fragments. Whatever the thickness of the crust, it may always be got rid of by the use of tepid lotions, emollient poultices, and slight friction. The head of the child when cleansed ought to be covered for some days afterwards a little more carefully than before.

1189. *Prognosis and treatment*.—I have seen sebaceous incrustation of the nose, cheeks, and hairy scalp, accompanied with, or followed by, the loss of a large quantity of the hair of the head and eyebrows, continue in spite of the use of the vapour douche and purgative medicines, for such a length of time, that it became at length impossible to assign any probable limits to the duration of the malady. Of all the means recommended for the cure of the complaint, the vapour douche is, notwithstanding, the most efficacious. I have also made use, at least with temporary advantage, of lotions of the sulphate of alumen. I have tried saturnine lotions, but without marked benefit, as well as decoctions of nut galls and bistort-root, infusions of the *rosa gallica*, &c. It is generally advisable to prescribe purgatives at the same time that the vapour bath is employed externally.

#### *Historical Notices and particular Cases.*

1190. The morbid increase of the sebaceous secretion was described in the first edition of this work; it has since been spoken of under the name of acne sebacea. I have already had occasion to say that Bateman and Dr. A. T. Thomson have given two cases of the affection under the title of *ichthyosis of the face*.

CASE CLXXXI.—*Morbid secretion of the sebaceous follicles of the nose; thick concretion*.—A young woman, aged twenty-six, of weakly constitution, menstruating irregularly, perceived, about the beginning of the summer of 1825, that the alæ of the nose, and neighbouring parts, discharged incessantly a yellowish oily fluid, which was deposited on the surface, under the form of little worms. It was easy to see that these worms were nothing else than the sebaceous matter of the follicles, which was renewed as fast as it was taken away. The matter secreted accumulated gradually, became hardened, and formed thick unctuous laminæ, which could be removed without difficulty, and without causing any pain. Under them the orifices of the sebaceous follicles were more conspicuous, and much larger, than they are naturally. The principal functions of the body were regular. The slight affection mentioned, required two months of treatment by the vapour bath.

CASE CLXXXII.—*Morbid secretion of the sebaceous follicles, unctuous and ceruminous-looking deposit upon the skin of the face and scalp; partial baldness*.—In the month of August, 1826, I saw a woman, of the name of Gouette, thirty-two years of age, labouring under a disease of the sebaceous follicles of the face. She had suffered from various illnesses in the earlier part of her life, and about eighteen months previously to the above date, had had first one, and at differ-

ent intervals subsequently, two other paralytic attacks of the left side of the face. She is now at times slightly deranged.

The affection of the sebaceous follicles began in June, 1825, and had never been treated upon any particular plan. In August, 1826, the disease occupied the face and scalp exclusively. These parts are covered with a brownish-yellow and unctuous incrustation, very similar to the cerumen of the ears, which extends over the middle of the forehead, and from the ridge of the nose over both cheeks, the left especially. It is lamellar, and composed of small compartments two or three lines in diameter, in contact by their corresponding edges, which are slightly raised and whitish. The integument underneath the incrustation is healthy in appearance, presenting no trace of inflammation. On the left cheek the component laminae are thicker, more numerous, smaller, and separated by lines which traverse their whole thickness. Several parts of the skin, from which this incrustation has been detached, are covered with furfuraceous squamæ. On the right cheek the incrustation is less continuous, the laminae composing it are thinner, and the skin over a space about an inch in breadth, presents a slight erythematous blush. The thickness of the laminae of the incrustation varies on all these different places, from a sixth or an eighth to a quarter or half a line. The compartments appear to adhere to the skin closely everywhere except on the forehead, where they are loosened and somewhat raised at their edges. The pieces of incrustation are larger and thicker on the surface of the scalp generally than elsewhere; on the upper and posterior parts of the head, however, they are small, dry, and furfuraceous in appearance. The left lateral part of the sinciput is bald over a space as large as the palm of the hand. On no part of the affected surface is any thing like a pustule, papula, or vesicle, to be discovered. The unctuous incrustation is plainly due to an increased secretion of the sebaceous follicles. The parts affected are the seat of an habitual smarting sensation. On the 7th of September, 1826, the patient experienced, at five different times, the following sensations, which she designated by the title of attacks: in the left cheek and temple she first felt severe painful twinges; some seconds afterwards, very violent contractions occurred in the cheek, which lasted five or six minutes, and were followed by quivering or trembling in the muscles of the face. The patient did not lose her consciousness, and the intervals between each attack were nearly of ten minutes' duration. I had made up my mind to combat the symptoms of the cutaneous affection by means of the vapour-bath, when I ceased to perform the medical duties of the hospital.

CASE CLXXXIII.—*Morbid secretion of the follicles of the left eyebrow and forehead.*—I had once a girl of eighteen, of sanguine temperament and enjoying habitual good health, under my care, on account of a morbid affection of the sebaceous follicles of the left eyebrow and neighbouring part of the forehead. An unctuous, thin and uneven stratum of a yellowish-coloured substance, like the cerumen of the ears, was spread over the affected parts, which were neither red nor tumefied. This incrustation, which had formed about two months before I first saw the patient, without known cause, was undoubtedly the effect of an exudation from the sebaceous follicles of the skin. Fifteen vapour-baths caused this incrustation to be detached, and it was not reproduced.

CASE CLXXXIV.—*Morbid secretion of the sebaceous follicles; ceruminous deposits on the forehead, scalp, abdomen and extremities.* A woman, twenty-six years of age, the mother of several children, had suffered much from grief, and her catamenia had become irregular. She felt a kind of numbness in her arms, and experienced some difficulty in performing certain motions. Soon after this she was attacked with a disease in the sebaceous follicles. When the alæ nasi are compressed, the follicles of which are extremely apparent, numerous filiform and yellowish-coloured bodies are forced out, consisting of an unctuous matter, rather less consistent than the sebaceous fluid generally is. These bodies wiped away, the follicles were very speedily filled again. The forehead and scalp, the cheeks and abdomen, the breast and thighs, were entirely covered with this unctuous matter, which there formed a thick yellowish layer, of the consistence of the yellow wax or cerumen of the ears, and divided into an infinity of small triangular and quadrilateral compartments, which gave the deposit an appearance of being composed of squamæ;

but the epidermis had no share in the formation of the incrustation, which could be readily removed without pain to the patient, when the skin it concealed was found to be healthy, but shining and unctuous. The part thus denuded was speedily covered anew with unctuous matter, which smelt like rancid oil. The hands were also completely concealed by this substance, which on them was harder, browner and less shining, by which it acquired a still greater resemblance to squamæ, although the epidermis situated under it was healthy. The vapour bath, used every other day for two months, effected the partial detachment of these ceruminous plates. But a yellowish oily fluid, abundantly secreted by the follicles affected, gave occasion to the speedy reproduction of the ceruminous-looking matter. The vapour bath was again tried during three months at different times. The hands and fingers, which could not previously be moved without great suffering, became freer. The incrustation of the face, in part detached, was no longer renewed, though the skin still continued shining and unctuous in appearance,—the sebaceous matter was not now secreted in such quantity as to harden and form a stratum upon the surface. The abdomen, breast and thighs were almost entirely freed from the deposit; but it still continued to adhere to the hairy scalp. The hair was clipped short, and by and by the crust was lessened considerably in size. It was still more obstinate on the hands. Nevertheless the cure was nearly complete at the end of a year.

CASE CLXXXV.—*Chronic rheumatism. Morbid secretion of the sebaceous follicles of the scalp, trunk and extremities.* J. Thiolé, aged twenty-seven, became a patient in the Hôpital de la Charité on the 21st of March, 1827. He had always enjoyed good health till 1823, when he was attacked, whilst with his regiment in Corsica, with acute rheumatism, which continued for about eight months. In the month of August of the same year, he was attacked with a quotidian intermittent fever, which yielded to a fortnight's use of a cooling regimen. He has always felt more or less of the rheumatism since this time. His arms have lost flesh; they are stiff, and moved with difficulty, and almost useless to him. The motions of the legs are also slightly implicated, although they have not fallen away.

The consequence of the patient's inability to use his arms has been great neglect of his person; and a yellowish and unctuous scurf, from the drying of the matter secreted by the sebaceous follicles, has been formed over the skin of the parietes of the thorax and surface of the hairy scalp. On the chest, this deposit possesses the consistency, and all the other sensible properties of the ceruminous secretion of the ears; it is uniformly spread, and forms a layer from an eighth to a quarter of a line in thickness. It is thickest under the clavicles and over the sternum, and ends three or four inches below the level of the mammæ. A similar ceruminous-looking deposit occurs on the back, and forms a yellowish band, of the breadth of the palm, along the whole length of the vertebral column. The incrustation is divided into an infinity of little irregular compartments, from one to three lines in diameter, between which, parts of the skin are seen here and there uncovered. The matter, which is soft and unctuous to the touch, can be detached from the skin, which appears healthy, when it has not been irritated by rubbing. There is a deposit of the same kind above the clavicles, and on one or two points of the face. On the eyebrows it occurs in the shape of narrow and furfuraceous-looking lamellæ. It is thicker over the rami of the lower jaw, and forms a thick layer within the meatus auditorius externus. It is less marked upon the external ears. The secretion of the meibomian glands does not seem to be augmented. The eyelids are never glued together when the patient wakes. The orifices of the sebaceous follicles of the nose are extremely apparent, and look like small black points. The skin of the whole face is habitually unctuous, as if it had been anointed with oil. The morbid secretion of the sebaceous follicles is more abundant on the hairy scalp than elsewhere, especially over the left temporal and parietal regions. The crust which it there forms is split into small compartments, most of which are loose and adherent to the hair, which is extremely unctuous to the touch. The scalp, freed from this deposit, appears perfectly healthy; it is neither painful, nor affected with pruritus. Several locks of the hair are agglutinated, as it were, with this unctuous matter. Ceruminous-looking deposits of a similar kind exist on

various other parts of the body. The principal vital functions of this patient were healthy. He was immediately subjected to the action of the vapour bath, which appeared alike calculated to prove beneficial to the affection of the skin, and to the rheumatic paralysis of the upper extremities. The ceruminous-looking incrustation was speedily detached and the remedy was ordered to be continued. (a)

(a) *Sebaceous Ichthyosis*.—"A remarkable case of this disorder, disseminated in patches over the surface of the head, neck, and trunk, is recorded by Dr. Jacobovics,<sup>1</sup> under the erroneous appellation of '*tubercules bigarrés*,' a new variety of molluscum. Dr. Jacobovics' case differs from ordinary instances of this disease, in the longer duration of the malady, its disseminated character, the excoriations which resulted from its continuance, and the presence of inflamed tubercles intermingled with the patches.

"The patient, M. N., was a tailor of bilio-sanguine temperament, fifty-six years of age, the nineteenth child of healthy parents. His mother had a slight cutaneous affection on the neck; another had furfuraceous desquamations on the face; two sisters had several small tubercles on the neck and bend of the elbow; a sister's child had a similar growth. At the age of thirty, M. N. was attacked with severe pneumonia, which left him in unsound health for some years. On reaching his thirty-seventh year, the cutaneous disorder first made its appearance; it commenced on the neck in the form of small yellowish spots, beneath which one or more white points, the apertures of sebaceous ducts, loaded with secretion, were perceptible. These yellow spots gave rise to pruritus during the summer season, which subsided in the winter. Three years afterwards, on the occasion of a severe mental affliction, the disease showed a disposition to increase, and quickly spread over his neck, breast, and back. The disorder now assumed the appearance of little crusts,<sup>2</sup> having a roundish or irregular figure, and various colour; for instance, some were yellowish-white, others fawn-coloured and brownish, others again blackish and livid, and covered with slight desquamation, but there was no constitutional disturbance, nothing to induce the patient to apply for medical assistance until the year 1833, when, annoyed by the violent pruritus and unsightly appearance of the disease, he presented himself at Saint Louis. He was treated at this hospital for two months without benefit, and he returned to his business. Three months later his case was undertaken by Dr. Jacobovics, and presented the following characters:—

"His hair was remarkable for its greasiness, as were several other parts of his body, particularly the skin of the front of the neck, which the author describes as feeling viscous and unusually soft. At the roots of the hair were numerous yellowish patches and scales of sebaceous substance; these greasy scales were also met with dispersed over many parts of the skin. On the forehead, the *alæ nasi*, the cheeks, the back, and in several other situations, the apertures of the sebaceous ducts were very perceptible, and many of them were obstructed by inspissated secretion, which was dark-coloured in some, yellowish in others, and rose above the level of the surrounding skin in several. In other situations the sebaceous substance retained its softness and whiteness, and distending the excretory ducts, appeared like white points in the midst of the yellowish and discoloured laminae<sup>3</sup> by which its escape was prevented. The crusts commence

<sup>1</sup> "Du Molluscum, Recherches critiques, &c., suivies de la description détaillée, d'une nouvelle variété. Par M. M. Jacobovics. Paris, 1840."

<sup>2</sup> "With no better reason, apparently, than that of adhering to the erroneous appellation which he had assigned to this disease, Dr. Jacobovics styles the crusts, *tubercles*, or *tumours*, throughout his essay. They were unquestionably extravascular formations, and mere depositions on the surface. In accordance with this view, I have, in every instance, altered the terms *tubercle*, or *tumour*, to *crust*. Besides, it does not accord with my notions of pathology to admit the possibility of a *tubercle*, or *tumour*, being converted by progressive development into a *crust*. But to agree with Dr. Jacobovics, such a doctrine must be embraced; for, after indicating a number of progressive stages of growth completed by the crust, he remarks, in conclusion.—'Les tubercules bleuâtres et noirâtres, les *croûtes* noires et verdâtres, et les taches qui leur succèdent sont des formes secondaires.' That is to say, that the black and greenish crusts are the secondary forms of 'les tubercules brunâtres.' Those who would peruse the statements of Dr. Jacobovics, I must refer to his essay presented to the 'Académie Royale.'"

<sup>3</sup> "Dr. Jacobovics speaks of patches of a dirty yellow, or yellowish-white colour; these patches he seems to regard as discoloured epidermis, and he describes the white points as being beneath the epidermis. From the observation of cases of this kind, and particularly of the one above recorded (§ 504), I feel convinced that the

1191. Under the name of *worms* or *grubs* of the skin those small filiform bodies that can be squeezed out of the sebaceous follicles, are familiarly known. These are soft, unctuous, easily crushed between

by a whitish-yellow or brownish spot, of the diameter of a millet seed or lentil, but without prominence, and passed through a succession of stages which the reporter has accurately detailed. The yellow spot is attended with pruritus, and examined with a lens, a minute white point may be discerned in the centre of each. In a more advanced stage the yellow spot has increased in diameter, and is raised in the centre, when it presents three or four white points in place of one. By degrees the yellow spots become transformed into brownish crusts, having a maximum elevation from the surface of two lines (French), and a maximum diameter of six lines. These brownish crusts appear studded beneath the surface with white sebaceous points, which give the mottled (*bizarre*) character to the production, which awakened in the mind of Dr. Jacobovics the specific designation which he has assigned to the disease. The succeeding stages which the author has observed the sebaceous concretions to assume, are bluish crusts, punctated with white, and having a lobulated appearance, produced by the linear markings of the skin, and blackish crusts, punctated only around the edges, and intersected by deeper furrows, corresponding with the dermic lines. These latter were chiefly met with in the dorsal region; after a time, the linear furrows increase in depth, even to the splitting of the crust into a number of small polygonal masses,<sup>4</sup> which adhere firmly to the epidermis, and assume a deep black colour. The desiccated patches, rubbed by the dress, or scratched with the nails, are liable to excite suppuration of the dermis, and the pus, oozing from between the fractured masses, forms upon the surface a succession of irregular crusts, which resemble those of impetigo. Other crusts of a yellowish-green colour are also met with, resulting from the immediate desiccation of the brownish punctated patches, and these also become broken in the direction of the natural furrows of the dermis.

"Besides the sebaceous crusts above described, there were interspersed on this man's skin a number of small tumours and tubercles. Some of these were round or oval, prominent in the centre, of a bright red colour, smooth, and shining, covered by a thin and desquamating epidermis, and the seat of a troublesome pruritus. Others were of a bluish-gray colour, with raised and livid borders. These were the principal causes of a violent itching, and indulgence in scratching gave rise to excoriation and chapping of the edges, with a discharge of sero-purulent fluid. A third variety were vividly red, indolent, and of small size, varying from that of the head of a pin to that of a small lentil. But these tumours bore no proportion to the sebaceous crusts. They were, probably, the consequence of irritation caused by the sebaceous concretions, and can only be regarded as a complication of the sebaceous disease.

"As regards diagnosis, Dr. Jacobovics unfortunately allowed himself to be dazzled by a word, and that word the most unmeaning in the entire vocabulary of cutaneous disease, I mean, *molluscum*. Thus, after recapitulating the physical characters of the preceding case—e. g., hereditary tubercles, varying in size from that of a lentil to that of a pigeon's egg (there were none so large in his case), round or irregular, usually sessile, brownish colour, consistent or softish, generally solid, no constitutional disturbance, &c.—he remarks, 'Among the tuberculous diseases of the skin, none but the present genus is capable of assuming the whole of these characters, so I am bound to establish this in the genus *molluscum*.' An unfortunate preference, for *molluscum* is already synonymous with heterogeneity. In the treatment of this case the author employed purgatives and warm baths, but with only partial success."—E. Wilson, (*op. cit.*)

yellow patch is a thin layer of inspissated sebaceous substance, adhering very closely to the epidermis; this I conceived to be gradually raised by the deposit of fresh sebaceous matter beneath it, until the elevated crusts are formed, which are the distinguishing feature of this case. The white points will consequently be seen beneath the sebaceous scale. I have already alluded to this appearance, and have before me a preparation in which it is well shown."

<sup>4</sup> "The masses are identical with the sebaceous ichthyosis described at the commencement of this section."

the fingers, and vary both in length and thickness; they consist of concrete sebaceous matter pent up within the follicles; they are very commonly black or brown at the outer extremity; they commonly occur in greatest numbers upon the alæ of the nose and the parts of the cheeks in immediate connection with these; they are also frequently met with over the sternum, about the nipples, and in other situations where the follicles are known to be very abundant. These sebaceous concretions, moulded within the cavities of the follicles, may be forced out by pressing a fold of the skin, where they occur, between the points of the fore fingers; or they may often be seized with a pair of tweezers, or turned out with the point of a pin. They occasionally occur in such numbers as to constitute really a disagreeable and annoying disease of the skin. I was once consulted by a man, a tiler, who from his infancy had had the skin of his face, and of the inter-scapular and sternal regions, beset with grubs. The skin on these districts appeared to be studded with black points, and a multitude of filiform bodies, from one to two lines in length, could be extracted, when the orifices of the follicles became extremely apparent. The patient informed me that these concretions were more remarkable in winter than in summer. I merely recommended him to use the tepid bath frequently.

These sebaceous concretions are sometimes few in number, when they generally occur of large size. A woman, forty years of age, had four on the right cheek, the tops of which were as large as the head of a pin; and I have seen one under the right nipple in a young woman which was as large as a black-currant.

These sebaceous concretions of the follicles of the nose are occasionally complicated with psudracious pustules, and the inflammation of a certain number of the sebaceous follicles themselves (*acne punctata*). In this case one of the best applications is an emulsion of bitter almonds used frequently.

## FOLLICULAR ELEVATIONS. (a)

1192. Under this title I designate those whitish globular elevations, generally of the size of a pin's head, formed by the sebaceous follicles, full of an unctuous, whitish, solid matter. These follicular elevations are most commonly encountered on the *eyelids* and *face* generally. It is sometimes possible with the naked eye or a magnifier to distinguish a minute dark point on the surface of these elevations; this is the orifice of the follicle. If these small elevations be punctured with the point of a lancet, the sebaceous matter they contain may be squeezed out of them readily, and it is often very long before it accumulates again; but this is more certainly prevented by destroying the follicle by means of caustic. Follicular elevations of the kind under review are often associated with the inflammation of the follicles which I have spoken of under the name of *acne*. They also occur, however, along with other lesions; I, for instance, once attended a young woman affected with lupus of the nose, whose forehead was covered with these elevations. Among children of from seven to eight years old they are very frequently seen about the chin and over the cheeks. They occur but rarely among the aged. They occasionally disappear spontaneously.

## MOLLUSCUM.

Under the name of molluscum *contagiosum*, Bateman has described a contagious disease, the seat of which appears to be the sebaceous follicles.<sup>1</sup> This affection I have not myself had an opportunity of observing. (b)

(a) Under this may be mentioned the sebaceous horns, described in § 1117 and in note to § 1122.

(b) *Molluscum*.—M. Gibert remarks that the genus molluscum

<sup>1</sup> A distinguished physician recommended to the care of Dr. Bateman a patient afflicted with molluscum which appeared to have been communicated by contact. The face and neck of the patient, a young female, were covered with rounded prominent tubercles, of different sizes, from that of a pin's head to that of a small bean. These tubercles were hard, slightly transparent, and nearly of the colour of the skin. They were sessile. A milky fluid could be squeezed out of the largest of them,

CASE CLXXXVI.—*Follicular elevations of the face*. Q \*\*, aged twenty-five, had small-pox when seven years old, and had ever since continued subject to inflammation of the edges of the eyelids.

comprehends several species, which have no characters in common with each other except these—cutaneous excrescences that are indolent, of a firm consistence, having nearly the same colour as that of the skin, and generally incurable. Most writers have described three species of it, viz.: 1. The endemic and contagious molluscum of amboyna; 2. The sporadic and non-contagious M.; and 3. The ætheromatous M. described by Bateman. M. Gibert makes a fourth, which he calls stearin molluscum (*Med. Chir. Rev.*, 1844).

*Molluscum contagiosum*, says Dr. Paterson, writing in 1841 (*Edinb. Med. & Surg. Journ.*), is as yet to be regarded as entirely British—the latest authorities in France, Germany, and America, making no mention whatever of it in their respective countries. From Bateman's description (*Synopsis*) we learn that molluscum is characterized by the appearance of numerous tubercles, of slow growth and little sensibility, and of various sizes, from that of a vetch to that of a pigeon's egg. These contain an ætheromatous matter, and are of various forms, some being sessile, globular, or flattish, and some attached by a neck and pendulous. The growth of the tubercles is apparently unconnected with any constitutional disorder; they show no tendency to inflammation or ulceration; but continue through life, having apparently no natural termination.

A little farther on Bateman thus speaks of molluscum *contagiosum*. "The face and neck of this young woman were thickly studded with round prominent tubercles, of various sizes, from that of a large pin's head to that of a small bean, which were hard, smooth and shining on their surface, with a slight degree of transparency, and nearly of the colour of the skin. The tubercles were all sessile, upon a contracted base, without any peduncle. From the larger ones a small quantity of a milk-like fluid issued on pressure, from a minute aperture, such as might be made by a needle's point, and which only became visible on the exit of the fluid. The progress of their growth was very slow; for the first tubercle had appeared on the chin a twelvemonth ago, and only a few of them had attained a large size. Some of the latter had recently become inflamed, and were proceeding to a slow and curdly suppuration; and the cervical glands, lying under those on the neck, were also swollen, and discoloured as if proceeding to suppurate. The eruption was still increasing much, and not only disfigured her greatly, but had recently impaired her general health, and occasioned a considerable loss of flesh, by the irritation which it produced.

"She ascribed the origin of this disease to contact with the face of a child, whom she nursed, on which a large tubercle of the same sort existed; and on a subsequent visit, she informed me that two other children of the same family were disfigured by similar tubercles; and besides, that the parents believed that the first child had received the eruption from a servant, on whose face it was observed. Since my attention was drawn to this species of tubercle, I have seen it in another instance, in an infant brought to me with porrigio larvalis; and, on investigation, it was found that she had apparently received it from an older child, who was in the habit of nursing it. In this case the milky fluid issued from the tubercles, and may be presumed to be the medium of the contagion."

In a "*Notice of the Molluscum Contagiosum*" by Dr. Henderson,

through a very small orifice, similar to what might have been made with the point of a pin. These tubercles had grown very slowly; the first had appeared upon the chin, about a year ago, and only a small number had attained a large size. Several had suppurated and disappeared; the cervical glands had also enlarged, and seemed inclined to suppurate. The eruption caused great irritation, and weakened the patient, who had lost flesh. This woman had nursed a child affected with a large tubercle of the same description, and she was of opinion that she had caught this disease herself from the child. She informed me that two other children of the same family were similarly affected, and it was supposed that those who were first affected with the malady had received it from a nurse who had an eruption of the same description on her face.

I have since seen another case of this affection in a child labouring under porrigio larvalis, which was communicated to the child by the woman who had charge of him. In this case, the milky fluid that exuded from the tubercles might be regarded as the means of the contagion. The liquor arsenicalis was prescribed to the young woman in small doses, and in a short time the number and size of the tubercles diminished, several also suppurated.—(Bateman. *Pract. Synopsis*, 7th ed., p. 382.)

His forehead, cheeks and chin were beset with follicular elevations, from half a line to a line in diameter, and rising about half a line above the general level of the integuments, a size they had attained

(*Edinb. Med. & Surg. Journ.*, 1841), he describes four cases of the disease which he had an opportunity of seeing among children of poor parents residing in Edinburgh.

"Three of these cases were children of the same family, and the fourth was a child of a neighbour in the habit of associating with the others. Though the circumstances are calculated to excite a suspicion that the disease was communicated from one to another of these by contagion, I could not trace the transmission so conclusively as Bateman and Thomson have done. One of the three children had exhibited the disorder six months previously, but from what source was unknown. A second became affected a month later; and the third only a fortnight before the date of my attendance.

"The child first affected was eighteen months old when the molluscum appeared. The tubercles presented themselves first on the left upper eyelid, and successively affected the other eyelids and the face. When I saw the child, there were about a dozen tubercles on the face in various stages of development, and one only elsewhere,—on the right ankle. From the account I received from the mother of the progress and duration of the tubercles, it appeared that they differed much in these respects. Two had existed on the right upper eyelid for nearly six months; while several which had appeared on the hands had run their whole course in about a month. This diversity was doubtless dependent on the degree of exposure of the tubercles in the different situations to injury or irritation, for their disappearance, as stated originally by Bateman, is owing to inflammation, in consequence of which they suppurate slowly, presenting ultimately the characters of a prominent pustule.

"It does not appear that the tubercles are necessarily numerous. A twin brother of the child to whom I have just referred, though affected with the disease five months before I saw him, never had more than two tubercles, one on the leg, and another on the shoulder. These had not then become inflamed. At the time when I saw the other two children, each had but one tubercle, but I did not learn the subsequent history of the disease in them. The twin children were very unhealthy. When committed to my care, the child who was the most affected with the tubercles had a tumid belly, emaciated limbs, was subject to diarrhoea, and had a squalid appearance. The other was not in so bad a state at that time; yet both continued sickly; were in the following year affected with *psoriasis gyrata*; and ultimately died within a few hours of each other, with the symptoms of acute hydrocephalus. I had not an opportunity of watching the course of the molluscum until its final disappearance in these children; but I ascertained, nine months after they first came under my care, that the disease had disappeared, and that its duration had extended to twelve or thirteen months. The description and plate contained in Bateman's continuation of Willan's treatise on cutaneous diseases, correspond, in every essential particular, with what was presented in the cases to which I have been referring.

"Lately a fifth case of *molluscum contagiosum* has fallen under my notice, and has afforded me an opportunity of examining the structure of the tubercles, and the microscopic characters of the ætheromatous matter which they contain. I am enabled by Dr. Paterson, of Leith, to mention the existence, at the moment of my writing this, of three other cases which have recently occurred in his practice, so that now twenty cases of this curious disorder are on record.

"Of the following case I could obtain no history, either of the source of the disease or of its duration. The boy appears to have been an orphan, and was removed from the workhouse to the Royal Infirmary, where he fell under my care.

"Philip Walker, aged eight, admitted April 17th, 1841.

"This patient can give no exact account of the history of his case, but on admission he presents the following appearances.

"His head is covered in several places with large prominent scabs, varying in size from that of a sixpence to that of a half-crown.

"On the lower part of the abdomen, the penis and scrotum, and about six inches in extent of the inner surface of both thighs, there are seen from three to four dozen tubercles, varying in size from a

from having begun in the form of points that were nearly invisible. The greater number presented a small black point in their centre, similar to the puncta lachrymalia, from which I forced out a whitish

millet seed to a pea. They are in general of a round form, but a few of them appear flattened, as if from pressure. In the majority the point of attachment to the skin is distinctly smaller than the remoter part; still it cannot be called a peduncle. At the apex of each tubercle, a small dark-coloured point is seen, which marks the seat of an opening communicating with its interior, and exuding a milky-like fluid on pressure. On the left side posteriorly, about a finger's breadth from the spine, and at the lower part of the chest, there is a soft swelling an inch and a half in length from above downwards, and an inch and a quarter in breadth, of an elliptical form. In the centre of this swelling there is a smaller and gentler elevation, of a dull purplish colour, with vascular ramifications, in the apex of which there is a small rounded aperture, from which a thickish matter, closely resembling finely ground rice boiled, can be squeezed. There is no pain in the swelling; he says he has noticed it for many months, and that it was at one time much smaller. On the right arm, four tubercles, similar to those found on the pubis, exist, and ten are seen on the left arm. At the bend of the right knee, and upon the inner ankle of the left foot, a small superficial ulceration exists, which, in the latter situation, is partly covered with a dark-coloured scab. The feet are œdematous; the skin over them is red, and they are tender on pressure. The abdomen is very tense, and yields a tympanitic sound on percussion. He has frequent and rather severe cough, especially at night. His tongue is foul, and pulse above 100. His bowels are somewhat loose, several thin yellow stools being passed daily.

"The sound of percussion is impaired all over the right front, also from the axilla downwards laterally. Behind, percussion on the right side is less resonant than on the left, but not absolutely dull. The sound of respiration is somewhat harsh upon the right back, and upon the right front is dry and blowing, mingled with some sibilant rattles. The left side of the chest moves much more freely in inspiration than the right. The heart appears to beat in its natural situation; its sounds are heard with remarkable distinctness over the left, as contrasted with the right side. The left side of the chest, by measurement, is three quarters of an inch larger than the right. The skin is harsh and dry; pulse 108; bowels regular.

"May 6th, noon.—At six, this morning, he became affected with sudden and severe pain in the hypogastric region, and now the pain and tenderness of the belly are general, with more timidity and tension than formerly. Has had three stools since the pain came on; is now breathing quickly, with some tracheal rattle and bronchitic thrills on the right front. There are several lymphatic glands considerably enlarged in both axillæ and right side of the neck. Pulse 126, scarcely perceptible at the wrist; extremities rather cold. He died eight hours and a half from the time when the pain occurred.

"The body was examined on the 8th of May. It was much emaciated. A considerable quantity of turbid serum was found in the abdomen, with recent coagulable lymph in both iliac regions—in the basin of the pelvis, and on the upper surface of the liver. The subserous cellular membrane of the bowels, and of the parietes of the abdomen, was the seat of innumerable small whitish tubercles. The omentum was contracted on the colon, and filled with tubercular matter. The mesenteric glands were large, and most of them filled with tubercular matter. The right lung was at its apex, and in several parts near its surface, the seat of tubercular masses; the whole lung, a good deal loaded with blood, and an ounce and a half heavier than the left, which was not affected with tubercle, and not particularly engorged. In a narrow, transverse, and old ulcer of the ileum, a perforation was found. Several of the patches were dark, elevated, and firm."

Dr. Paterson, in the paper already cited, gives a case that occurred in the practice of Professor John Thomson, of Edinburgh, which I introduce here:

"March, 1821.—In a family, resident in the Canongate of Edinburgh, there are three children, two boys and a girl, affected with *molluscum contagiosum*. About six months ago, small tubercles ap-

substance, similar to curdled milk, but of rather greater consistence. The skin of the parts affected was not inflamed, or otherwise altered. The malady had appeared about four months ago. For the last five

years his hands had been covered with a great number of warts. He slept with his brother, who had no similar affection of the follicles of the skin.

appeared upon the face of the eldest boy, who, it is supposed, had caught the disease from some of his playfellows, although none of them at present are known to have had it, nor has it been known ever to have existed in the neighbourhood. From this boy the disease was communicated to his sister, and to his little brother, a child of about nine months old, whom he occasionally carried about in his arms. The contagious nature of the disease is well evinced in the child. On the back of its hands a considerable number of tubercles are seen which have been produced by applying them to the face, and scratching those situated there during their inflammatory stage. Some of the tubercles are small, others large, some in a state of active inflammation, others nearly of the same colour as the skin, and quite free from pain. A few of them are pedunculated, but the greater of these number are attached by broad bases. They are seen on different parts of the face, on the forehead, eyelids, nose, lips, red of the lips, cheeks, and under the chin. Those under the chin have produced a considerable degree of inflammation of the skin, and tumefaction of the submaxillary glands. Two or three appear to be decaying, are shrunk and corrugated, and of a reddish-brown hue. It is three months since the first appearance of the disease. The mother, though in the constant habit of nursing the youngest child, has not been infected."

Dr. Paterson continues:—"I am also enabled, through the kindness of Professor Thomson, to add another series of cases of this rare affection, which, some time after the last-mentioned ones, came under his observation.

"Professor Thomson was consulted regarding the child of a farmer, in the immediate vicinity of Edinburgh, who was affected with this disease in its characteristic form. It was traced to have been communicated to this child of the farmer's by a child of one of the farm servants; but this case could not be traced further. The farmer's child suffered severely from conjunctivitis, produced by the irritation of the tubercles on the edge of the eyelids. The disease was next communicated to the servant girl, who was in the habit of keeping the child during its illness, and appeared in its usual form on that side of the neck alone, against which the child was in the habit of laying its face when affected with the ophthalmia. The above cases appear to me extremely interesting in so far as they point out in the most unequivocal manner the contagious nature of the disease.

"The first case of this disease, which I had an opportunity of witnessing, occurred at the village of Newhaven, in the month of December, 1840. The child, a girl about eighteen months old, extremely robust and active, and belonging to one of the cleanliest and best class of fisher people, had been affected with the eruption for the last three months. It was first observed in the neighbourhood of the mouth and nose, and it now occupies the same localities, together with the lower eyelids, and a few thinly scattered over the cheeks and neck. The mother states that, when it was first seen, the tubercles had very much their present appearance. This child was nursed on one breast, and, although weaned, has the habit of still sucking it. The tubercles vary in size from that of a pin head to a horse-bean—the smaller ones having very much the white opaque appearance of pearly granulations, the larger ones being a little more coloured. The smaller ones are round, the larger ones oblong and irregular in shape, very much resembling that of a horse-bean. They are sessile, on a contracted base, not pediculated. The larger ones only emit a whitish fluid when pressed. They seem to be not the slightest source of uneasiness to the child, and do not even appear painful when pretty roughly handled.

"This child communicated the disease to the breast of the mother, and it appeared entirely confined to the sebaceous glands around the nipple of that breast, which the child continued to suck.

"The tumours on the breast are of various sizes, from that of a pea to a hazelnut, three of the larger ones being clustered together; all exude a thick whitish matter, when pressed between the fingers, and they seem to be equally insensible to the touch as those on the child. They first appeared on the breast about a month and a half after those on the face of the child.

"The largest of these tumours latterly became inflamed and extremely troublesome, from the irritation of the rubbing of the clothes against them.

"Particular inquiry was made as to any other members of the family being affected with a similar eruption; but no trace of it could be discovered, and an attempt to find out the source of contagion to the child proved equally unsuccessful; indeed, from the inquiries made, had any similar case existed in the village, it must have been discovered. This series of cases was seen by my friends, Professor Simpson, Dr. W. Thomson, Dr. Mercer, and Dr. Lund, all of whom looked upon them as very characteristic of the disease in question.

"Treatment.—Mrs. C., the mother, was anxious that something should be done for the tumours, as they afforded her considerable inconvenience from rubbing against her dress, and, at the suggestion of Professor Simpson, the tops of them were touched with caustic potass. The application afforded little uneasiness to the patient; the escharotic destroyed a portion of the tumours, and the remainder soon sloughed off by their bases, leaving a healthy granulating surface, which healed kindly, and no return of them took place.

"As the child's health was not in the slightest affected, no treatment whatever was had recourse to. The tumours as they enlarged generally suppurated, scabbed, and then fell off by their base, and as this happened to more of them than was generated, a decided diminution soon took place, and at the present time there are only a very few remaining.

"CASE II presented itself at the Leith Dispensary for consultation on the 2d of April last. The child, Ann M'Queen, two years old, strong and healthy, has been affected with the disease for the last two months. The mother ascribes it to her having been carried about by a girl who had some 'similar lumps' upon her body, while they resided at Dundee, and immediately before they came to Leith. The eruption at present occupies the left side of the neck and shoulder, and a few are scattered here and there upon the same side of the face and trunk of the body. The disease resembles very much in appearance the case last described. The small tumours have the same pearly appearance, and the larger ones, being slightly redder than the skin, and exuding a milky fluid from the orifice at their apex. The tubercles at present appear in groups, and irregularly scattered over the surface of the skin; their number may be from thirty to forty on the present patient. The mother states that the girl, who was primarily affected at Dundee, used to carry this child chiefly against that side of her neck. But neither the mother nor any other of the children in the family have any appearance whatever of the eruption. This, however, may be partly accounted for by the fact that the dress of this child being tied up round the neck, prevents, in a great measure, at least, any immediate contact between the eruption and the skin of the other children. Several of the largest of these tumours were cut off with a pair of seissors, and the skin healed well afterwards; others were destroyed with the caustic potass and nitrate of silver, but still the number of them on the body of the patient is not much diminished.

"The next case which presented itself was that of a young married man, whose wife I had attended in labour some weeks previous. It was observed during the progress of the labour, that numerous small tumours existed at the orifice of the vagina, and in the neighbourhood of the vulva, but, thinking that they might be condylomata, or warts, no further attention was paid to them. The husband, however, shortly after, showed me a number of tumours on the penis, which bore the characteristic marks of *molluscum contagiosum*. Upon inquiry regarding similar tumours on his wife, he informed me that they were of the same kind as those on his penis. They occasioned him considerable annoyance, and he applied for the purpose of getting them removed. The larger ones were cut off with the seissors, and the smaller touched with nitrate of silver, and they have all entirely disappeared.

"Since the above cases occurred, I have had an opportunity of witnessing a beautiful and well-marked case of this rare disease,

CASE CLXXXVII.—*Follicular elevations of the face.* D \* \*, aged twenty-three, of a sanguine temperament, had observed for the last five months, six small, hard whitish lumps, two lines in diameter, and

occurring in a child, under Dr. Henderson's care, in the Royal Infirmary.<sup>1</sup>

In the same volume of the Edinburgh Journal a case is reported by Dr. William Turnbull of Huddersfield.

From Mr. E. Wilson we procure the following particulars of a cure of molluscum contagiosum, and description of the appearance of the tumours. Mr. Wilson does not believe the disease to be contagious:

"An instance of this disease lately (March, 1842) presented itself to my notice, which was remarkable for the active development of the tumours. They were first perceived, about fifteen or twenty in number, dispersed upon the skin of the neck, face and shoulders of a little girl, four years of age. By the advice of the family medical attendant she was sent into the country, and in the course of a few weeks became quite well, all the tumours having disappeared, and no new ones being formed. Soon after her return to town, the mother brought her two other children—an infant and a girl six years old—to me. The mother and children were of blonde complexion; they had light hair, and a thin delicate skin; the mother was much alarmed at the development of these little tumours on her two other children as well as on herself, 'caught,' as she imagined, from the child first affected. I quieted her alarms relative to contagion, but was much struck by the fact of the almost simultaneous appearance of the disease upon four members of the same family. On the neck of the mother I found four or five of these little tumours closely resembling and of the size of currants, constricted at their base, and each presenting an umbilicated depression of impacted sebaceous substance, the aperture of the excretory follicle; and she directed my attention to three ugly scars upon the face left by similar tumours recently healed. On the neck, face, and shoulders of the eldest child I found eight or ten little tumours, presenting all their stages of growth. One upon the shoulder was so completely pedunculated, that I was tempted to place a ligature around it, and in a few days it fell off. On the infant they were less advanced, they were just rising from the integument, and each possessed in its centre the dark point of an excretory sebaceous follicle. The little tumours presented no signs of inflammation; they were of the natural hue, or somewhat lighter than the surrounding skin, from the whiteness of the secretion which they contained in their interior, and there was no areolar redness around their base.

"Since the above account was written, I have again (August, 1842) been visited by this patient, on account of the development of a small angry tumour of a similar kind upon the margin of the upper eyelid of her little girl, involving two or three of Meibomian glands. With this exception the children have remained free from any return of the tumours. Upon inquiry as to the manner in which they disappeared, the mother tells me, that they became black, and shortly after were rubbed off accidentally. One of large size, and situated behind the ear, in the child first affected, was snipped off by Mr. Tyrrell. The mother, who is out of health, has three still remaining, one of small size near to the angle of the right eye, and two upon the back of the hand. The former has supplied me with a fresh stock of matter for examination.

"Upon examining these little tumours, I found them to present all the characters of a small conglomerate gland,<sup>1</sup> consisting of several lobules held together by areolar tissue, and the lobules composed of ramified ducts and terminal sacculi. The ducts were remarkably dilated, particularly the central one, and were filled with inspissated secretion. The latter was identical in composition with the concretion sebaceous substance of the comedones (§ 511). The cells were of the same size, had the same appearance, and were intermingled in considerable number with epidermic scales. I differ in opinion with Dr. Paterson in not considering these cells as peculiar organisms, capable of nucleolar propagation when transferred to an appropriate nidus in another individual. I regard them as the normal sebaceous cell, which, as I have before remarked (§ 511), contains a granular substance, filling it more or less completely. In its early stage of

a line and a half in height, and of an irregularly circular, conical or flattened shape. A small black point, similar to what might be produced by the puncture of a needle dipped in ink, could be seen with

formation, the cell, like all epithelial cells, is an adherent envelop of a nucleolated nucleus; subsequently the cell increases in bulk by endosmosis, and assumes the oval and more or less flattened form, in proportion to the larger or smaller quantity of fluid present in the ducts. The granular contents of the cells are due to the breaking up of the nucleus, and in proportion to the bulk of the cell and the quantity of its fluid; they either fill the cell completely, or leave an unoccupied interval around their circumference. In the myriads of cells of a small fragment of the concreted substance of one of these little tumours, I perceived cells of both the above kinds; but the number of the latter, few on the first examination, had very much increased on the following day, after I had left the tumour in weak spirit for twenty-four hours.

"The difference in the appearance of the cells examined by Dr. Paterson, and by myself, appears to me to be immediately explained by reference to the physical difference in the contents of the tumours. In Dr. Paterson's case, the contents, as in Bateman's, were milky, and consequently, semi-fluid. Here, then, were the conditions favourable to the production of cells, having a considerable interval filled with fluid between the granulous nucleolar substance and the membrane of the cell—a deposition which induced Dr. Paterson to regard them as being composed of an external vesicle and an internal vesicle, the latter containing the granular substance. In my cases, on the other hand, the contained substance was concreted; there was a deficiency of fluid, and the granulous substance filled the cell; and in exceptional cases only were any perceived in which a peripheral interval was observed. But on the second day, as I have before remarked, when the mass had been steeped in weak spirit for a number of hours, the peripheral interval was evident in a considerable number.

"On examining my new stock of sebaceous matter, (August 1842,) fresh from the patient, I found it to consist of cells heaped together like a pile of eggs, and intermingled with a large quantity of epidermic scales in flakes. The mass consisted solely of these two substances, without any granular matter or oil-globules. The cells were variable in their form, some being more or less cuboid, others irregular from compression, some oblong, like the eggs of the ant, others, again, oval, but the most common form was ovoid, like that delineated in the figures of Dr. Henderson and Paterson. The cells presented equal diversity in size, varying in their long diameter from  $\frac{3}{16}$  to  $\frac{1}{8}$  of an English inch, and in their short diameter from  $\frac{1}{16}$  to  $\frac{1}{11}$ : some of the cuboid cells measured  $\frac{1}{16}$  by  $\frac{1}{16}$ ; the general size of the oval form was  $\frac{3}{16}$  long, and  $\frac{1}{8}$  broad; there were several oblong cells, measuring  $\frac{3}{16}$  by  $\frac{1}{16}$ ; and the common dimensions of the ovoid cell were  $\frac{3}{16}$  by  $\frac{1}{8}$ . This size corresponds very closely with the cells of ordinary inspissated sebaceous substance, whether it be concreted or pulpy; and also with the dimensions of the epidermic scales lying scattered among the cells. The contents of the cells were also various; some were filled with granular substance, in the midst of which, at some one point, the nucleus was perceptible; others contained a homogeneous substance, separated into polygonal masses, mostly of a cuboid shape; while others, again, were more or less filled with minute oil-globules. It is difficult to say which kind of cells were most numerous. I saw nothing like the double vesicle described by Dr. Paterson, and I think it possible that the appearance which he has delineated may have been produced either in the manner I have already suggested, or by the superposition of a single cell by several connected scales of epidermis; or again, by the accidental position of the cell upon the epidermic scales in such a manner as to constitute a thin margin around it."

Of treatment and the literature of the disease, M. Wilson thus discourses:—"In the case above detailed, I prescribed laxative medicine, and touched the tumours with nitrate of silver several times. By this treatment, I succeeded very speedily in removing them. I have mentioned that a ligature was placed around one; a more expeditious mode of getting rid of them would be to snip them off with scissors. In adults, they may always be snipped off. On the mother of these children, I opened several with a lancet, and touched their

<sup>1</sup> This observation confirms the description given by Dr. Henderson, § 531.

the naked eye, towards the centre of each of these, from which, by compression between the thumb and forefinger, a globule of sebaceous matter could be forced. The parts affected were the seat neither of pain, heat nor itchiness. Several boils had recently appeared on the abdomen, and for the last three weeks the patient had complained of slight soreness of the throat.

## FOLLICULAR TUMOURS.

1193. Besides the worms and elevations of follicular origin, now described, the retention and accumulation of the sebaceous matter within these organs, occasionally give rise to the formation of true *follicular tumours*,<sup>1</sup> which have often been described under the names of *wen*, *meliceris*, *atheroma*, *steatoma*, &c., and have been confounded with proper eneysted tumours. These follicular tumours may appear on almost any part of the body, but they have been principally observed on the scalp, on the face, and on the back. They are soft, indolent, and unattended with alteration of the skin around, or which covers them. The stuff they contain very often resembles curdled milk. It acquires a very offensive odour when the parietes of the distended follicles are accidentally inflamed. A quantity of hair is not unfrequently found mixed with the sebaceous matter.<sup>2</sup> When the tumours

interior with nitrate of silver. Their return may be prevented by the plan of stimulation of the skin, recommended for the treatment of comedones. Dr. Thomson used sulphate of copper, and Dr. Paterson potassa fusa, in their treatment.

"In the mode of cure of these tumours, I perceive another argument against their contagious nature. They disappeared in the first child, on the recovery of her health, during a short visit to the country, without local treatment. In the case of the other two children, many of the little tumours fell off, and the disease got well under the use of the compound senna powder. The three at present upon the skin of the mother are attributable to a disordered state of health. Indeed, I have no hesitation in asserting that this family is the subject of a *sebaceous constitution*, and that any recurrence of disordered health will bring with it a disposition to the formation of sebaceous tumours.

"After having determined the nature of the small tumours above described, and having assigned to them the position which they appeared entitled to occupy in a natural system of classification of diseases of the skin, I read, for the first time, with attention, the cases narrated by Bateman, under the head of Molluscum, and was struck with the identity of Bateman's cases with those I had just witnessed. Pursuing my inquiry with a view to ascertain the true meaning of the term, and that which seemed to be intended in its original application, I came to the conclusion expressed by Dr. Jacobovics,<sup>3</sup> that Bateman must have borrowed the appellation from the essay of Dr. Ludwig,<sup>4</sup> the reporter of the celebrated case which occurred to Tilesius. The author, in his preface, remarks—'Reinhardi, visu fœdum, corpus tectum est verrucis mollibus sivi molluscis.' Alibert, Bielt, Cazenave, and Schedel, on the contrary, attribute the origin of the term to some resemblance existing between the cutaneous tumours and the knots on the bark of the maple.

"The earliest case on record of this affection, and the one in fact which, according to the above supposition, gave the designation to the disease, is that of Tilesius, recorded by Ludwig. I propose to make an analysis of this case, as well as of those which have been published on the same subject to the present time, in order to ascertain the opinions entertained by their respective authors of the cases which have appeared in their names. The result of this inquiry will, I trust, be a confirmation of my opinion respecting the pathology and true position of molluscum."

<sup>1</sup> Bateman appears to have described follicular tumours under the name of *Molluscum*, vide his Pract. Synopsis, 7th ed., p. 380, in which place he quotes a case from Ludwig, of a man whose whole body was covered with ætheromatous tumours. Ludwig. *Historia Pathologica singularis cutis turpitudinis*, fol. Lips., 1793.

<sup>2</sup> Cooper and Travers' Surgical Essays, vol. ii.

<sup>4</sup> "Historia Pathologica singularis cutis turpitudinis J. G. Reinhardi viri 50 annorum, &c. By Dr. C. F. Ludwig. Lipsiæ, 1739."

of the follicle often continues visible for a very long time; but no traces of it are generally to be discovered when the tumours have attained a certain size. I have examined one of the tumours developed on the fronto-parietal region, and of the size of a partridge's egg. Towards its centre it rose about four lines above the level of the integuments. The portion of the scalp raised by the tumour had preserved its natural colour; but it was, in a great measure, bald. The inner surface of the tumour was applied immediately to the bone of the cranium, being separated from it neither by piliferous bulbs, nor by adipose vesicles. On the outer surface the tumour adhered to the skin, from which it could not be removed in various places, where it was only separated by a small number of adipose vesicles and hair bulbs. This follicular tumour formed a perfect cyst without any opening. It contained a matter, the surface of which was white and of the consistence of wax, whilst that of the centre was soft and of a brownish-yellow, like a coffee-custard or cream. The portion of the cyst which adhered to the skin was cellular, red, and vascular; that of the opposite side was smooth and white, like a serous membrane.

According to Meissner,<sup>5</sup> many of the tumours which have been described as *polypi* of the meatus auditorius externus, are owing to the excessive development or distension of a ceruminous follicle.

In the body of an aged woman, who had died of pulmonary catarrh, six small follicular tumours, of the diameter of a silver threepenny piece, were found on the scalp, and ten others of various sizes, between the shoulders and on the back. The majority of these were of a yellowish-white colour. I opened several of the smallest of them with the point of a lancet, and found that they contained ætheromatous matter.

In examining the body of another old woman, aged eighty-seven, who had died in the Hôpital St. Antoine, I found a follicular tumour on the right side of the pubes, in the direction of the inguinal canal, of the size of a hen's egg, on the centre of which there was a small black point like that of a grub of the faec. I have seen a tumour of the same description, as large as a filbert, behind the right ear, upon which a similar black point was also remarked. In this case there was the rudiment of another follicular tumour behind the opposite ear, that is to say, a follicular worm of considerable magnitude. I have frequently seen tumours of the above description become the seat of chronic inflammation, and pus accumulate within the cavity of the follicle, the orifice of which then resembled a fistula.

1194. Follicular tumours generally occur in numbers together. I have counted as many as fifteen on the scalp. They are always evolved with extreme slowness and successively; they feel firm, and do not fluctuate under the finger; they are not so hard as encephaloid formations, the parietes of which are stronger and less yielding.

It is not so common to find so large a number of follicular tumours evolved on the trunk and extremities. The eight *wens* (loupes) situated on the body of the young woman whose case has been published by M. Dagorn,<sup>6</sup> differed in point of size and of structure from follicular tumours. But it seems to me that we ought to refer to this class of accidental formations the *ætheromatous* tumours evolved on the face, trunk and extremities, of which mention is made by Ludwig,<sup>7</sup> and which Bateman quotes as a case of molluscum. According to some anatomists, these follicular tumours are evolved as a consequence of the obliteration of the orifice of the follicle. I have, however, seen many of large size in which the orifice continued very apparent.

1195. The *etiology* of follicular tumours is very obscure; they occasionally appear due to an hereditary disposition; to follow the application of repeated pressure, &c. They are more frequently observed among the aged than the youthful and full grown.

1196. *Treatment*.—When the orifice of the distended follicle remains apparent, after having introduced a probe into the cavity, the sebaceous matter may generally be pressed out without much difficulty. This is but a temporary remedy, however, for the matter soon accumulates again; to cure them permanently they must be laid open, and either cauterized or extirpated. Laid freely open, follicu-

<sup>5</sup> Dict. de Méd., en 18 vol., Art. Polype.

<sup>7</sup> Ludwig. *Hist. Sing. Cutan. turpitudinis*, fol. Lips., 1793.

lar tumours are readily voided, and the inflammation that follows the operation is occasionally followed by their obliteration. They are also very readily dissected out, when they are not of very long standing and large size. This operation performed on the scalp, is apt to be followed by erysipelatous inflammation, sometimes of considerable intensity; so that many practitioners prefer to leave them alone there than to attack them with the knife, especially when they are numerous. These tumours are sometimes successfully treated by having inflammation excited in their interior, either by drawing a fine seton through them, or better by the injection of some stimulating fluid, as of diluted alcohol, &c.

Follicular tumours, especially those of the eyelids, may also be got rid of by being touched with the nitric acid,<sup>1</sup> or the butter of antimony, caustic potash, &c. The ligature is seldom applicable to this species of tumour.

Follicular tumours of the scalp differ in their indolence, and in various other characters, from encephaloid tumours, which are occasionally developed upon this part.

#### CALCULI OF THE FOLLICLES.

1197. Instead of sebaceous matter, the follicles occasionally secrete a hard and stony substance; Meckel found the whole of the sebaceous follicles of the haunch full of small calculi, in a boy; the piece of integument thus affected is preserved in his anatomical collection. In two other children, calculi of this description have been found in the skin of the forehead and of the root of the nose.<sup>2</sup>

#### SPECIAL DISEASES OF THE PILIFEROUS FOLLICLES, AND ALTERATIONS OF THE HAIR.

1198. This group<sup>3</sup> includes congenital or accidental absence of the hair (*alopecia*); *supernumerary* hairs; changes in the *colour* of the hair (*canities*, *accidental staining of the hair*); *anomalous direction* of the hair of particular parts, as of the eyelashes (*trichiasis*), the study of which falls within the domain of the surgeon; defective conformation or structure of the hair-bulbs, the nature of which is still little known; and the disease entitled *plica*, the characters of which I shall detail in the *Appendix*.

1198. The greater number of the alterations which the hairs undergo result from an affection of their bulbs or secerning organs. The hair-bulbs are implicated in many diseases of the scalp, in favus, impetigo, &c. *Plica* itself, according to Schlegel, is nothing else than a particular inflammation of these organs. Inflammation of the bulbs generally occasions the loss of the hair; when the hair begins to grow again it is commonly finer and lighter in colour than that which was lost.

The piliferous bulbs may be *atrophied* or destroyed by the com-

pression of subcutaneous tumours; they suffer still more commonly from the progress and long continuance of favus, of syphilitic ulcers, &c.

The growth of the hair has little influence on the other functions or organs of the economy, yet observations are not wanting to show that cutting the hair may be prejudicial in some acute diseases.<sup>4</sup>

Comparative pathology may, possibly, some day, throw new light on the subject of the alterations of the hair; it has hitherto been but little cultivated under this particular point of view. M. Fred. Cuvier has observed the bulbs of the feathers in various birds very much injected and inflamed; and after pulling out the feathers a very considerable development of the papillæ has been noticed. Is depilation followed by an analogous increase of the piliferous papillæ; and are they capable of inflaming in the same way as the bulbs of feathers?

1199. *Congenital deficiency* of the hair is a malformation very rarely met with. It very seldom continues longer than the few first years of life, and ought rather to be regarded in the light of a late development of this appendage of the skin.

1200. *Supernumerary tufts* of hair, i. e., patches of hair in situations where none is generally met with,<sup>5</sup> have been seen in different parts of the body: A young man had a congenital blackish patch on the upper and inner part of the thigh, which was not prominent, from two to three inches in diameter, and the edges of which were irregular and scolloped. This spot was covered with hair, and each particular hair presented a little enlargement at the place where it issued from the skin. I once saw a young man, sixteen years of age, who exhibited himself to the public under the name of a new species of savage or wild man whose breast and back were covered with light brown hair of considerable length, the surface upon which it grew being of a brownish hue, different from the colour of the surrounding integument. Almost the whole of the right arm was covered in the same manner. On the lower extremities several small tufts of hair were observed, implanted upon brown spots from seven to eight lines in diameter, symmetrically disposed upon both legs. The hair was brown, of the same colour as that of the head.

Ph. Fred. Von Walter<sup>6</sup> has published a very remarkable case of *nævus pilaris lipomatodes*.

Bichat informs us<sup>7</sup> that he saw at Paris, an unfortunate man, who, from the period of his birth, had had his face covered with hairs like those of a wild boar; and he adds, that the stories which are current among the vulgar, of individuals with a boar's head, with a wolf's head, &c., undoubtedly referred to cases in which the face was covered in a greater or less degree with hair. M. Vilermé saw a child of from six to eight years old, at Poitiers, in 1808, whose body, except the feet and hands, was covered with a great number of brown, prominent spots, of different dimensions, beset with hair, shorter and not so strong as that of the boar, but bearing a certain resemblance to the bristles of that animal. These spots occupied, perhaps, about a fifth of the surface of this child's skin.

Grivet, aged twenty-six, became a patient in the hôpital de la Pitié, Nov. 16th, 1826, on account of a bronchial affection. On both of this man's shoulders there was a quantity of black hair from six lines to an inch in length, fine and slightly frizzled, and different from the hair of other parts of the body, by appearing to be set within slight brown elevations of the skin which surrounded the root of each hair individually. I once met with a man of mature age, on the fore and outer part of whose thigh, over an extent of about six inches one way by about four the other, there was a thick crop of hair. The opposite thigh was but thinly beset in the same situation. This hair had appeared at the age of puberty, along with that which then began to sprout on other particular regions of the body.

M. L. Dufour<sup>8</sup> has detailed the case of a young man, twenty years of age, whose sacral region was beset not with simple short hairs, but with a tuft as long, black, thick and pliant as that of the head.

<sup>3</sup> Hippocrates speaks of the loss of the hair as an unfavourable symptom in phthisis; he also mentions baldness and whiteness of the hair. Celsus describes alopecia. Galen goes at great length into the varieties of colour of the hair. Aretæus only notices the loss of the hair in elephantiasis. Ætius and Paulus give a great number of recipes against grayness, baldness, &c. Avicenna begins his chapter: *De decoloratione* (jen. 7), with a lengthy account of the alterations of the hair, and the remedies they require. Mercurialis has entered still more fully upon this subject. The accounts of Lorry are even more complete and more accurate. But for the best details in regard to all the affections of the hair, the particular treatises published by the following authors, ought especially to be consulted:—Plempius (*De affectibus capillorum et unguium*, Lovani, 1662), Solwick (*Diss. de morbis pilorum*, Frib. 1777), Meibomius (*De pilis eorumque morbis*, Helmstaedt, 1740), J. P. Pfaff (*De varietatibus pilorum naturalibus et præternaturalibus*, Halæ, 1799), G. Wedemeyer (*Historia Pathologica pilorum*, Götting, 4to., 1812), Bueck (*Diss. de pilis eorumque morbis*, Halle, 1819), Villermé (*Art. poil*, Dict. des Scienc. Médicales); and especially the researches of Dr. B. Eble (*Die Lehre von den Haaren*, etc., 8vo. 2 vols. Wien., 1831, fig.).

And what is particularly remarkable in this case is, that the skin from which it grew was as white and fine in its texture as the integument of the rest of the body. M. Campaignac showed me a similar case in which there was a large tuft of long black hair growing from the shoulder.

1201. Certain pathological conditions may give rise to the accidental growth of hair. Boyer used to quote a case in his lectures of a man who, having had an inflamed tumour in the thigh, perceived this part become covered, in no long space of time, with numerous long hairs. I have seen a case of the same kind myself: A blister having been applied to a child two years old, was kept open for three months. Some time afterwards, the mother of the child called my attention to the circumstance that the whole of the part which had been raised by the blister was now covered with hair, which has remained ever since.

A student of medicine lately showed me a number of hairy patches which he had on his skin, and gave me the following account of the circumstances under which they were developed: "During the summer of 1829, I bathed frequently in the sea. I used to get out of the water, and dry myself in the hot sun of the South; I then returned to the water. One day in particular, I continued in the sea longer than usual. Some days afterwards, changing my linen, I happened to look down upon my breast, and saw with amazement a broad sallow or coppery patch on the upper and outer part of the right side. Looking farther, I found another patch exactly like the first, over the iliac fossa of the same side. Both of these spots remain now exactly what they were in 1829; they have neither changed in colour nor extent." These patches are not uniform: they seem to consist of a great number of small patches, separated by intervals of different extent, where the skin has continued healthy. The colour of both patches forms a strong contrast to that of the rest of the skin, and may be compared to the tint of some white wood, which has been handled and soiled, rather than to that of copper. The colour is deepest in the centre of the patches. They are not affected with any kind of tingling or other unpleasant sensation. But they are the frequent seat of the pustules of acne. It is long since the hair that covers them made its appearance. Nothing had ever been tried to disperse these patches. They seemed owing to the prolonged action of the sun's rays. Were the whole of the small spots of which the broader patches are made up to be uniformly blended together, the tint of the surface would differ little from that which the forehead of the neck of labourers, who are constantly exposed to the heat of the sun, presents.

The following case, which I have from M. Bricheteau, is a more remarkable instance still, of the occurrence of these accidental hairy spots. A young woman, nearly twenty-four years of age, having a white skin, and hair of a deep black, of weakly constitution, and reduced by a pregnancy during which she had suffered much, a miscarriage and an extraordinary difficulty of swallowing, to the last stage of marasmus, began to recover in the summer of 1826, after six or seven weeks endurance of an illness which every one thought must inevitably carry her to the grave. Scarcely had she begun to take a little food, and to recover her strength, than the skin, which was dry, earthy, and, as it were, wrapped round the bones, became covered, especially on the back, breast and abdomen, with a multitude of small elevations, analogous to those which appear under the influence of exposure to cold. These little risings became brownish at the end of a few days, and a hair was soon afterwards observed on the summit of each. This, at first, was very short, fair, and silky; but it grew rapidly, so that before the lapse of a month, almost the whole surface of the body, with the exception of the hands and face, became completely *velvety*. The hair thus evolved was afterwards thrown out spontaneously, and was not reproduced.

1202. I have several times observed a well-marked, excessive development of the hair upon the *chin* and *upper lip* in young women whose menstrual functions were disordered.<sup>1</sup> Hippocrates speaks of the same thing: "In abderis, Phætusa Phytææ uxor, priore quidem tempore fecunda erat; cum autem maritus ipsius in exilium abiisset, menses multo tempore suppressi sunt; postea rubores et dolores ad

articulos oborti sunt. Hæc autem ubi contigissent et corpus virile factum est, et hirsuta penitus evasit, et barbam produxit et vox, aspera facta est: . . . idem hoc contigit etiam Nammysie Gorippi uxori, in Thaso" (Epid. lib. vi. sect. vii).

I may also remark that this growth of the beard is very common among females of a certain age, and that it is not unfrequent among those who are mothers of several children.

In the beard and on the scalp, *compound* hairs, of a larger size than those around them are occasionally observed.<sup>2</sup> These compound hairs are often cleft at their free ends, and are sometimes formed of hairs of different colours, which separate when seized between the blades of the forceps, to be pulled out. They are produced by follicles set closely together, and communicating with the exterior by a single opening.

1203. The hair on different parts of the body may accidentally grow to a *considerable length*. This unusual development of the hair is occasionally confined to a single region of the body. I once saw a Piedmontese, aged twenty-eight, strongly built, having the chest broad and large, and the muscles of an athlete,—the arm was above twenty-one inches, and the calf of the leg nearly two feet in circumference. This man had little beard, and the trunk was very scantily furnished with hair, but his scalp was covered with the most extraordinary crop: frizzled on purpose, it was above four feet ten inches in circumference. The hair was of a dark brown, approaching to black, extremely fine and silky. This phenomenon—excessive lengthening of the hair—has been particularly observed in plica. In phthisis the hair and eyelashes are often extremely long and very strong.

1204. The growth or development of the hair may be accelerated by the state of the organs of generation. Moreau de la Sarthe showed a child to the Medical Faculty of Paris, in whom the precocious development of the testicles had influenced that of the hair to such a degree that at the age of six years the chest of this boy was as thickly beset with hair as it is usually in adults. It is well known, on the other hand, that eunuchs often lose the greater part of their beard.

1205. The hair sometimes grows in a *wrong direction*, to remedy which, it is not always enough to pull them out; it is often necessary farther to take away or destroy their generating bulbs. This is particularly the case in Trichiasis, for which Vacca<sup>3</sup> has proposed a new and very advantageous mode of operating.

Other instances of faulty direction of the hair are related by authors. Thus the hair has been seen growing in a direction the very reverse of that which it usually follows, sometimes towards the inner or adhering side of the skin. All these vicious directions of the hair are occasioned by deviations of the bulbs, or of the parts in which they are implanted. It is not uncommon, either, on the extremities to observe the hair rolled up spirally under the epidermis. The slight degree of irritation to which this gives rise, is followed by the formation of a little elevation, from which a silky hair may be drawn out twisted round upon itself.

1206. The hair presents several peculiarities in point of strength, dryness, moisture, &c. M. Alibert speaks of a woman whose hair was very crisp before marriage, but after pregnancy became so constantly moist, that it was quite impossible to make it curl. The hair of the axillæ became unctuous in the same manner.

#### FELTING OF THE HAIR.

Vocab. *False Plica*.

1207. Felting of the hair consists of an inextricable interlacing of this production. It is chiefly seen among individuals who, for many weeks or months, have paid no attention to their hair. It often occurs among females after long illnesses, &c. It is very common in Poland, where it has been observed by Messrs. Davidson, Kreuzer, Boyer, Rousille-Chamseru, Gasc, and others. Several writers have confounded it with plica.

<sup>1</sup> Burlin (Jac.). De fœminis ex mensium suppressione barbatis, 4to. Altdorf, 1664.

<sup>2</sup> Ollivier. Art. Poil (Dictionnaire de Médecine, en 18 vol.).

<sup>3</sup> Arch. gén. de méd., t. ix.

1208. Felting of the hair occurs independently of any alteration of the hair itself or of its bulbs. It may take place among individuals labouring under chronic affections of the hairy scalp, especially when the hair has been allowed to grow to a great length. The felted mass may present very different appearances. The process is similar to what takes place in plica; but the circumstances under which it happens are different, and the simple phenomenon of felting of the mere appendage, must not be confounded with a serious affection of the generating bulbs of the hair themselves.

1209. When the felted mass of hair cannot be unraveled, it should be cut off.

#### CHANGES OF COLOUR OF THE HAIR.

1210. The hair is liable to undergo certain *changes of colour* connected with some modification of that part of the bulb which secretes its colouring matter. M. Alibert gives us the case of a young lady who, after a severe fever which followed a very difficult labour, lost a fine head of hair, amidst a discharge of viscid fluid, which inundated the head in every part. He tells us, further, that the hair grew again of a deep black colour, after the recovery of the patient. The same writer details the case of Jerome B \* \* \*, born with brown hair, who, having lost it all in the course of an illness, had it replaced with a crop of the brightest red. White and gray hair have also been known to be replaced, under particular circumstances, by hair of the colour which the individual had had in youth. We are even assured that the white hair of a woman, sixty years of age, changed to black a few days before her death. The bulbs in this case were found of great size, and appeared gorged with a substance from which the hair derived its colour. The white hairs that remained, on the contrary, grew from shriveled bulbs, much smaller than those that produced the black. 'This patient died of phthisis.'<sup>1</sup> A very singular case has been published lately of a woman whose hair, naturally fair, assumed a tawny red colour, as often as she was affected with fever, and returned to its natural hue as soon as the febrile symptoms abated.<sup>2</sup> To conclude this subject, M. Villermé alludes to the case of a young lady, sixteen years of age, who had never suffered except from trifling headaches, and who, in the winter of 1817-18, perceived that the hair began to fall off from several parts of her head, so that before six months were over, she became entirely bald. In the beginning of January 1819, her head became covered with a kind of black wool over those places that were first denuded, and light-brown hair began to spring from the rest of the scalp. Some of this fell out again when it had grown to the length of from three to four inches; the rest changed colour at different distances from its ends, and grew of a chestnut colour from the roots. The hair, half white, half chestnut, had a very singular appearance.<sup>3</sup> The hair, as I have said, has occasionally been known to return in age to the colour it exhibited in youth.<sup>4</sup>

I shall only further add, with regard to the changes of colour undergone by the hair, that it may be dyed green,<sup>5</sup> blue, red, &c., by a variety of colouring matters with which it may be impregnated. The hair does not so long retain any accidental tint as the epidermis.

#### CANITIES. [BLANCHING OF THE HAIR.]

1211. *Canities* is the word used to signify the congenital and the senile or accidental loss of colour undergone by the hair. This blanching may be general or partial.

1212. The hair begins to be blanched at its free extremities; yet the hair is often seen white in that portion of its length which is nearest the skin, and black or brown in the rest of its extent. This disposition, the opposite of the former, is owing to the hair having

first been secreted black, and then, in consequence of some affection of its bulbs, secreted white.

1213. Among the aged, the hair of the head is that which first becomes white. Men usually begin to get gray between the thirtieth and fortieth year of their age. The beard, the hair of the pubes, axillæ, &c., generally become white later in life. The change almost always begins over the temporal regions. The white hairs are at first few in number, but they soon multiply, and end by spreading over the whole head. When these whitened hairs fall out, they are rarely followed by any reproduction from the bulb, so that grayness is often followed by baldness. Fair hair does not often become white, yet it frequently falls off at a very early age.

1214. *New-born infants*<sup>6</sup> sometimes present tufts of hair upon their heads completely white. Schenckius speaks of a young man, whose beard grew white from its first appearance. Young men of from eighteen to twenty occasionally become gray. Paroxysms of rage, unexpected and unpleasant news, diseases of the scalp, such as favus, wounds of the head, habitual headache, over-indulgence of the sexual appetite, mercurial courses too frequently repeated, great anxiety, &c., have been known to blanch the hair prematurely.

1215. Grayness is sometimes only partial. An adult, whose hair generally was brown, had a tuft of white hair over the right temple. Several other cases of the same kind have been recorded in periodical publications. Lorry tells us, that grayness of one side only is sometimes occasioned by severe toothache.<sup>7</sup> Ludwig has known the eyelashes become white after small-pox.<sup>8</sup> The beard has also been observed to be extremely white in one place and black in another;<sup>9</sup> it has also been known to become white on one side of the face whilst it continued of its former colour on the other.<sup>10</sup> Cases of canities of the whole of one side of the body have also been detailed. (*Dict. des Sciences Méd.*, t. iv. p. 76.)

1216. The blanching of the hair generally takes place slowly; but there are very authentic instances on record of the occurrence of canities almost suddenly.<sup>11</sup> A person of my acquaintance, says Bichat, became almost entirely gray in consequence of some distressing news that reached him.<sup>12</sup> A similar case has lately been recorded by M. Cassan.<sup>13</sup> A woman of the name of Pérat, summoned before the Chamber of Peers to give evidence in the trial of the assassin Louvel, was so much affected that her hair became completely white in a single night. In these instances certain changes depending on the state of the vital processes generally, must take place in the hair.

When hair grows from cicatrices that are without pigment, it is generally colourless. The coincidence of the want of colour in the skin and in the hair, has been observed in the majority of instances of general or partial leucopathia. In senile canities the skin of the cranium does not participate in the absence of colour observed in the hair.

1217. Gray hairs have been said to be without *marrow* or matter in the interior, in place of which there is an empty canal. Vithof assures us that the bulbs of those hairs which have become white, are of diminished size.

1218. *Treatment*.—The blanching of the hair which accompanies general and congenital, partial and accidental leucopathia, and the canities which occurs with the progress of years, cannot be made the subject of any kind of remedial treatment. It were in vain to pull out the white hairs by their roots, or to bring about their fall by the use of depilatory powders and pomatums; the hairs that spring in their places would be no less white. Hair-dressers frequently make use of a solution of the nitrate of silver to dye the hair when it has become white or gray; it has the inconvenience of rendering the hair crisp and brittle. (a)

(a) More illustrious examples might be cited in the cases of Sir Thomas More, Marie Antoinette, Queen of France, Mary, Queen of

1219. When canities is partial, and consequent upon a chronic inflammation of the scalp which has extended to the piliferous bulbs, the hair, although thrown out, or eradicated, is often produced with its pristine form and colour. It sometimes happens that a hair is partially secreted white, and partially coloured. When eradicated, these hairs are followed by others that are generally entirely coloured. Veterinary surgeons have made similar observations upon animals. Horses exhibit white hairs upon the cicatrices of any wounds they may have chanced to receive; these hairs are frequently replaced by others of the colour, or very nearly of the colour of the animal; more frequently still, however, a second crop of white hair succeeds that which is lost; and sometimes the parts once denuded are never covered again. It is almost superfluous to say that those parts whose bulbs have been destroyed by wounds, ulcers, &c., are never covered with hair at all.

#### Historical Notices.

1220. The ancients<sup>1</sup> ascribed natural canities (πολιότης and πολιώς of the Greeks; *canities*, *canitia* of the Latins), to a deficiency of sap in the hair, comparing it to the change which the leaves of trees undergo on the approach of winter.

Celsus does not mention accidental canities. I have quoted several cases of premature blanching of the hair, in consequence of depressing moral emotions of different kinds, and have alluded to some extraordinary instances of sudden grayness occasioned by great mental anguish (§ 1216). Several other cases are mentioned by different authors.<sup>2</sup>

#### ALOPECIA. BALDNESS.

Vocab. *Area*, *Calvities*, *Ophiasis*, *Porrigio decalvans*.

1221. Under this title are designated the senile, accidental or premature, partial or total loss of the hair, and farther, the non-development of this appendage on those parts which are generally provided with it. These phenomena are, therefore, distinct from the loss of the silky and colourless down observed on the body of the fœtus, which is detached as well previously to birth as after that event; it is also different from the moulting, or periodical fall of the hair and feathers among the lower animals.

The scalp and chin, especially the former, are the usual seats of alopecia in man; the genital organs, axillæ, eyebrows, and edges of the eyelids in both sexes, may be affected with general or partial baldness. (a)

1222. *Congenital absence*<sup>3</sup> and *ulterior defective development* of the hair are phenomena of considerable rarity, which I have nevertheless had opportunities of observing. Such was the case of the man Beauvais, who was a patient in the hôpital de la Charité, in 1827. The skin of this man's cranium appeared completely naked; although on examining it narrowly, it was found to be beset with a quantity of very fine white and silky hair, similar to the down that covers the scalp of infants; here and there upon the temples there were a few black specks occasioned by the stumps of several hairs which the patient had shaved off. The eyebrows were merely indicated by a few fine and very short hairs; the free edges of the eyelids were without cilia, but the bulb of each of these was indicated by a small whitish point. The beard was so thin and weak that Beauvais only clipped it off every three weeks. A few straggling hairs only were observed on the breast and pubic region, as in young people on the

approach of puberty. There was scarcely any under the axillæ. It was rather more abundant on the inner parts of the legs. The voice had the pitch and intonation of that of a full-grown and well-constituted man. Beauvais is also rather of an amorous disposition,—he has had syphilis twice. He tells us that his mother and both his sisters have fine heads of hair, whilst his father presented the same defect in the commodity of hair which he does himself.

The loss of the hair in consequence of the advance of years (*calvities*), happens slowly and progressively, without appreciable alteration in the scalp. Among men who are bald, the hair of the whole upper and anterior part of the head is generally lost, so that nothing more remains than a semicircle of hair extending backwards from the one temporal region to the other. Among women the hair becomes white; but bald women are much more rarely met with than bald men. Bichat has observed that before the hair drops out in the aged, the bulbs become gradually shallower, and that the slender canal which receives the roots, ends by disappearing. The follicles are also destroyed in certain partial baldnesses occasioned by the development of subcutaneous tumours. On the other hand, Bichat, in the body of a man almost completely bald, who had died of a fever which is designated as *putrid*, met with the slender conduits in their normal state, and even containing small sprouting hairs at their bottom. There is, therefore, a difference between the fall of the hair in the aged, and that which is occasioned by certain diseases. The whole secreting organ perishes in the first, the stem of the hair alone is detached in the second.

1223. *Partial alopecia* may be the consequences of various alterations of the secreting follicles of the hairs.

1st. Some of these cases occur in convalescence from acute diseases, and appear to have been preceded by slight erythema, or pityriasis of the scalp. This loss of the hair is often accompanied with a pretty copious furfureous desquamation. The comb then detaches a large quantity of epidermic furfuræ, which are renewed with great promptitude; the skin under them is generally found to be erythematous. In this variety of alopecia the hair falls off by degrees from the whole surface of the scalp. The hair looks thin, dry and brittle.

2d. In other instances the hair falls off in consequence of various morbid affections of the skin, as of sycosis, impetigo,<sup>4</sup> favus, syphilitic eruptions, morbid secretions of the sebaceous follicles, &c.

3dly. Alopecia is also occasionally the consequence of inflammation of the piliferous bulbs, induced by the previous occurrence of favus, impetigo, chronic eczema, &c. I once saw a young woman labouring under impetigo sparsa of the whole surface of her body, who lost her nails, her epidermis and her hair simultaneously. (a)

(a) The remote causes of alopecia, acting by constitutional disturbances, or modification of nutrition, are well exhibited in the following

<sup>4</sup> Impetigo; loss of the eyelashes and hair of the head. P \* \*, twenty years of age, entered La Charité, April 3d, 1827, labouring under impetigo of the upper lip and nose. For seven months he has had a constant discharge from the nose; during the last two, incrustations have been formed on the alæ nasi, septum and upper lip. These are now from two to three lines in thickness and almost obstruct all access to the nostrils. Several pustules evolved nearly an inch from the alæ nasi, and on the surface of the chin, have all the characters of those of impetigo. The right eye is inflamed; the eyelids also inflamed have lost their cilia here and there. (V.S. ad §xii; veal broth with two drachms of sulph. sodæ.) The incrustations were got rid of by means of emollient cataplasms, and the course which is proper in these cases was prescribed (vide Impetigo) with such success, that the patient left the hospital well on the last day of April. He had a relapse, however, and returned on the 16th of May, the disease having now attacked the scalp, and the hair of the districts implicated being much thinner than elsewhere. Sulphureous washes and baths, infusion of wild endive with a course of sulphate of soda, dissipated the disease a second time before the 1st of June, when a fresh crop of hair was beginning to appear on the regions that had been made bald.

Impetigo of the left cheek; permanent alopecia; Siroux, a dyer, was attacked when two years old with impetigo of the left cheek, and since this time the same disease has recurred repeatedly. He had been twice a patient in the Hôpital St. Louis, and I had myself had him as often under my care on account of it. The disease has constantly recurred upon the left cheek, between the temporal region and the chin, and between the ear and nose. In some of the previous attacks, the beard of this side of the face had fallen out, and in many places had never reappeared. There are now but a few straggling and colourless hairs, which may be pulled out with the greatest ease. On the right side the beard is rather strong. It is probable that the repeated attacks of inflammation of the left cheek, have ended by destroying or altering very materially the piliferous bulbs of the part and rendered them incapable of performing their office.

Scots, &c. I knew two individuals whose hair had become prematurely white from strong mental emotion—fear and anxiety.

(a) Men are much more frequently affected with alopecia than women.

<sup>3</sup> Danz met with two Jews who had neither hair nor teeth. (Starks, Archiv. fuer die Geburtshülfe, Bd. iv. p. 884.)

4thly. One of the most remarkable varieties of alopecia, is that which Willan has described under the name of *porrigo decalvans*.<sup>1</sup> The scalp, or skin of the chin and cheeks of individuals affected

extract from an article on the subject, by Dr. Todd, in the *Cyclopædia of Practical Medicine* (p. 72-3):

"Alopecia may be a *sympathetic* affection, not a symptom of a constitutional disease, but caused by a diseased or disordered state of some other organ or system of organs. The most common form of this description which has come under our observation, is that which proceeds from chronic inflammation of the mucous membrane of the stomach, giving rise to a particular form of dyspepsia, which has, for this reason, been called *inflammatory*. Of this nature, probably, was that mentioned by Galen (*De Cur. Morb. Sec. Loc.*, lib. i. cap. 2.) arising from eating poisonous mushrooms; and that other noticed by Hippocrates (*De Internis Affectibus*, sect. 4.), in which the reader will readily recognize a well-marked case of the above-named form of dyspepsia (*gastritis chronique*), and to which case there is, in an excellent record of modern medicine, (*Journal des Progrès*, 1830, tom. ii. p. 43,) a parallel in form as well as in cause, and which, it is deserving of attention, was afterwards succeeded by an attack of diabetes mellitus. Of the same nature, also, was in all probability that species of alopecia termed by the Arabians (*Avenzoar*, *Avicenna*), *bilious*, in contradistinction to the other species which they called *phlegmatic*; which last, in all appearance, corresponded with that form described by Celsus as most difficult of cure, 'pejus est quod densam cutem et subpinguem ex toto glabrum facit,' coinciding with the observation of some modern writers, that if the skin is pale or insensible, and it is difficult, by friction, to produce redness, the case is irremediable. Of the same nature is the case given by Lemery, of a man, who, some months after excessive catharsis, lost successively all the hairs from his body; and also another strikingly singular case, which, both in its cause and its cure, justifies the opinion which we have ventured to give of the nature of this species of alopecia. It is so illustrative that no apology is required for relating it. "Lodovico Gnemmi, a Piedmontese, fifty-seven years of age, a person of great vivacity of temper, of a plethoric habit, but spare form of body, having the skin of a dull white colour, began, in the winter of 1825 and 1826, to feel severe pains in the head, with a sensation of burning heat over all the body, but most particularly in the skin; it was to such a degree, that, during the coldest night of winter, he was obliged to throw off his bedclothes. After having passed fifteen days in this painful state, he began, by degrees, to lose all the hairs of his head, then those of the beard, eyebrows, eyelashes; and in the course of a month, there was not to be found a hair upon the surface of his body, neither in the arm-pits, on the breast, on the genital organs, surrounding the anus, nor upon any of his extremities. All his skin was as smooth as polished marble, and the slightest trace of hairs could not be felt by the hand. He remained for two years in this state, so deformed by the loss of his hair that he hardly ventured to show himself in public, but always feeling on the surface of his body a sense of pungent acrid heat, more especially on the surface of the scalp, which was always morbidly sensible and painful to the touch. In the beginning of March, 1828, he was attacked with a severe peripneumony, which was treated and cured by the most active antiphlogistic remedies, viz.: low diet, general and local blood-letting, cupping, purgation, blisters, &c., and, strange to say, under the influence of this treatment, on the decline of so severe an inflammatory disease, and in a state of the greatest weakness of the circulation, the hairs which had disappeared for the space of two years, began again to shoot forth, and continued to do so during all his convalescence. On their first appearance they resembled fine soft wool, almost colourless wool; but they continued, every day, to approach nearer to their natural character, which they had fully recovered at the end of a month, when, owing to some imprudence in regimen, he was seized with an acute attack of gastro-enteritis, which carried him off." (*Journal des Progrès*, tom. xiv. p. 244.)

"Of the same nature, also, are many cases of partial alopecia (por-

with this disease, presents one or more circular patches, entirely divested of hair, though surrounded with as thick a growth as is usually met with. The skin of these patches is smooth, without redness, and often even of remarkable whiteness. The areas of these patches extend gradually. When several exist near each other, they often end by uniting,<sup>2</sup> and if allowed to go on unchecked, a large portion of the scalp may be thus completely stripped of its covering. Neither vesicles nor pustules, nor any other form of eruption exists on the surface of these patches. *Porrigo decalvans* differs essentially in this particular from the partial baldnesses which are observed after favus, the annular syphilides, &c.

The first hair reproduced on the surface of these bald patches, the skin of which, as has been said, very often appears somewhat blanched, is generally finer and of a lighter colour than the old hair in its vicinity. I have observed this affection both among children and adults. I am not acquainted with the cause or causes which occasion it.

1224. The Messrs. Mahon, under the title of *teigne tondante*,<sup>3</sup> have described a disease of the scalp, which both in its form and in many of its characters, resembles *porrigo decalvans*, but which differs from this affection in the appearance of the surface affected and the presence of several altered and brittle hairs. On one or more circular patches, the hair appears broken off to within a line or two of the skin. The surface of these patches is extremely dry, and presents *asperities*, cognizable by the eye, but especially by the touch, like the skin of a fowl. The part affected is slightly bluish, and by scratching, a fine and very white powder can be detached from its surface. The affection begins in a point which spreads from its circumference; a similar spot often forms in the neighbourhood of the one which appeared first, and the two may unite; the authors quoted have thus, in three or four instances, seen the head become entirely bald, and covered with *asperities*. They have observed the affection among several members of the same family.

This variety is extremely rare; I have only seen a single case of it in a child.

1225. Alopecia is occasionally a symptom of constitutional syphilis. This effect of the venereal poison, which is mentioned by Ragonus, Fallopius, Massa, and Fracastorius, differs from the partial baldness occasioned by the development of syphilitic tubercles or ulcers, inasmuch as the skin does not appear altered. Alopecia from this cause is extremely rare at the present day.

1226. The existence of mercurial alopecia is extremely equivocal.

(*porrigo decalvans*), which we have observed in adults as well as in children, and which we have had the satisfaction of remedying by treating the primary disease—chronic gastritis, or inflammatory dyspepsia.

"This origin of alopecia also accounts for the connection which we have observed between it, lichen, urticaria, and pityriasis; sometimes coexisting; sometimes succeeding each other; all differently modified operations of the same cause.

"To this description of alopecia ought probably to be also referred those which have been attributed to the use of certain kinds of food, and which have been said to prevail at particular places. Thus it is said not to be unfrequent in countries where the inhabitants live chiefly on fish; as, for instance, formerly in the Shetland Islands, where baldness from this cause was so common, that it was a familiar saying that 'there was not a hair between them and heaven.' (Sir R. Sibbald's Description of Shetland.) Thus Tournefort relates, that in the island of Mycone, one of the Cyclades, the children are either bald, or seldom arrive at the age of twenty without being so. And, though it is difficult to assign the cause, it must be acknowledged that alopecia (*porrigo decalvans*) has appeared to be more common at Brighton than in other places, and that all the cases the writer has observed in this place have afforded symptoms of chronic irritation of the mucous membrane of the stomach."

The influence of constitutional causes, by enfeebled or perverted nutrition, is manifested in the falling off of the hair during phthisis; and after protracted fevers, and gout and rheumatism. Pregnancy is sometimes an exciting cause.

<sup>1</sup> Dr. Elliotson met with a case of extensive *porrigo decalvans* in a child, who was at the same time affected with symptoms of a disease in the brain. *Lond. Med. Gaz.*, vol. vii. p. 639. *Ibid.*, vol. viii. p. 30. *Ib.*, vol. xi. p. 229.

<sup>2</sup> This is probably the state which the ancients described under the name of *ophiasis*.

<sup>3</sup> Mahon. *Rech. Sur les Teignes*, p. 133.

I have seen a great number of gilders, silverers of mirrors, &c., in the different hospitals of Paris, affected with tremblings and paralysis of the limbs, but in none of them did the mercury appear to have exerted any unusual influence on the hair. (a) Nevertheless in Forestus we read of the *loss of the hair*, accompanied with trembling of the extremities, and other accidents produced by mercury in a young gilder, eighteen years of age, (Forest, Opera, lib. viii. obs. 5). Arsenic would seem to have a more direct action upon the hair follicles of the skin; it consequently enters into the composition of a number of *depilatory* preparations. (b)

The beard may be affected with the whole of these varieties of alopecia, even with the affection denominated *porrigo decalvans*. It is more rarely that we observe the transient or permanent loss of the hair of the trunk and extremities.

Alopecia has been seen evolved on one side only of the body. There is a case related by Ravaton, of a man, who, after a violent paroxysm (of rage), was attacked with amaurosis of the right eye, and with blanching and loss of the hair, eyebrows, and eyelashes of the same side.

1227. Alopecia, to conclude, may be *general*.<sup>1</sup> The hair of the head, axillæ, pubes, &c., is then lost gradually and successively. Lemery tells us, that a man, after enduring hypochondriasis for several months, observed the hair gradually falling off all parts of his body. At the end of a year from this time his body was still naked; the beard, which had formerly been strong, was now extremely thin; the hair alone had come in as thick as ever, but much finer in its quality.

We have just seen, says Peter Frank, a young man attacked with *general alopecia*. Except having had the venereal disease, from which he recovered, about thirteen years before, this patient has never been unwell; his health, indeed, at this time appears to be perfectly good. Nevertheless, about two months ago, he lost the whole of his beard, almost his entire head of hair, his eyelashes, and the hair of the pubes. The nails are, at the same time, lifeless, and consumed by a kind of dry sordes. The whole of this man's organic and animal functions appear to be in a state of perfect integrity; the sexual appetite is not implicated, and his voice is unchanged. He only complains of a feeling of weakness during the last few days. (c)

1228. *Treatment*.—The baldness of old age is incurable. *Congenital* alopecia is generally the effect of a tardy development of the hair which does not appear till towards the end of the first or second year. In some very rare cases this baldness is permanent, in consequence of the follicles being wanting.

The treatment of *accidental* alopecia is as various as that of the conditions which give rise to it. When it is occasioned by eczema, impetigo favus, &c., no other form of medication is required than such as is proper in these diseases. When these get well the hair sprouts naturally of itself,<sup>2</sup> unless the bulbs have been deeply altered, when no kind of *trichogenous* pomatum or oil avails to make it sprout again. When the skin is dry, tense, and furfuraceous, it is often well to shave the parts affected, and to anoint them with oil, or any other unctuous substance.

In the affection called *porrigo decalvans*, and in all those cases of baldness that do not appear to be accompanied with inflammation of the skin, and consequent implication of the piliferous bulbs, we have been recommended to stimulate the parts affected with decoctions of

walnut-tree leaves, of the leaves of the *solanum nigrum*, of the *centaurea minor*, of mustard-seed, or with vinous or spirituous aromatic washes of various kinds, with unguents of cantharides, embrocations of the essential oils, as of the thyme, lavender, chamomile, &c., but I cannot take upon myself to say how far these applications are calculated to determine or to increase the secreting powers of the piliferous bulbs, having employed them all, without any very evident advantage, in different cases of the affection entitled *porrigo decalvans*. [The translator has known the *common mercurial ointment*, used upon the patches, useful.] (d)

The *tinea tonsura* (Mahon) is also a very obstinate affection.

#### Historical Notices and particular Cases.

1229. Baldness (the *μαδαρόσις*, *φαλακρόσις* of the Greeks, the *calvities* of the Latins), was anciently distinguished from the morbid fall of the hair, entitled *ἀλωπεκία* and *ὀφίασις*, the skin, in these affections, being blanched in the parts implicated. Both of these varieties have been included by Celsus, under the name of *area*; *ophiasis*, in fact, does not differ from *alopecia*, save in its serpentine form. The fall of the

(a) Dr. Todd (*op. cit.*) thus sums up the treatment of alopecia.—It would be difficult to say as much to the point, in the same compass.

“From the distinctions of the different forms of alopecia which we have endeavoured to point out, may be easily understood how it may sometimes have been cured by phlebotomy; by local depletion, as leeches, scarifications, and acupuncture; by purgatives, low diet, and other antiphlogistic remedies; how, at other times, simple local means may have succeeded better, as friction, no matter whether with the fat of the mole, the snake, the hedgehog, or the bear; or with warm exciting substances, as camphor, turpentine, naphtha, laudanum, resin; with volatile oils, as those of laurel, rosemary, mace, or cinnamon, or with the distilled water of bees-wax; with acrid substances, as thapsia, euphorbium, stavesacre, nasturtium, mustard-seed, garlic, onions, and tincture of tobacco; with irritating applications, as friction with fig-leaves, nettles, tincture of cantharides, and even the application of a blister; how at other times advantage may have been derived from alkaline ingredients, which explains the use of the laxisia of wood-ashes, of burnt-cane, of the burnt hair of bears, and of applications containing the bile of different animals, and the ordure of birds, as the ancient remedy of *stercus columbinus*; how at other times such astringent applications as alum, cimolian earth and wine, or green vitriol, the *atramentum sutorium* of Celsus, may have answered better; and how, whatever be the form of the disease, or the nature of the treatment, the frequent shaving of the diseased parts, which has been recommended by all writers, is a remedy always applicable.

“When there exist signs of an inflammatory state of the pilous follicles, or erythema of the surrounding skin, leeches may be applied with benefit, and a course of purgative remedies is of great service. But when the disease of the follicles appears to arise from an inflammatory state of the mucous membrane of the stomach, leeches must be applied to the *scrobiculis cordis*, and a regimen of mild bland diet must be insisted upon. In the first case the best local application is any mild demulcent liquid, as decoction of bran, or mallows. But when the skin, from which the hairs fall, indicates a deficient degree of vitality, the parts may be excited by local stimulants. (R. *olei macis* ʒii; *alcohol* ʒiv. M.) Penciling the surface with a solution of nitrate of silver, or rubbing it with a liniment of olive-oil, and as much nitric acid as makes it pungent, but not acrid, has been found to answer the same purpose. Of the use of the celebrated oil of Macassar in such cases we have no experience, but the solution of sulphate of copper in alcohol, lately very much recommended by a German physician, has failed in our hands. When the skin is furfuraceous, or the cuticle hard, shining, and impermeable, like parchment, it is of great use to wash it frequently with some alkaline or sulphurous solution (R. *Liq. ammoniæ acetatis* f.ʒii; *ammoniæ carbonatis* ʒii; *alcohol* f.ʒss; *aq. fontan.* f.ʒiv. *Fiat lotio*). But when either of the foregoing states of the skin is connected with a deranged state of the general health, it is unnecessary to say that this demands the chief attention.”

(a) Mr. Lugneau (*Diction. de Med.*), participates in this opinion.

(b) Late hours, and their frequent concomitants, intense thought, dissipation, also excessive venery, rank among the remote causes of alopecia.

(c) Syphilitic alopecia has been already described (§ 925).

<sup>1</sup> Heister (*Misc. Nat. Cur.*, dec. 1, ann. ii. obs. 103). P. Frank (*Epitome de curandis hom. morbis*, t. iv. p. 124), and Wells (*Transact. of a Society for the improvement of Medic. and Chirurg. knowledge*, vol. ii. pp. 264–267), have related cases of general alopecia. There is one particularly detailed by Negronis, in the *Journ. Gén. de Méd.*, vol. v.—*Dict. de sc. méd.* Art. *Cas rares*. General alopecia has been seen to follow intermittent fever. (*Gaz. des Hôpitaux*, t. vii. p. 422.—*Gaz. Méd.*, 1834, p. 564.)

<sup>2</sup> When the hair is reproduced, after alopecia, it is not always restored of the same colour as that which was lost. (L. Lemery. *Obs. d'un homme de 45 ans, robuste et fort velu, lequel perdit son poil, qui était noir et qui revint blond*.—*Mém. Ac. sc. Paris*, an. 1702, hist. p. 29.)

eyelashes received the name of *ptilosis*, from the Greeks, and this title it has retained. Mercuriali treats of these affections at length; but he ought to have distinguished them from the fall of the hair—the *degluvium capillorum*, which occurs as a consequence of many acute diseases.

The loss of the hair, as a disease, or a symptom of disease, has not been viewed as possessing so much importance in modern times, except during the prevalence of Greek elephantiasis and syphilis, in the middle ages, when it constituted one of the striking features in these diseases.

Willan, as the name implies, chose to class circumscribed alopecia among the porrigo, with the epithet *decalvans*.

CASE CXc.—*Alopecia of the scalp, under the form of circular patches. Alopecia circumscripta* (Porrigo decalvans, Willan). A. T. Doucet, eight years and a half old, was presented among the out-patients at the Hôpital de la Charité, June 16th, 1827. This child is well grown for his years. He has laboured for several months under partial alopecia of the scalp, in the form of circular irregularly circumscribed patches. The oldest of them appeared about seven back, on the upper and posterior part of the head, and has extended gradually, till it is now an inch and a half in diameter. Examined narrowly, its surface is found to be covered with a considerable quantity of fine downy colourless hair. Other three patches were formed from three to four months ago; the largest of these is an inch in diameter. The skin is free from all traces of inflammation; neither is there any desquamation from the parts affected. The patches are smooth, and look paler than the rest of the scalp; the hair is as thick immediately around them as it is elsewhere. The fall of the hair goes on circularly and without changing colour previously; the fall is certainly owing to an affection of the secreting bulb, the precise nature of which it is impossible to specify. There are a good many pediculi on the surface of the scalp, which is quite free from vesicles, pustules, seabs, &c. The affection seems to implicate the piliferous bulbs alone. The father of this child informed us that he had never had any thing the matter with his head beyond what we saw. The glands of the neck were neither painful nor enlarged; the principal functions were regular. The father, having informed us that the down upon the largest patch had appeared since he had rubbed the part with butter, I recommended him to continue the same application.

CASE CXCI.—*Partial alopecia of the scalp and beard, preceded by blanching of the hair over the affected patches.* O. Duvau, twenty-five years of age, of a sanguine temperament, having chestnut hair and a brown beard, presented himself among the out-patients at the hôpital de la Charité, April 4th, 1827. On the left side of the chin there was a whitish circular patch, twenty lines in diameter, devoid of beard on a cursory view, although, when examined more narrowly, it was found to be beset with a fine, soft, and colourless down. The spot was the more remarkable from being bounded by the brown stubble of the beard. The hair began to be detached from it from eight to ten months ago; and it enlarged circularly, from the centre towards the circumference. Another small spot, about half an inch in diameter, occurs towards the middle of the lower margin of the jaw, and on the opposite side of the face there is a third spot, nearly of the same dimensions, which dates about four months back, and has long continued stationary. On the right parietal region there is a tuft of light hair, covering a surface of about an inch in diameter, which succeeded a corresponding tuft of the chestnut hair that suddenly became white, and fell off without any appreciable cause. Several of the individual hairs of the whiskers have turned in the same manner. Although the skin of the naked patches presents no signs of inflammation, the patient assures us that he feels a kind of numbness in the parts, and that their circumference, especially on changes of weather, is tender to the touch. The hair upon the axillæ and genital organs presents nothing unusual.

This patient had a gonorrhœa about eighteen months ago, that is to say, previously to the affection of the hair bulbs. He caught a second about six months since; in both instances he was treated by means of diluents, and the disease lasted several months; the naked patches showing no disposition to extend, and new hair even beginning to appear on their surface, I did not recommend any of the topical applications usually prescribed in these cases. I had but recently

gone the round of them without manifest advantage, in the case of a young man, affected exactly in a similar manner, for whom M. Bourdois de Lamotte was also consulted.

## SPECIAL DISEASES OF THE UNGUEAL MATRICES AND OF THE NAILS.

1230. The greater number of the alterations which the nails undergo depend on an affection of the portion of skin which secretes them. Still, they may be modified in their conformation and texture without the skin which produces them appearing to have suffered any appreciable lesion. Of this kind especially are the changes produced by the habitual contact of the alkalies, acids, neutral salts, various colouring matters, &c.<sup>1</sup>

1231. The portions of skin which secrete the nails, and which are in relation with them, are subject to inflammation of different kinds (*onychia*). They are also liable to a variety of other diseases, which are common to them and the other regions of the body, such as ecchymosis, eczema, psoriasis, lepra, &c.

### ONYCHIA.

1232. The matrices of the nails are liable to become inflamed during the course or as a consequence of different cutaneous phlegmasiæ. These pulpy and vascular tissues, however, do not present such a variety of forms of inflammation as the skin at large. I designate under the general title of *onychia*, the whole of the inflammatory affections of that portion of the corion which is in relation with the nails.

1233. Onychia may be *partial*, or *general*. It may occur on the edges or towards the root of the nail. It also presents specific characters according to the cause which has produced it, and as the disease assumes an *acute* or *chronic* type. The following varieties of the affection have been distinguished. 1st. Onychia from *outward violence*. 2d. *Lateral onychia*,—the nail growing into the skin. 3d. Onychia from an *internal cause* (*onychia eczematosa, scrofulosa, syphilitica*, &c.).

1234. Onychia from an outward cause.

1235. 1st. One of the most common varieties of onychia is that which is occasioned by contusions of the ends of the fingers, and by punctures under the nail. Punctures of this kind, though trifling in appearance, are often followed by acute inflammation of the matrix of the nail, characterized by heat, acute pain, and, by and by, the formation of a layer of pus between the skin and the nail. A quantity of purulent serum is now secreted around the nail, between it and the epidermis, which is detached after having been raised by pus effused beneath it. At length the nail drops off, after a lapse of time of various extent, the shorter commonly as the inflammation has been more acute; the dermis is then exposed, and a new nail is not in general long in being reproduced.

This inflammation, which has been classed by several pathologists along with panaris (*whitlow*), or phlegmon of the points of the fingers,

<sup>1</sup> Hippocrates studied the nails with reference to diagnosis and prognosis. De intern. affectionibus, sect. v. p. 549, ed. Foës.—Ibid. Prænotionum liber, p. 39.—De morbis: καὶ ὁ θυμὸς ἰκκύνται, unguis adunci. Celsus was the first who described onychia. Avicenna (Libri in re medicâ omnes, Venet., 1564, lib. iv.), speaks of the different alterations the nails undergo, of their inflammation, their fissures, their deformities, their becoming white, of sub-ungueal ecchymosis, &c. Sennertus (Opera, t. iii. De Unguium vitiis, p. 858), mentions the greater number of the affections to which the nails are subject: "Ungues crassi, inæquales, rugosi; unguium labrities; unguium color mutatus; curvatura unguium; fissura unguium; unguium casus; redutivæ; paronychia." The diseases of the nails have in fine been especially studied by Franc. de Franckenau (Geo. Fred.) (Onychologia curiosa, sive de unguibus tractatio physico-medica, non tantum eorum physiologiam ac therapeiam tradens, etc., 4to. Jenæ, 1641), Werner (Diss. de unguibus humanis varioque modo quo possunt corrumpi, 4to. Lipsick, 1773), Bleck (Philipp. Ed.) (De Mutationibus unguium morboris, cum tabula æneâ, etc., 4to. Berolini, 1816), and Patissier (Art. Ongles, Dict. des Scienc. Méd.).

is, however, a very different affection. It commonly resists emollient applications, fomentations, the local abstraction of blood, &c. When it is caused and kept up by a foreign body under the nail, this part must be cut and scraped down, until nothing more remains than a thin, soft and unresisting lamina, and this being divided, the pus which has been secreted is allowed to escape, and the foreign body is easily extracted. This plan of proceeding is much better than to divide the nail forcibly and at a single stroke either of the knife or scissors.

1236. When this kind of onychia is caused by a *bruise*, the nail may be split; the matrix then becomes deeply altered, secretes, for a great length of time, a sanguinolent and very fetid matter, and the skin and subjacent cellular membrane often become the seat of most painful inflammation, which must be treated by absolute rest of the part, general blood-letting, the local application of *leeches*, emollient cataplasms, and fomentations, &c. Among the aged, and in scrofulous subjects, a wash of a solution of chloride of lime is successfully used to destroy the fetid odour of the discharge.

1237. 2d. A second and not less remarkable variety of onychia is that which is commonly spoken of, as *the nail growing into the flesh*.<sup>1</sup> This affection is often the result of the mechanical irritation accidentally caused by the nail in consequence of a faulty configuration, irregular growth, a great convexity, &c., of the part. It is also induced, perhaps more frequently than by any other cause, by the pressure of tight shoes.

1238. The great toe, and especially its outer edge, is almost always the seat of this kind of onychia; it is at all events extremely rare in the other toes, and never occurs in the fingers. In the beginning of the affection the patient experiences a certain degree of difficulty in walking, to which he very commonly pays little or no attention; the pain, however, increases, and the skin where pressed upon by the edge of the nail gives way; walking now becomes almost impossible; an ulcer is formed covered with sprouting fungi, so acutely painful as to prevent the patient from putting his foot to the ground. At a still later stage, the inflammation extends to the root of the nail, which then becomes partially loosened. The patient, if he attempts to walk at all, can now only do so by resting his heel on the ground. The suppuration is often profuse, being poured out from the surface of a soft and spongy fungous mass, and is rendered more offensive by being mixed with that of the perspiration of the feet. When left to itself, the fungous growths become larger and larger, and the inflammation sometimes extends to the periosteum and bone.

1239. This variety of onychia is said to have been mistaken for gout in a particular case. Such a mistake could only have arisen from a very superficial examination of the parts affected. It is more difficult to distinguish the accidental form of the disease now described from certain other varieties. Still, as Dupuytren has judiciously observed, the fungous excrescences to which partial lateral onychia, caused by the mechanical irritation of the nail, gives rise, occur in front of and on the side of the nail, whilst in the onychia that is independent of this cause, the fungous excrescences commonly sprout from the root of the nail.

1240. When *lateral accidental* onychia has only existed for a few weeks, and the affection has evidently arisen from the pressure of the soft parts against the edges of a hard and crooked nail, this may be cut away or reduced in its thickness, whilst the pressure of the neighbouring toes is prevented by a pad of cotton or wool put between these and the suffering member; and this, with rest for a time, the use of emollient cataplasms and fomentations, and a shoe sufficiently easy afterwards, will often prevent the disease from going further, and even effect its cure. But when one of the edges of the ungual matrix is deeply cleft, ulcerated, and covered with fungous excrescences, other steps are required to remedy the evil. Albucasis and Paul, of Ægina, recommended us to detach the nail from the neighbouring parts, with a probe, and after having raised it, to remove the fungous excrescences surrounding it with a knife, and afterwards to

touch the surface with some form of liquid caustic. The actual cautery was also once in vogue for this disease, and has been used lately by Mr. Wardrop. Ambrose Paré directs us to push a straight edged bistoury through the base of the soft parts covering the nail, to remove these, and then to cauterize with the red hot iron. This procedure of the old surgeon has been recently employed by Messrs. Lisfranc and Brachet, with success. Fabricius ab Aquapendente recommended little pads of lint to be insinuated under the edge of the nail raised and gently loosened from the parts below it, and the fungous excrescences to be flattened by direct compression. Desault modified this procedure, and placed a piece of tinned iron of proper breadth and bent into a gutter, between the edge of the nail, and the soft parts around it, at the same time that he used compression to reduce fungous flesh. Richerand proposed to replace the tinned iron plate towards the end of the cure by a piece of sheet lead. This mode of treatment, which is both painful and of difficult execution, is frequently followed by relapses. M. Guibourt advises the half of the nail on the healthy side to be cut away by thin lamellæ. The nail being then no longer compressed on this side, grows towards it, and escapes from the tender and irritated structures of the diseased side, so that at length the cure is accomplished. Faye would have us to reduce the thickness of the middle of the nail in the direction of its length by scraping, then to make an incision in the form of the letter V, the base towards the free end of the nail, removing the parts included between the legs of the letter, and lastly, by means of a fine metallic wire, passed through holes drilled in the free extremity of the nail, to approximate the edges of the wound. The portion of the nail that presses in upon the quick is thus elongated from the tender parts, and the cure is effected. Dupuytren employs the following plan. The patient is seated on a chair before the surgeon, who passes one blade of a pair of straight, strong and sharp scissors rapidly under the middle of the nail nearly to its base, and divides it at a single stroke. He then, with a pair of pliers, seizes that half of the nail which keeps up the disease, by its anterior part, or both halves in succession, according to circumstances, and by turning each back upon itself, detaches it from its connections with the matrix. He next applies the actual cautery to the fungous growths, if they chance to be very considerable. This procedure is extremely painful; but it frequently leads to a speedy and permanent cure.

1241. Onychia from an internal cause.—Five principal varieties of this affection are reckoned: 1st. Onychia *eczematosa*; 2d. Onychia *squamosa*; 3d. Onychia *scrofulosa*; 4th. Onychia *syphilitica*; and 5th. Onychia *maligna*.

1242. 1st. *Eczematous* onychia generally attacks the matrices of several fingers or toes, at the same time that eczema appears on some region or other of the body. I once saw an old man above eighty years of age, who, at the age of twenty-one, had had an attack of gout for the first time, and had every year, for nine successive years, had a severe return of this complaint. A milk diet continued undeviatingly for three years, interrupted these renewals of the gout, which was thirteen years in showing itself again. Since then it has recurred at various intervals, five or six years generally elapsing between each new attack. This old man remembers to have had a *tettery affection* of the axillæ when he was about eighteen years of age, which was attended with considerable discharge. For the last twelve years he has been subject to eczema, at one time in the squamous, at another in the humid state, between the buttocks and about the margin of the anus. Two years ago an affection of the same kind made its appearance about the nails of the toes, and subsequently about those of the fingers. The nails of the toes are particularly remarkable for their deformity; they are of a greenish-yellow colour, and are detached from their matrices, being raised upon a mass of solid matter of the same colour, and of a faint and sickly smell, three or four lines in thickness, which even extends beyond their ends and edges. The nails are painful when cut, the action of the knife or scissors jarring the roots. A yellowish liquid matter occasionally exudes from under the lateral parts of the nail, which are then more than usually painful. I did not recommend any active form of treatment in this case to the eczema of the breech and nails. The patient was merely advised to keep the parts clean, and small doses of sulphur were prescribed internally. It is now three years

<sup>1</sup> Royer-Gollard (Hypopl.). De quelques altérations des ongles et de la peau qui les environne (Répertoire général d'Anatom. et de Physiolog. Patholog., etc., 4to. t. ii. 1826).—Robbe (L. C.). Que l'affection désignée sous le nom d'ongle rentré dans les chairs se compose de deux affections entièrement différentes par leurs causes, leur nature et leur traitement, 4to., 1826.—Michaelis. Considérat. sur l'ongle rentré dans les chairs. (Journ. complém. des sc. médic., t. xxxviii. p. 373.)—Lawrence. Lectures on onychia and paronychia. (Lond. Med. Gaz., vol. vi. p. 226.)

since he consulted me, and, notwithstanding his great age, his general health has improved.

I once gave my advice to a woman who was affected with a running eczema, entirely confined to the last phalanges of the fingers, and even to the parts over the roots of the nails, without implication of their matrices.

1248. I have already given the characters of *squamous* onychia (686), of *scrofulous* onychia (739), and of the onychia that is a consequence of the venereal disease, (926). To complete the history of this form of the affection I subjoin the two following cases from M. Lelut's paper.

CASE CXCH.—*Venereal infection. Onychia.* J. L., a widow woman, aged thirty-seven, underwent a mercurial course for the first time at the hôpital des Vénériens, on account of an eruption of pustules upon the skin, and a discharge from the vagina. When the patient left the hospital the eruption had disappeared, but the discharge continued, and there was a slight sore at the left corner of the mouth. A week afterwards, this sore spread, aphthæ appeared in the mouth, and the eruption of the skin recurred. The patient was put anew upon a course of sudorifics, and of corrosive sublimate, and all symptoms of disease disappeared, except the leucorrhœa. In the month of September, the patient, to relieve a violent headache, put her feet into hot water with a quantity of flour of mustard in it. Almost immediately afterwards the toes of the right foot became chapped; the parts around the nail of the left forefinger next inflamed and suppurated, and the left thumb, the right forefinger and thumb, and all the toes of the right foot became affected successively in the same manner. The patient returned for the third time to the hospital on the 10th of October, labouring under the infirmity described, incapable of walking or of using her hands. (*Emollients; leeches to the back of the right foot; veal broth.*) 13th. The nail of the left finger was taken away. 20th. The extremity of this finger has the form of a spatula; red vascular lines appear on the back of the left hand (*leeches*). The last days of October, tumefaction of the lymphatic glands of the inner aspect of the left arm (*the sore of the great toe only dressed with calomel ointment*). The nails of the thumbs are forced forwards without being completely loosened from their matrices. The horny laminae of the nail appear on the matrix of the left forefinger; the sore of the great toe, behind the root of the nail, bleeds: the nail of the right forefinger is taken away; new horny lamellæ show themselves on the back part of the sore of the left forefinger, and by and by on that of the right. Nov. 5th. The nail of the great toe removed. The whole of the sores are dressed with a weak solution of chloride of soda in water. No mercurial medicine is prescribed; the sores are all cicatrizing. The thumb nails are growing with all their normal characters. Nov. 21st. A piece of the nail of the great toe that had been left is taken away, and the sore soon cicatrizes, but no new nail is reproduced. The sores of both forefingers are also healing around the horny plates of the matrix. Dec. 2d. The nail of the left great toe is detached spontaneously without pain. 5th. The patient left the hospital with the whole of the ulcers cicatrized.

CASE CXCHII.—*Venereal infection; onychia.* A. M\*\*\*, aged twenty-two, a prostitute, was discharged from the Hôpital des Vénériens, in the month of August, 1826, after having gone through a mercurial course for an eruption of flat tubercles about the vulva, and a discharge from the vagina. On quitting the hospital, there were symptoms of incipient inflammation of the soft parts covering the ungueal matrix of the left forefinger. The right forefinger and great toe soon afterwards became affected in a similar manner. The patient returned to the hospital on the 21st of September. The nails of the fingers mentioned are partially detached; the suppuration under them is profuse and very fetid. The patient is put anew upon a course of the solution of corrosive sublimate, and afterwards of sudorifics. The sores are dressed with emollients and anodynes alternately, and the nails are extracted. The suppurating surfaces then look red and uneven; they are extremely tender, and surrounded with a prominent rim; the pain is very severe; the patient is incapable of walking; she sleeps badly, although she has a pill every night, containing a grain of the extract of opium. The sores bleed when exposed to the air; they are dressed with solution of chloride of

soda, and two grains of opium are prescribed instead of one. Leeches were subsequently applied to the left finger. The sores continue nearly stationary. In the beginning of November, anomalous horny plates begin to appear upon the matrices of the right forefinger and great toe; but the sores in general do not appear to have improved. Nov. 14. The nail of the forefinger is taken away. The anomalous horny plates increase in extent. The sublimate is continued. In the beginning of November, these horny productions are taken away, and the diseased ungueal matrices are touched with the actual cautery. After the detachment of the eschars, fresh anomalous horny plates are secreted by the matrices. The suppuration is still fetid, and the patient walks with great difficulty.

1249. Under the name of onychia maligna, Mr. Wardrop<sup>1</sup> describes an inflammatory affection, characterized in its earliest stages by a slight degree of swelling and a red circle surrounding the root of the affected nail. The thumb and great toe are much more frequently the seat of this affection than any of the other toes or fingers. The kind of crescent formed by the skin over the root of the nail by and by changes into a roll of a purple red colour, more elevated and more acutely sensible at the point where the nail appears to adhere most intimately; this is before long occupied by bleeding and fungous sores. Purulent matter, of a brownish, grayish, or greenish-yellow colour, generally very copious in quantity, extremely offensive in its odour, and often mixed with blood when the affected parts have been exposed to the air, exudes between the root of the nail and the skin. The nail thickens, loses its colour, becomes of an earthy yellow or blackish-green hue, and is detached at its root, when it deviates from the side which happens to adhere most intimately, and soon leaves the greater portion of the matrix from which the root has receded exposed. At length it falls spontaneously, or is easily taken away, when small portions of its substance are frequently left on the anterior and posterior part of its matrix. Thus divested of its natural covering, this secreting organ looks red, uneven on the surface, inflamed, overspread with yellowish or grayish fetid pus, surrounded with an inflammatory roll, which bleeds when brought into contact with the air, or when the diseased fingers are moved. It generally happens that pretty broad horny productions are now eliminated from the surface of the diseased matrices. These are soft at first, and for some time seem to blend and be confounded with the concrete pus that adheres to them; they are of a brownish, often of a greenish-yellow colour, and shoot in general obliquely, sometimes perpendicularly, from the middle or edges of the matrices. Two or three of these of smaller size are often seen uniting into one more or less irregular in its shape. These abortive ungueal productions often appear to keep up irritation, and the finger then acquires the form of a spatula. The inflamed skin which surrounds the horny productions bleeds when exposed to the air, and is the seat of pain of the most intolerable kind. Red lines on the affected parts announce the extension of the inflammation to the lymphatic vessels, or to the neighbouring veins. If the toes be the seat of the affection, walking is impossible. A febrile state frequently accompanies the disease when arrived at this severe stage; and sleep, entirely broken, cannot always be procured by the exhibition of opiates.

This variety of onychia,<sup>2</sup> the cause and nature of which are but little known, is not to be confounded with the two preceding varieties. And yet the *nail in the flesh*, when it has been long neglected, or aggravated by irritating topical applications, fatigue, &c., does occasionally assume very many of its characters.

Onychia maligna is always a troublesome, protracted, and painful disease.<sup>3</sup> Cases have been seen in which six months of sedulous

<sup>1</sup> Wardrop. On diseases of the toes and fingers, in *Med. Chirurg. Trans.*, vol. v. p. 129, 1814.

<sup>2</sup> A young man, eighteen years of age, who had never had venereal disease, after a severe attack of dothineritis, had onychia in both of the great toes, which got well under the use of the sulphureous bath.

<sup>3</sup> A man, twenty-six years of age, had suffered from suppuration around the outer edge, first of his right great toe nail for two years, and next of the same part of the left foot, which he ascribed to the pressure of too tight boots. The parts on the anterior lateral aspect of the right toe were removed, and the wound touched with the nitrate of silver. Four days after this, fungous excrescences arose on the inner edge of this toe-nail, for which nothing was done. June 6th. 1834. The nail of the right great toe appears of a pale rose colour; its conformation and thickness are natural. The edges of the ungueal matrix are red, painful, and in a state of suppuration. The

treatment have scarcely produced any apparent amendment. It rarely gets well under the antiphlogistic plan. Mr. Wardrop found mercurials of more avail. Frequently the only recourse that is left us, is to destroy or to remove the ungueal matrix entirely. In performing this operation, M. Dupuytren was in the habit of seizing the affected finger or toe between the thumb and forefinger of his left hand; with a convex-edged scalpel in the right, he then made a semi-lunar incision, the concavity pointing forwards, upon the dorsal aspect of the digit, at the distance generally of about four lines behind the roll of integument overlapping the root of the matrix; the flap was then seized with a pair of forceps and dissected off. The wound that results from this operation generally cicatrizes in from a fortnight to three weeks.

The following case appears to me deserving of being assimilated to onychia maligna:

CASE CXCIV.—*Chilblain, and contusion of the left great toe; onychia.* Sophia Brachet, twelve years and a half old, was admitted into the Hôpital des Enfants Malades on the 25th of April, 1827. Of sanguine temperament, and well grown for her age, she has never been affected with chronic inflammation of the skin or swelling of the lymphatic glands. Last winter the great toe of the left foot was affected with chilblain, which had got nearly well, when the toe was violently bruised, by some one treading on the child's foot. The ungueal matrix inflamed after this accident, became very painful, and poured out a profusion of fetid discharge. The child had to keep her bed for some time. During the first month of her stay in the hospital, local and general sulphureous water-baths were employed alternately without success. About the end of May the whole point of the toe was swollen and livid. The skin at the root of the nail formed a semi-lunar roll, nearly a line in thickness in its middle, which was ulcerated, fungous, blackish, or of a vivid red, according to the quantity of blood which had exuded from it. Two-thirds of the anterior surface of the ungueal matrix were in a state of suppuration; it looked like an elliptical hollow space, surrounded by a circular roll of tumefied and tender integument. The nail was perceived at the bottom of the hollow, its two anterior thirds detached from the matrix, raised, and turned back upon the dorsal aspect of the remaining adhering third. The nail was of a brownish hue, and traversed by transverse striæ. On the 30th of May the nail was seized with a pair of dissecting forceps, and removed. It presented something of the appearance of a miniature saddle. Its anterior part was rough and corroded; its posterior portion, which adhered intimately to the skin, was smooth and natural. (*Simple dressings.*) On the third day, the wound looked sanious; the suppuration was scanty. By and by the surface affected looked red, and secreted healthy pus; the violet hue and swelling of the skin, which had existed before the operation, had disappeared, and the wound began to cicatrize. June 8th. The sore somewhat sanious; and a new nail began to be seen at its upper part (*compresses watered with solution of chloride of lime*). The wound looked better; cicatrization advancing. 11th and 12th. The wound again became sanious; the cicatrice appeared to give way. The new nail advances apace; the swelling and violet colour of the toe recur. 13th. The sore is cauterized with the acid nitrate of mercury. 18th. The eschar produced is detached. 19th. The swelling and violet tint have almost disappeared. The sore is bright, and secretes laudable pus. If the disease recurs, the matrix of the nail will be excised.

#### Historical Notices.

1250. Celsus,<sup>1</sup> under the name of *περὶ γύριον*, appears to indicate the fungous excrescences that sprout from the inflamed matrices of the nails. He recommends these growths to be treated with cathartics, and, if the disease returns, to excise or to cauterize the matrix: "Si malum non vincitur, purgandus scalpello, tenuibusque ferramentis aduren-

surrounding skin, especially that which covers the root of the nail, is red but not broken. The great toe of the other foot is in the same state, but rather less inflamed. Eighteen months ago, the outer half of the nail was eradicated, and the surface cauterized. A new nail was produced, which causes the patient as much pain in walking as the old one. All the other nails are healthy. The patient has never been affected with syphilis.

<sup>1</sup> Celsus. De re medicâ, lib. v. sect. xix.

dum." Galen<sup>2</sup> specifies certain remedies against *paronychia*; Ætius<sup>3</sup> is more diffuse in his therapeutical principles. The description of the inflammation of the nails, which Paulus<sup>4</sup> gives very fully, bears considerable resemblance to the description of onychia *maligna* with which Wardrop has presented us. Paré was acquainted with the advantage of removing the soft parts implicated in lateral accidental onychia,<sup>5</sup> a procedure lately recalled to notice by M. Amussat. Still more recently, onychia has been made the subject of especial study by Dupuytren and his pupils.<sup>6</sup> I have already signalized the principal observations that have been made on scrofulous (729) and on syphilitic (926) onychia.

#### SUB-UNGUEAL ECCHYMOSES.

1251. Bruises of the dorsal aspect of the points of the toes and fingers are transmitted through the thickness of the nails to the pulpy substance upon which these organs are implanted, and frequently there occasion ecchymoses, and extravasations of blood often of considerable extent. When the nail is injured to its root, it is soon loosened and detached, after which it is replaced by a new one.

When any of the nails have been bruised, it is well to plunge the hand into cold water, and if pain and swelling afterwards come on, recourse should be had to emollient cataplasms; the processes by which the old nail is detached, and the new one formed, may then generally be left safely to nature.

When the fingers are crushed and wounded, and the nails broken and torn, those portions of these last that are half detached, should be cut away with flat scissors; those that adhere, though ever so slightly, should be left. To take them away at once would only cause a great increase of pain, and of the inflammation that must necessarily follow from the reparation of the injury that has been done.

When the nails are removed by a surgical operation, the matrices occasionally bleed rather profusely. This hemorrhage is readily commanded by compression and the use of some form of cautery.

#### FAULTY CONFORMATION OF THE NAILS.

1252. The nails may be *entirely wanting*, or be only imperfectly evolved. This deficiency, which occasionally appears to be hereditary, is extremely rare. Bleck informs us that there is a fœtus in the anatomical museum at Berlin, which presents this anomalous conformation of the fingers.

1253. The nails are occasionally lost *accidentally*, in consequence of injury, onychia and ablation. If their matrices have been superficially inflamed, they are reproduced, but not always with perfect regularity of shape.

1254. The detachment of the nail is a frequent consequence of acute or chronic inflammation of their matrices following a bruise, a burn, frost bite, venereal infection, and sometimes happening from no evident cause. But the nails are also occasionally lost, like the hair, in certain cases of alopecia, without their matrices appearing to be affected with inflammation at all (*alopecia unguealis*).

1255. The nails may be *faultily developed* in various degrees. In some individuals labouring under paralysis, the secretion of the nails appears retarded. When their matrices have been partially destroyed by ulceration, or removed, they are secreted ever afterwards uneven and imperfect.

1256. *Supernumerary* nails are also observed on the hands of individuals with six fingers. A man of the name of M \* \* \* had a supernumerary finger attached to each of the thumbs; one of these consisted of one phalange only; the other of two; both were furnished with nails, like the other fingers.

<sup>5</sup> Paré (Ambr.). Œuvres complètes, lib. xviii. ch. 32, fol. Paris, 1561.

<sup>6</sup> Lélut. Etudes sur l'onglade.

1257. The *anomalous growth* of the nails<sup>1</sup> constitutes a kind of deformity, the origin of which is not always the same. 1st. The nails left long to themselves, among the aged,<sup>2</sup> often acquire a considerable length. I had an old man under my charge lately, who had suffered for several years with prurigo and lichen, and who had allowed his nails to grow to the length of talons, in order to have a good implement always by him with which to allay the intolerable pruritus he endured. Rouhout, in 1719, sent a description and drawing of some monstrous nails, to the Academy of Sciences of Paris. The largest of these was the left great toe nail, which, from its root to its extremity, measured four inches and three quarters; the laminae of which it consisted were placed one over the other like the tiles upon a roof reversed. This nail and several of the others were of unequal thickness, and were curved variously, probably in consequence of the pressure of the shoe, or of the neighbouring digits. My friend, M. Bricheteau, physician of the Hôpital Necker, lately sent me two monstrous nails from the great toes of an old woman who had lived in the Salpêtrière. They are very thick, about three inches in length, and spirally twisted, like the horns of a ram. Saviard informs us, that, in 1817, he saw a patient in the Hôtel Dieu, who had a horn, like that of a ram, instead of a nail, upon each great toe, the extremities of which were turned to the metatarsus, and overlapped the whole of the other toes of each foot.<sup>3</sup>

1258. *Excessive growth of the nails* has occasionally been observed in individuals labouring under Arabian elephantiasis,<sup>4</sup> chronic rheumatism, and ankylosis of the joints; the skeleton of Simorre, preserved in the Museum of the School of Medicine of Paris, is remarkable for the ankylosis of all the articulations, and the considerable size of the nails. The fingers and toes, spread out and ankylosed, are terminated by nails of great length, and nearly of equal thickness. A woman of the name of Melin, surnamed *the woman with the nails*,<sup>5</sup> presented another and not less curious instance of the same thing.

Malformed nails of large size have also been seen among *children* and *adults*, who, at the same time, presented horny productions upon the skin. Ash has published the case of a girl, twelve years old, in the Philosophical Transactions,<sup>6</sup> upon almost every one of whose articulations there were horny growths tuberculated at their base, and hard at their summit. The fingers and toes, the knees and elbows, were beset with these productions, some of which were four inches in length. They fell off occasionally, and were replaced by others of the same description. Musæus<sup>7</sup> has given an account of a similar case: the nails of a girl, aged twenty, grew to such a size that some of those of the fingers were five inches in length. They were composed of several layers, whitish in the interior, of a reddish-gray on the exterior, full of black points. These nails fell off at the end of four months, and were succeeded by others. There were, besides, horny laminae on the elbows, knees and shoulders, which bore a perfect resemblance to nails, altered in their structure. These horny productions looked like talons; they were only sensible at their point of insertion into the skin. Various other parts of the body, particularly the backs of the hands, presented these horny productions; one of them was four inches in length. This horny growth appeared after small-pox.

1259. To whatever the anomalous growth of the nails be owing, it is well to remove those portions which project beyond the extremity of the finger or toe, to prevent them from interfering with the motions of the hands and feet. If not excessively thick, they may be cut off with a pair of scissors, after having been softened by soaking in warm water. Cutting pliers, or a fine saw, will always enable the operator to take them away without pain to the patient, when they are exceedingly strong and hard.

1260. The nails are sometimes *misplaced*. Th. Bartholinus tells us

<sup>1</sup> Several writers have given representations of these mal-formed and monstrous nails—vide commercium literarium Norimb., 1734, p. 173.—Eph. Nat. Cur., dec. 2, ann. 1, p. 385, fig.—Bartholin. Acta Hafn., i. obs. 16, epist. 2, pp. 732-737.—Malpighi. Op. Posth., p. 132, tab. 19, fig. 3, 6.

of a young woman, the nail of whose forefinger was situated on the side, not the back of the extremity of the digit. In another case, in which the fingers were wanting, the same anatomist found the nails implanted on the stump of the hand.<sup>8</sup>

1261. The nails are occasionally observed to become exposed towards their roots, as if the skin, which covers these parts, had shrunk upwards (*ficus unguium*). I have remarked this peculiarity among curriers. At other times, on the contrary, the cutis and cuticle extend a considerable way down upon the back of the nail, where they form a kind of tunic, which has been entitled *pterygium unguis*.

1262. The nails occasionally present certain peculiarities of shape: they are sometimes exceedingly arched or hooked (*ungues adunci*, Hippocrates), among the consumptive who have become very much emaciated. This remark has been reproduced by Duretus in his commentary upon Hippocrates ("Phthisicis unguis sunt more cujusdam serræ uncinati").

1263. When the matrices of the nails have been once diseased, their products occasionally present one or more longitudinal ridges, or grow in the shape of irregular cones. Those nails that have been divided and torn out after the mode of Dupuytren, occasionally continue long to overlap in the line of the division.

1264. Loder informs us that he has seen the nails become of a *chalky whiteness* in a person labouring under paralysis. All have observed the small white specks that often appear in the nails, which the ancients denominated *flores unguium*, to which Fallopius tells us the vulgar of his time gave the title of *lies* (*Mendacia*), as they do in France at the present day.

1265. Among convalescents from malignant fevers, Reil<sup>9</sup> has several times seen the nails become white. In icterus they occasionally become yellow; in subungueal ecchymoses they look black; in intermittent fever, in cyanosis, and under exposure to cold, they appear livid; in anasarca<sup>10</sup> they are of a pale white, &c.; but all these various tints are merely reflected through the nail, according to the varying colour of the matrix.

1266. To conclude this part of the subject, the nails are often observed stained of different colours by a variety of inorganic substances; they become brown when rubbed with nitrate of silver, black when impregnated with sulphuret of lead, sulphuret of mercury, &c.

1267. Tumours of various descriptions are occasionally developed in the structures that lie under the nails. Royer Collard speaks of a case in which the nail of the great toe was raised by a bony tumour, which had existed for several months, and grew from the last phalanx of the digit. I have met with the nails deformed and forced back from their bases towards their roots by warts evolved under part of the matrix near their free extremities: L. Lion, aged twenty, had a very voluminous wart on the extremity of the left forefinger; it consisted, in fact, of several confluent warts evolved under the extreme end of the nail, which was raised almost vertically. The wart was uneven, very hard and almost horny in its structure, of a grayish colour, and extended across almost the whole of the point of the finger, along the outer edge of the nail beyond its root. This compound wart was destroyed by the application of nitric acid. *Melanotic* tumours (§ 756) and vascular tumours, have also been seen evolved beneath the nails.

1268. Besides these various malformations, original or accidental, of the nails, their substance may be altered,—thickened, softened, hardened and eroded (*defœdatio*, *degeneratio*, *scabrities unguium*). These alterations, which are almost always the effect of chronic onychia, have also been observed among individuals affected with plica; some of them, appearing under these circumstances, have been figured by De Lafontaine.

The horny substance of the nails has been seen to undergo extensive changes, without the agency of outward and appreciable causes, as well as without any evident affection of their matrices. Black relates a case of this kind which is the more remarkable from the affection appearing to have been hereditary: "Est mihi amicus carissimus cui quum nonum ætatis annum ageret, in digito annulari manûs dextræ

<sup>8</sup> Hist. Anat. cent., ii. lib. 44, t. p. 240.

<sup>9</sup> Reil. Memorabil. Clinic. Fascic., iii. p. 206.

<sup>10</sup> Double. Signes séméiotiques fournis par les ongles. Journ. génér. de Médec., t. i. 33, p. 397.

unguis monstrosus, carvatus, rugosus, et asper excrevit, in quo usque ad hoc tempus nil morborum animadvertat; quam formam monstrosam unguem subisse ille narrat sine causâ internâ seu externâ morbosâ vel mechanicâ. Adfuit autem hæc deformitas jam in matre, et eodem temâ ætatis eademque lege, quam antea diximus, nempe ut simulacrum ad ætatis annum proventi essent, in sororibus et fratribus appareret." (*Op. cit.*, p. 9.)

1269. I have already said that a part at least of varying extent, of the nail, that is reproduced after an attack of chronic onychia, presented neither the semi-transparency nor the smooth and polished surface of the original nail. Under the agency of a very different cause, the action, namely, of dilute acids on the nails, they occasionally present a multitude of parallel lines on their surface, and are occasionally even resolved into a kind of brush.

1270. Several anatomists have been of opinion that the nails were formed by the superposition of a series of horny laminae. I have observed this structure of the nails in a man of the name of Meyer, seventy years of age, who came into the Hôpital de la Pitié, labouring under chronic inflammation of the bladder. The nails of this patient's fingers were thickened and composed of numerous superposed and softened horny laminae. The ends of the nails were worn away obliquely, or beveled off, so as distinctly to exhibit the different layers of which they consisted, and which were by so much the more extensive, as they lay more superficially. The surface of the nail of the left ring finger was uneven, that of the right corresponding digit was traversed longitudinally by an angular ridge.

1271. *Reproduction and accidental production of the nails.* When a nail is torn away by violence, or detached by the progress of diseased action in the subjacent integuments, it is slowly reproduced, and at length restored with more or less of the character of the original nail; but it is very seldom, indeed, that nails are observed to be developed upon those phalanges of the fingers or toes which are not usually or naturally provided with the peculiar vascular tissue that constitutes the ungual matrices. Tulpus appears to have met with this pathological condition: "Ungues, in digitorum apicibus semel deperditos, iterum renasci novum non est; sed raro id conspicitur fieri in secundo aut tertio articulo, prioribus amputatis, in quibus tamen non semel eosdem vidimus non secus progerminare debitamque acquirere formam ac si in digitorum consistentem apicibus, deponente nunquam sollicitudinem suam officios naturâ." M. Maréchal de Rougères,<sup>2</sup> Voigtel<sup>3</sup> and Ormancey<sup>4</sup> have since related instances of similar productions developed on the second phalange of a finger after the loss of the first: A woman had for several months laboured under an ulcer of the point of the middle finger of the right hand, in consequence of a whitlow which had occasioned the loss of the third phalange, and the whole of the distal articular surface and part of the compact bony structure of the second. On examining the sore, M. Ormancey saw a bony sequestrum which appeared to keep it open. This he extracted, and dressed the stump with saturnine cerate, until cicatrization was complete. Some months afterwards the patient returned to call on M. Ormancey, who now saw, not without astonishment, that the nail had been reproduced; instead of following the ordinary direction, however, it lay directly over the face of the stump, growing from the back towards the palmar aspect of the digit, as if to cover and protect the stump. M. Blandin<sup>5</sup> has met with a case of the same description; and a third occurred very recently at the Hôpital de la Charité, in the person of a woman who had lost the whole of the third phalange of one of the fore-fingers in consequence of whitlow. The soft and fleshy cushion which here covered the second phalange was terminated by a small, blackish nail, like a grain of *spur rye*. It is probable that the soft parts of the third phalange, and the ungual matrix especially, had not been wholly destroyed in these cases. Mr. Chevalier speaks of analogous cases in his Lectures.<sup>6</sup>

## GANGRENE OF THE SKIN.

1272. Gangrene of the skin may result from pustula maligna, from erysipelas of a severe kind, from frost bite, deep burns, the action of concentrated and strong alkaline solutions, compression, the ligature of the principal artery of an extremity, &c. It may also follow other gangrenous affections in different parts, as is occasionally seen in the gangrenous mouth of young children, and of the external parts of generation in little girls. It is likewise met with in the gangrene of the aged, and in cases of spontaneous gangrene with the formation of clots in the principal arterial trunks of the limb affected; lastly, external gangrene has been known to prevail epidemically.

Gangrene of the skin may, further, occur in the course of serious diseases of another nature. There was an old woman who died in the Hôpital de la Charité from the effects of a simultaneous affection of the lungs and intestines, added to erysipelas of the face and scalp, who, during the course of her illness, had an oblong gangrenous tumour developed on the sacral region, accompanied with vivid redness of the skin. Near this tumour a considerable number of very superficial eschars were seen, which looked at first sight like the crusts of a pustular eruption, but differed evidently from these in the smooth appearance of their surface, their dryness, their uniformity, and especially in the mode in which they were set or framed within the substance of the skin. Some of them were surrounded by a deep red blush, similar to that which bounds parts when stricken with gangrene; others began to be separated from the living tissues by a ring of suppuration. In endeavouring to detach them, their intimate connection with the tissues beneath was conspicuous. In other places the eschars were destroyed in their circumference, and were only visible in the form of a patch in the centre of a superficial ulcer. Lastly, in a great number of points, slight superficial excoriations were observed, without puffing of their edges, of a circular or somewhat indefinite shape, different in their appearance from ordinary ulcers, and in all respects similar to those which have already been indicated as consequences of the detachment of gangrenous eschars formed by the most superficial laminae of the skin.

Very shortly before this patient died, the whole of the eschars were separated; the edges of an incision which had been made through the principal gangrenous swelling over the sacrum, were loosened, very much swollen, red and painful. Shreds of grayish and mortified cellular tissue were seen at the bottom and around the edges of the wound, to which they adhered but slightly. On opening the body after death, the extent of the loosening around the edges of the great wound, was ascertained to amount to several inches. The sacrum was not denuded. The edges of the sore were flaccid and without redness. The cuticle had disappeared from its circumference, as if the skin had been long in maceration; and even where it still appeared, it could be detached to a considerable extent with great ease. A piece of the skin affected presented the following alterations: 1st, its surface was denuded of epidermis; 2d, two or three round bluish ecchymosed spots, the effect of leech bites, were perceived; 3d, the whole of this surface was pierced with very small holes. The regular arrangement of these holes, their slightly elliptical form, the possibility of penetrating into their interior with a pin, which entered a small oblique, and very superficial cavity, showed that they were formed by the orifices of the cutaneous follicles. 4th. The most superficial stratum of the skin was destroyed in a great many places, whence resulted excoriations of variable extent and depth. The smallest of these could only be distinguished with minute examination, or the aid of a magnifying glass, and might readily have been mistaken for the orifices of follicles, such as those I have mentioned; but they differed from these in resisting the entrance of the point of a pin into any cavity. They were very superficial; their bottom was almost on a level with their edge; in fact, they were only distinguished by their somewhat paler colour from the rest of the integuments. The excoriations, of middling size, were still less distinguishable. The appearance they presented might have been very accurately produced by shaving off the most superficial strata of the integument with a sharp instrument. Their edges were without tumefaction, or redness; their bottoms smooth; their colour very nearly that of the surrounding skin. A number of minute open-

ings were visible on all, into which the point of a pin penetrated obliquely and gained the sebaceous follicles, whose orifices had been destroyed. The holes in these parts were consequently of larger size than the orifices mentioned a little ago, and instead of leading to the shut sacs of the follicles merely, permitted the pin to penetrate as far as the subcutaneous adipose tissue through the areolæ of the corion. The alteration resembling, as has been said, the surface which is produced by shaving away the corion horizontally, the areolæ were observed to increase in size, in proportion as the excoriation extended more deeply. Where this was the case not only did the openings on the surface lead directly down to the subjacent adipose tissue, but the head of a pin could even be passed through one of them. The subcutaneous cellular tissue in this point was inflamed, and the corion detached by the effusion of a little pus beneath it, which by pressure could be forced through many of the little openings that have been described.

### CICATRICES OF THE SKIN.

1273. Cicatrices of the skin are distinguished : 1st, into those which result from a particular modification undergone by the skin after certain inflammatory affections; 2d, into those which consist of a tissue of new or recent formation, bearing a closer or more remote resemblance to the portion of the skin which it replaces.

1274. Among the first order of cicatrices there are some, a knowledge of which is important, inasmuch as they are characteristic of the affection which has produced them, such as those of vaccinia, of lupus *non exedens*, those also that are occasioned by the action of tartar of antimony, the bites of leeches, ulcerated blisters, superficial burns, &c. The whole of these cicatrices have many features in common; their colour is in general of a duller white than that of the healthy skin which surrounds them, and their surface appears to be beset with a great number of minute depressions, which in many cases exhibit pretty closely the areolar structure of the corion. These cicatrices occasionally present particular appearances: the cicatrices of blisters and of variola, for instance, are often seen covered with excrescences; when they occur on parts that are covered with hair, this appendage is generally white or colourless. I have seen a large cicatrice covered with small reddish tumours similar to the cheloid formation in its earliest stages. Some of these cicatrices do not rise above the level of the skin; they are even in many cases rather below it (the cicatrices of *cow-pox*), in others they are elevated (leech bites, the cicatrices of *acne*, &c.). I have observed the cicatrices that follow the action of the tartar emetic ointment on the skin, presenting this prominence in a very remarkable manner: there was a man under my charge in the Hôpital de la Charité almost the whole of the skin of whose abdomen was covered with prominences of a dull white colour, slightly wrinkled and nearly of the size of sixpences, which at first sight bore no inconsiderable resemblance to some peculiar species of tubercular eruption.

1275. When a portion of the integuments and even of the subjacent parts has been destroyed by a wound, by sloughing or ulceration, a new integument is often produced which resembles, or at least is analogous to that which has been destroyed, and is always the same in its whole extent, whatever the diversity of parts that are to be covered (*second species of cicatrice*). After the primary symptoms, which vary with the nature of the cause giving rise to them, have subsided, a series of secondary phenomena commence, the nature and succession of which are constantly the same. These are, 1st, the production of a layer of coagulable lymph, similar to that by which simple solutions of continuity are repaired; 2d, the formation of granulations and the secretion of pus; and 3d, the cessation of this purulent secretion and the formation of a cicatrice. The layer of coagulable lymph, similar to that which constitutes false membranes, inorganic, at first, but soon organized, becomes covered with small conical, red, fleshy elevations, and then constitutes the granulating membrane. This membrane is cellular, vascular, very contractile, and extremely apt to

disappear and to be reproduced; by and by it is covered with a distinct cuticle, and acquires the appearance of the skin.

The corion of cicatrices, extremely thin and flimsy at first, more vascular and consequently redder than the normal membrane, becomes by slow degrees whiter, denser, and harder than this last. It also assumes a smooth and shining appearance, very probably depending on the absence of papillæ and of piliferous bulbs, as well as from its tension and intimate adherence to the subcutaneous cellular tissue. The epidermis and rete-mucosum are reproduced gradually: the layers first formed are readily detached from the surface of the dermis; if the pigmentary matter is deposited at all, it is always at a later period. Bichat, indeed, maintained that this structure was never reproduced, and that cicatrices were alike colourless among all the races of mankind; but this position is untenable, and the cicatrices that follow solutions of continuity in the negro are often as black as the rest of the skin.<sup>1</sup>

1276. The corion of completely formed cicatrices is less elastic, and adheres more intimately to the subjacent cellular tissue than the tissue it replaces; in fact it is continuous or forms one with the cellular tissue from which no art can separate it. It is not so tough as the natural corion; even old cicatrices of the lower extremities are readily and frequently torn.

There are some cicatrices which, in point of conformation and structure, partake of the nature of those both of the first and second species; such are those that result from confluent variola in some cases, from simple rupia, from certain syphilitic eruptions, and frequently from burns.

1277. The situation, extent, form and depth of cicatrices often indicate in some sort the nature of the affections that have preceded and occasioned them: such are the cicatrices of variola, vaccinia, zona, the serpiginous syphilide, lupus, &c.

1278. When a cicatrice is very irregular, when it interferes with the motions of the muscles or articulations over which it lies, we have scarcely any efficient remedy for the evils it induces, but a surgical operation, analogous to that which Celsus<sup>2</sup> recommends and describes in a remarkable passage, and which Fabricius Hildanus,<sup>3</sup> Dutertre,<sup>4</sup> H. Earle,<sup>5</sup> and Dupuytren have all performed with success.

The effects of great distension of the skin ought to be distinguished from cicatrices. When, for instance, the mammæ have been excessively distended during the period of nursing, and after women have suckled several children, the skin covering them is intersected with irregular lines, and wrinkled angular spaces of a brighter white than the rest of the integuments. These, as I have satisfied myself by dissection, are owing to a separation and deformity of the tissue of the corion, become thinner and less transparent. Individuals who are extremely corpulent, who are, or have been affected with ascites, and women who have had families, have the skin of the abdomen seamed with these white lines, which run in all directions, but especially transversely; these constitute, the *Vitiligo obesorum*, the *Vit. hydro-picorum*, and the *Vit. gravidarum*, of Frank.

1279. To bring this portion of my subject to an end, I shall only farther speak of certain anomalies in the structure of the corion, which are observed very rarely.

In the interior of the body, *cutaneous productions*<sup>6</sup> are sometimes, through with extreme rarity, encountered. These adventitious tissues, which are generally met with in the ovaries, have been ascribed to foetal abortions.

*Congenital deficiency of the skin to a greater or less extent over*

various regions only occurs in those cases in which the splanchnic cavities are not completely closed. The epidermis has been found primarily defective among new-born infants.

The skin has occasionally been known to undergo a remarkable extension in adults and the aged: Mr. Chevalier<sup>1</sup> mentions a case in which the skin of the breast and left side of the trunk generally was so loose that it could be folded or wrapped round a considerable portion of the body. Under the name of *Dermatylotie*, M. Alibert relates a considerable number of cases of this elongation of the skin of the face, eyebrows, neck and abdomen. The most interesting is that of a peasant of Gisors, whose head was of extraordinary magnitude, owing to the large folds of integument with which it was enveloped. The skin of the left eyelid was two inches in length, and fell down over the cheek. The edge of the upper eyelid projected like the mouth of a carp; the ear was dragged downwards; the parts covered with hair were beset with a stronger growth than usual. The united weight of these folds of the skin formed an uneven mass which dragged down the integuments covering the upper part and sides of the head.

The same author details another case in which the upper eyelids were the parts especially affected. They were so much elongated that they fell down over the eyes and the whole of the cheeks. Another case was that of a man, sixty-two years of age, the skin of whose neck, singularly lax and furrowed, formed a kind of triangle which fell over the front of the chest, and bore a very strong resemblance to the dew-lap of the ox, or the loose folds of skin that depend from the throat of some large species of mastiff. The face of this man was ploughed with longitudinal furrows which united together in the chin.

#### PARALLEL BETWEEN THE DISEASES OF THE SKIN AND THOSE OF THE MUCOUS MEMBRANES.

1280. Studied under the twofold point of view of conformation and structure, the tegumentary membranes of the outer surface, and of the inner passages of the body, have characters which are common almost in their whole extent. In both particulars, however, they present modifications that are sufficiently striking, according to the regions or variety of parts they cover. These features of resemblance, and these differences, explain the fact of the skin and mucous membranes presenting a great number of analogous and common alterations, and a certain number of others which are peculiar to each. The importance of the comparative study of these affections has been felt; but few physicians and pathological anatomists have hitherto given their minds to inquiries of this description.

The observations of Hébréard<sup>2</sup> have shown that the skin may become changed into a mucous membrane, and this, in its turn, into external integument, under certain circumstances. In fact, when any portion of the outer surface of the body is for a long time subtracted from the influence of the atmosphere, as during the treatment of certain fractures, when the leg is kept for many weeks bent upon the thigh, and the integuments of the femoral and crural portions of the popliteal region are maintained in contact, and in the folds of the skin of very lusty infants, we see that the cuticle softens and disappears, and that the surface of the cutis ends by secreting mucus exactly like a mucous membrane. On the other hand, we know that in old cases of prolapsus of the uterus, and of the anus, the mucous membranes of the vagina and intestines become thickened and dry, and by degrees acquire every appearance of the skin.

To the first sketch of Hébréard quoted, succeeded the more extensive work of J. B. Wilbrand,<sup>3</sup> who, after a careful study of the tegu-

mentary system of every region, proceeds to show that a certain number of alterations and affections are common to the two grand divisions of the general involucrum of the body. (a)

1281. The study of *inflammation* and of its products or effects, embraces so many the more objects, as the elementary tissues of the organ which is affected are more numerous and varied. It is therefore easy to perceive beforehand that the affections of the external integument or skin, the organization of which is so much more complex than that of the mucous membranes, will exhibit a greater number of morbid modifications than these latter structures; that among the mucous membranes, those of the mouth, pharynx and œsophagus, provided as they are with an epithelium, or cuticle, will present lesions more varied in their appearances than those of the stomach and intestines, which themselves may be expected to offer a greater number than the serous membranes, the organization of which is still more simple. (b)

1282. The greater number of the exanthematous inflammations, measles, scarlatina, urticaria, &c., attack both divisions of the tegumentary membranes simultaneously. The running of the eyes, the nasal, laryngeal and tracheal catarrhal affection of measles correspond to the exanthema of the skin, which characterizes the disease on the general surface, and the matter secreted by the bronchi presents a peculiar character in relation with the species of inflammation which is going on. In scarlatina the mucous membrane of the mouth and pharynx almost always, and that of the stomach and intestines occasionally, presents a dotted redness altogether analogous to that which is observed upon the surface of the skin. The eruption in this disease is followed by desquamation of the cuticle, and the mucous membranes furnished with an epithelium, cast this pellicle off in a precisely similar manner.

On the surface of the mucous membranes we also observe red patches, or efflorescences, which must be held as of the same nature with erythema, and probably, also, roseola of the skin. I have repeatedly seen red patches upon the lips and conjunctivæ, in cases of *erythema marginatum*; and I have known this affection complicated with pulmonary catarrh. The mucous membrane of the intestinal canal occasionally, also, presents circumscribed red patches, distinct from clusters of inflamed mucous crypts, and formed by the membrane itself, injected and thickened, and generally covered with a ropy red viscid mucus. On this membrane, too, we frequently encounter bands, and diffuse red suffusions, analogous to certain varieties of erythema occurring in the skin.

The submucous cellular tissue of the intestinal canal differs so essentially from the subcutaneous cellular membrane, that it is not difficult to assign a reason for our never meeting with inflammation in this situation, which we can approximate rigorously to erysipelas.

The skin, in a state of inflammation, never presents the *vascular ramifications* we observe on the surface of the mucous membranes in this condition.<sup>4</sup> This is owing to a remarkable difference in the mode of distribution of the submucous and subcutaneous vessels, and to the

(a) See *anté*, pp. 46–7, some observations on this point by the American editor.

(b) It is now asserted that all the mucous surfaces are lined with epithelium, either of a cylindrical or tessellated arrangement, and that it is formed, developed and detached in the same manner as the epidermis. See Mandl, *Manuel d'Anatomie Générale*, p. 543. As the epidermis is renewed some days after birth, and from time to time afterwards, so, likewise, is the intestinal epithelium often detached in long hollow or tubular pieces, like the fingers of a glove, and at all times it is freely given off and carried downwards by aliments and secreted fluids.

d'Anatomie générale, descriptive et Pathologique, trad. de l'allemand, avec des notes, par Jourdan et Breschet. Paris, 1825, 3 vol. 8vo.), have laid the foundation for this comparative study. Messrs. Roche and Sansen have also presented general considerations of great interest on the Pathological Anatomy and Physiology of the mucous and cutaneous systems in their *Nouv. Eléments de Pathologie Medico-Chirurgicale*, 4 vols., 8vo. Paris, 1827.

<sup>4</sup> Billard has made a particular study of the alterations of the mucous membrane of the intestinal canal. His observations have served me as points of comparison in contrasting the various diseases of this tissue with the affections of the skin,—vide Billard (C.). De la membrane muqueuse gastro-intestinale dans l'état sain et dans l'état inflammatoire, etc., 8vo. Paris, 1826.

dissimilar thickness of the skin and of the mucous membranes. The ramified vascular injections observed on the nose and cheeks, are generally to be regarded as an anomalous, non-inflammatory development of the vessels of these parts. The capillary injection of the skin, like that of the mucous membranes, is, in one instance, the consequence of inflammation, and, at another, of mere passive congestion, supervening after death; these two species of redness of skin cannot be distinguished, like those of the mucous membranes, by the state of the vessels in their vicinity.

In fine, if we except the white wheals of urticaria, and the patches of roseola, we find in the mucous membranes almost the whole of the varieties, in form and appearance, presented by the exanthematous inflammations of the skin. The internal exanthemata, however, are not accompanied with any desquamation corresponding to that which is observed on the exterior of the body, except in those regions—the mouth, pharynx, and œsophagus, in which the mucous membranes are furnished with an epithelium. In the stomach, intestines, trachea, &c., the loss of the epidermis is represented by a modification in the secretion of the mucus which covers their surface.

As to the brown, gray, or slate-like discolorations presented by the mucous membranes, in consequence of their inflammation, we observe very similar tints following chronic inflammatory affections of the skin.

1283. Affections analogous to the *bullous* inflammations of the skin, are observed in those mucous membranes that are provided with an epithelium. Large, prominent bullæ, indeed, are never observed on these parts; in the mouth they are always flattened. The serum, as it is formed, seems to permeate the epithelium, which becomes of a dull white colour. No bullæ are ever discovered in the stomach and intestines of those who have died whilst labouring under pemphigus. They cannot even be excited there by artificial means: Bichat applied a piece of blistering plaster to the mucous membrane of the intestine in a living dog; the effect of this was to produce a circular patch of inflammation, but no blister. It would be absurd to denominate as bullæ those collections of pus or serum occasionally met with in the submucous tissues, which ought to be assimilated to subcutaneous abscesses or infiltrations.

1284. It is familiarly known that on opening a blister produced by the action of epispastics upon the skin, a membraniform concretion is frequently observed. This, like the pseudo-membranous formations of the serous tissues is principally composed of fibrin. Blistered surfaces, too, occasionally become covered with a true membraniform pellicle. If this be removed the papillary surface becomes extremely red, and the network of vessels, loaded with blood, which traverse it in all directions, are observed to pour out a fluid which adheres to the inflamed surface and gradually concretes into a new pellicle, thin and transparent at first, but which soon acquires greater thickness and opacity. Oil impregnated with the active principle of cantharides, applied to the tongue and lips, produces an effect very similar to what it does when rubbed on the skin; yet the alteration bears greater outward resemblance to an inflammation with pseudo-membranous deposit, than to bullous inflammation. And there is, in fact, a pseudo-membranous pellicle deposited under the raised epithelium,<sup>1</sup> which, thin and semi-transparent at first, becomes, before long, thicker and more opaque, being in all respects very similar to the ordinary false membranes of blistered surfaces. It appears, therefore, that the stimulus which, applied to the skin, produces a bulla, with or without a sub-epidermic false membrane, when applied to the mucous membrane of the mouth, occasions a fibrous concretion under the epithelium, and when applied to the intestine, is followed by simple redness and inflammation. This diversity of effect, according to the part interested, is also observed among new-born infants affected with thrush, in whom pseudo-membranous deposits, sometimes apparent on the hands, are extremely distinct in the mouth, pharynx, and œsophagus, but have never been observed in the stomach and bowels.

The pseudo-membranous concretions produced upon the mucous membranes by the action of cantharides, although presenting the anatomical characters of those of diphtheritis, differ from these in one

essential feature peculiar to this disease, namely, in not being contagious, as diphtheritis unquestionably is. It would appear, also, from what Messrs. Bretonneau, S. Bard, and Trousseau say, that besides the false membranes of various forms and dimensions which are observed in the course of many bullous, vascular, and pustular inflammations, the skin may be primarily affected in some rare cases with inflammation, accompanied with the elimination of false membranes of the same nature as those of diphtheritis.<sup>2</sup>

In the course of the year 1814, I observed the blisters of a great number of patients in the Hotel Dieu, become covered with a thin membraniform fibrinous deposit, adherent to the papillæ, and precisely similar to that which I perceived at the same period upon the wounds and ulcers attacked with hospital gangrene. There seems to be some analogy between angina with formation of false membranes, and hospital gangrene occurring in inflamed skin: besides the similarity of their anatomical characters, both of these forms of inflammation are contagious.

1285. True *vesicles* are never seen, save on the mucous membranes that are covered with epithelium.<sup>3</sup> The lips are often attacked with herpes, and zona may extend to the inside of the mouth. The aphthæ that occur in the cavity of the mouth and on the surface of the pharynx, appear to be analogous to one or other of the varieties of herpes. I have met with eczema confined to the mucous membrane of the lips and extending into the inside of the mouth. It also occasionally appears confined to the mucous surfaces of the nipple, of the penis vulva, and verge of the anus. I have observed chronic and very rebellious coryzæ accompanied with discharge from the nostrils, and very considerable pruritus of the nasal fossæ, which were preceded by eczematous affections.

Mercurial stomatitis and angina are analogous to the affection of the skin which is described under the name of *hydrargyria*; the whitish patches of the mouth and pharynx that then occur, and that are often regarded as fibrous and pseudo-membranous, are principally formed by the epithelium, thickened and detached from the membrane beneath it. We never observe any affection of the mucous membranes that can be compared to scabies.

1286. *Pustular* inflammations have never been observed on the mucous membranes with the form and characters which they present on the skin, except on those that are furnished with an epithelium. When the cause producing the pustules has extended its influence to those parts of the mucous membranes that have no epithelium, the form of the inflammation is necessarily modified. Variola, for instance, which appears with the characters of a truly pustular eruption on the mucous membrane of the lip, inside of the mouth and pharynx, as well as on the skin, gradually loses its strong features as it appears on parts more remote from the surface of the body. In the trachea the pustules are replaced by small white circular patches of the dimensions of variolous pustules, but formed by a simple deposit of pseudo-membranous matter. In the stomach, and along the course of the bowels, nothing more is apparent, even at the height of the disease, than red, circular spots, which seen alone, would hardly recall variolous pustules to the mind.

Impetigo occasionally attacks the mucous membrane of the angles and of the interior of the mouth, as well as of that which lines the nasal fossæ. In the chronic coryzæ which often accompany impetigo of the alæ nasi, the nasal fossæ pour out a thick matter which concretes in the shape of crusts. When impetigo extends into the mouth, white and pustular-looking points are perceived in its interior. The inflammation of the follicles of the edges of the eyelids or of the hairy scalp, which frequently coincides with, or follows attacks of impetigo, is a disease analogous in its nature to this last affection.

The typhoid follicular eruptions (*taches typhoïdes lenticulaires*) and gangrenes of the skin occasionally observed, must be assimilated to the follicular eruptions and gangrenous patches that occur in the course of the intestinal canal in dothineritis.

The corion or dermis of the mucous membrane does not present,

<sup>2</sup> Lélou, études anatomiques sur l'épithélium 4to. Paris, 1827.

<sup>3</sup> When ulcers appear behind the ears, says S. Bard, or on different other parts of the body, they require peculiar treatment. The discharge ought to be encouraged by the frequent use of tepid milk and water fomentations; unctuous applications of all kinds are prejudicial, for they tend to suppress the secretion (Bretonneau, op. cit., p. 483).

<sup>1</sup> Bretonneau. Des inflammations spéciales du tissu muqueux, etc., 8vo. Paris, 1826, p. 356.

like that of the outer integument, a regular areolar or cellular tissue; it is rather spongy and fungous, and does not consequently present any alteration analogous to the *furuncular* affections of the skin. Neither has it been known to suppurate after the manner of the skin in the following case: I had directed the application of a large mustard poultice to the side of a young man, labouring under pleurisy, and who died from effusion into the cavity of the chest. Next day, and the day after that, the skin presented a red colour, similar to what it has in scarlatina; but on the third day, the irritated skin was perceived to have assumed a dull white or milky hue. The epidermis could be raised and detached with a pin, and the sensibility of the outer layer of the corion appeared to be blunted. The patient having died, the milky-white colour of the integument was ascertained to be occasioned by an infiltration of pus, with which the corion seemed to be impregnated. By squeezing the skin between the fingers, the pus could be forced by an infinity of small orifices from its surface, and flowed in a continuous current when one or two incisions were made into its substance.

1287. In *prurigo pudendi*, and *prurigo præputii*, it very rarely happens that true papulæ can be detected on the mucous membranes of the vagina and prepuce; they are almost always to be detected in the neighbourhood, on the pubes, scrotum, labia majora, &c.

1288. *Tubercular* inflammations have, on the contrary, been seen pretty frequently attacking the mucous membranes. Primary cancer of the velum palati, for instance, begins in the development of tubercles analogous to those observed on the skin. Cancerous tubercles of the cheek are occasionally observed at the same time that tubercles of the same nature exist on the velum palati and palatine arch; circular hypertrophied patches, and cancerous tubercles of the skin are also met with in those individuals who are affected with scirrhus of the mucous membrane of the stomach. The tubercles of Greek elephantiasis are evolved, not only on the exterior of the body, but very commonly also on the palatine arch and the nasal fossæ. Lupus is well known occasionally to commence in the interior of the nose.

1289. *Lepra* and *psoriasis* perhaps never implicate the mucous membranes; but *pityriasis* sometimes shows itself upon the lips. Were affections of the nature of any of these developed on the mucous membranes unprovided with epithelium, their appearance would necessarily be entirely changed.

1290. Several forms of *gangrenous* inflammation observed on the skin, may also appear on the mucous membranes; malignant pustule has, for example, been seen on the tongue;<sup>1</sup> and whilst it is evolved externally, the stomach and different other internal viscera may be simultaneously attacked (Case XCVI). Gangrene is occasionally, though rarely, observed attacking the ileum and cæcum as well as the skin, in typhus fever.

1291. The *multiform* inflammations are simplified in their forms when they occur on the mucous membranes. Still burns appear with the erythematous, bullous and gangrenous characters in the mouth and œsophagus.

It is certain that almost all the forms under which syphilis appears upon the skin, occur on the mucous membranes provided with an epithelium. Syphilitic exanthemata, pustules, tubercles, ulcers and excrescences have all been seen on the mucous membrane of the mouth, of the nipple, labia majora, glans penis, &c. Several forms of venereal inflammation have also been observed on the conjunctiva, in the interior of the nasal fossæ, of the mouth, pharynx, larynx, rectum, &c.; it is a very general opinion, however, that the œsophagus, stomach, intestinal canal and bladder are never the seat of syphilitic affections. Some have even gone further, and have said that since the irregular grayish ulcers, with peculiar characters, encountered in the intestinal canal, which they have even eroded in different directions, are not to be considered as syphilitic in their nature, neither are the ulcers of the skin which present corresponding characters, to be regarded as truly syphilitic. For my own part, I hold the characters of all the different forms of syphilitic eruption to be so definite and decided, that I am of opinion those ulcers of the intestines, which, in their external characters, approximate those of the skin, require to be examined with greater care and attention than have yet been bestowed upon them before any conclusion of the kind above indicated, can be come to.

<sup>1</sup> Lond. Med. Gaz., June, 1834.

1292. *Ulcers* and *perforations* of the mucous membranes, especially of the intestines, like those of the skin, follow inflammations of various kinds, abscesses of the subjacent cellular tissue and gangrene. *Softening* (*ramollissement*), rather rare in the skin, the corion of which is substantial and tough, is much more common in the mucous membranes.

1293. From this hasty sketch of the diseases of the internal and external integument of the body, it is easy to perceive that they bear a great analogy to one another. The epithelium, like the epidermis, is altered under the influence of inflammation, and the mucus which they both pour out under peculiar circumstances, is modified like these, in the points where it is secreted in their stead; the vascular rete of both becomes injected, and the corion thickened; the villi of the mucous membranes increase, and the papillæ of the skin are extended: the follicles of both integuments often enlarge, and accidental morbid secretions take place from the one as from the other. In a word, if the whole of the forms of phlegmasiæ observed in the skin, are not encountered in the mucous membranes, and several of them are modified in their outward appearance, it is entirely owing to the differences of structure presented by these two tissues, which are amply sufficient to account for every discrepancy observed in their morbid phenomena.

1294. *Congestion* and *hemorrhage* frequently take place into and from the external and internal integument simultaneously. In certain kinds of death, from apoplexy, strangulation, &c., the skin and mucous membranes alike present livid blotches on their surface, and occasionally spots of ecchymosis. The blue colour of cyanosis appears on the skin and mucous membrane of the lips, mouth, and stomach at the same time. Purpuræ, ecchymoses and petechiæ occur on the interior as well as the exterior covering. As to the material differences observed between the hemorrhages that take place from the mucous membranes and the skin, these are due, in very great part at least, to difference of structure. The vascular rete of the surface of the cutis vera or corion, is less developed than that of the mucous membranes; these, when covered with epithelium, have this membrane much thinner than the cuticle, and in many places are entirely without any tissue of the kind, circumstances which we may presume favourable to the flow of blood from their surface; whilst opposite conditions rather determine the deposit of this fluid under the form of petechiæ and ecchymoses, in the substance of the skin. The absence of epithelium on the membrane lining the nasal fossæ explains the greater frequency of epistaxis than of bleeding from the mouth.

1295. The *neuroses* of the skin, like those of the mucous membranes, ought to be made the subject of new inquiries; the effects of injury to, or alteration of, the subcutaneous nerves, are much better known than those of lesion of the submucous nerves.

1296. The absence of pigment in the mucous membranes of the human body explains why we do not find in these membranes any alteration which can be assimilated to leucopathia of the skin; for the morbid paleness of the mucous membrane of the intestines, almost always connected with a diminution of its thickness, is of a totally different nature, and appears to be generally consequent on inflammation.

Individuals affected with general nigritics do not generally present any corresponding alteration in the mucous membranes, although I have seen it extend in the form of brownish spots to the surface of the tongue.

The mucous membrane of the intestines has been several times observed discoloured black, particularly by Morgagni. Andral<sup>2</sup> has also seen the surface of the large intestines of a deep black colour, inhering in the mucous membrane, which had in other respects preserved its usual thickness, the mucous crypts only being particularly enlarged. The colouring matter came off and blackened a piece of linc with which the surface of the membrane was wiped; the colour was, in the judgment of M. Andral, perfectly distinct from the brown hue presented by the same surfaces when affected with chronic phlegmasiæ; he regarded it as the effect of an accidental secretion and deposition of colouring matter, similar to that which takes place naturally in the tunica choroidea of the eye. I have several times

<sup>2</sup> Revue médicale française et étrangère, t. ii. p. 148.

observed the surface of the tongue dotted with a bluish black. Ephelis, lentigo and chloasma have no counterparts on the internal mucous membranes, although these last, and especially those of the glans and vulva, occasionally exhibit accidental discolorations. They are tinted yellow, but in a less degree than the skin in icterus, and like this, they acquire a leaden or slate colour under the long-continued internal use of the nitrate of silver. I have, further, observed vascular nævi penetrating into the interior of the mouth.

1297. Under the title of *hypertrophy from an inflammatory cause*, indurated thickenings of the mucous membranes coincident with other inflammatory lesions, have been designated. With these we must assimilate those thickenings and indurations of the skin, which are observed along with psoriasis and lichen of long standing, with tubercular inflammations, &c. The title of *hypertrophy*, however, ought to be reserved for the indication of cases of simple *exaggeration* of the normal tissues of the skin. Such, with reference to the mucous membranes, are certain anomalous developments of their tissues generally, and of their villi and follicles particularly, which are sometimes encountered,—alterations, the counterparts of which are observed in the skin in cases of ichthyosis and elephantiasis arabica. Billard quotes several cases to show that the mucous glands of the intestines may acquire an anomalous magnitude independently of inflammation. The skin is also occasionally observed to be covered with a greater number of follicles than it exhibits in the usual state. I have seen this excessive development of the follicles, especially among individuals of mature years, and the aged, in the skin of the neck, on the sternal, on the scapular regions, and sometimes even over the whole surface of the body.

1298. The *submucous*, like the subcutaneous cellular membrane, may be the seat of œdema, ecchymosis, and abscess; but the development of tubercular matter, which takes place rather commonly in the submucous, occurs very seldom in the subcutaneous cellular tissue. The case is otherwise with regard to scirrhus, cancer, and melanosis, which occur with no less frequency in and under the skin than in and below the mucous membranes. A multitude of other alterations are common to the two integuments. Excrescences of the glans penis and female vulva correspond to warts developed on other parts. The diverticula of the intestinal canal even bear some analogy to the digitiform appendages of the skin; the mucous membranes are occasionally beset with accidental hairs like the skin; in the subcutaneous cellular tissue cysts are sometimes observed analogous to those occasionally discovered in the submucous cellular membrane; the peculiar tumours described by Dagorn and Tilesius, covered with the skin, may be regarded, in point of conformation at least, as analogous to certain polypi evolved below the mucous membrane, &c. The rudiments, of various rare affections of the corion and cuticle, are even to be traced in the mucous membranes. I have dissected the tongue in several cases, in which the papillary system, very highly developed, was covered with an epithelium whose thickness, the double or triple of what it is generally, brought forcibly to mind the appearance of the epidermis in certain cases of elephantiasis arabica, and of local ichthyosis. I once saw a child, eight years of age, the skin of whose axillæ, bends of the arms, popliteal regions, and anterior part of the neck, presented so considerable a development of the papillæ that the whole of these parts appeared to be covered with a

continuous crop of warts, almost as moist on their surface as the mucous membranes themselves. The skin of the abdomen was brown and rugous, as it is in certain cases of ichthyosis. Circumscribed hardnesses and horny appendages, similar to those pretty frequently met with on the skin, have also been seen developed on the mucous membranes.

With regard to the accidental ossifications of the integuments, it does not seem to me that any conclusion can be drawn from the imperfect case recorded by Gillaiseau (Bullet. de la Faculté de Méd. de Paris, t. i. p. 224), and several others still less decisive.

1299. The study of the *cicatrices* of the external integument is fraught with a greater degree of interest than that of the cicatrices of the mucous membranes. Cicatrices of these latter tissues acquire more speedily the appearance of the membranes themselves, and on that account, remain for a shorter while visible than those of the skin. They are also, like the primary tissue they represent, less complex than those of the external integument. In the skin, the epidermis and dermis are, of all the elements, those which are most speedily reproduced. The pigment is never deposited till a much later period, and the sebaceous follicles and piliferous bulbs are scarcely ever reproduced at all.

Several cicatrices of the skin, such as those of burns, of serpiginous syphilis, lupus, acne, and leech bites, present peculiar characters, familiarity with which completes the knowledge of the causes that produce them.

Various animals are occasionally developed on the surface of the skin of man, and on that of the internal integument also. The difference of the places they frequent is in accordance with the no less remarkable differences they exhibit in their organization.

1300. The teeth are the only dependences of the mucous membranes which it is possible to assimilate to the hairy appendages of the skin. Like the hair, the teeth, as it is well known, may be faultily formed in a greater or less degree, and run in a variety of directions other than those they follow in the normal state. The alteration of the dental pulp seems to correspond to that of the piliferous papilla, and the fall of the teeth in the aged is a phenomenon of the same description as senile alopecia.

1301. To conclude this subject: when the body begins to putrefy, the external and internal integuments present livid marks, which correspond to the larger veins of the subcutaneous and submucous tissues. It is often of importance not to confound this appearance with that occasioned by congestion or inflammation. The subcutaneous cellular tissue more frequently becomes emphysematous in the earlier stages of putrefaction, than that which is distributed under the mucous membranes; and there is one alteration exhibited by the skin, as the body is hastening to decay, nothing analogous to which is seen on the mucous membranes; this is a kind of blebs or blisters of different sizes, which are formed by a quantity of sanguinolent serum, frequently mixed with a few bubbles of air, effused under the epidermis. In the point upon which these phlyctenæ are formed, the corion has sometimes a greenish look; the epidermis is always readily detached from the part near these phlyctenæ; these two circumstances will always suffice to distinguish the alteration in question from the blisters occasioned by burns, frost bite, pemphigus, œdema, and the action of cantharides.

## APPENDIX.

1302. In this appendix I shall describe, first, the organized living creatures which are observed on the surface of the skin, in its substance, or in the subcutaneous cellular tissue; secondly, Arabian elephantiasis, a disease in which the skin is not at first implicated, which ends in causing the hypertrophy of its different component layers; thirdly, diseases peculiar to certain countries, or to certain epochs, several of which have been very imperfectly described; fourthly and lastly, certain diseases of animals which are capable of being transmitted to man.

### ORGANIZED LIVING CREATURES INHABITING THE BODY OF MAN. (a)

1303. Many animals may be developed, or may exist accidentally on the skin of the human subject. Some grow, live, and generate

(a) Notice has been taken already (in note at pp. 196-7) of *vegetable* organized matter, growing on the human skin in certain diseases, and more especially in favus. As the subject is a novel one, it may not be deemed amiss to introduce here the substance of Dr. John Hughes Bennett's observations, confirmatory of those of Mr. Gruby.—“On the Parasitic Vegetable Structures found growing in living animals. In Transactions of the Royal Society of Edinburgh.”

“In the *Comptes Rendus des Séances de l'Académie des Sciences*, for July and August, 1841, M. Gruby has inserted some observations regarding the crusts of *tinea favosa*, or *porrigo lupinosa* according to Bateman, for the purpose of establishing a more complete diagnosis of this disease than had previously existed. For this purpose, he had recourse to the microscope. By means of this instrument he ascertained—1st, that *tinea* consists in the aggregation of millions of mycodermatous plants. These are formed of articulated filaments of a diameter from  $\frac{1}{1000}$  to  $\frac{1}{500}$  of a millimetre; they spring from an amorphous mass of which the periphery of each capsule of *tinea* is composed, and give off towards its centre oblong or round homogeneous corpuscles, which are the reproductive spores. The longitudinal diameter of these corpuscles is from  $\frac{1}{300}$  to  $\frac{1}{100}$  of a millimetre, and the transverse is from  $\frac{1}{300}$  to  $\frac{1}{150}$ . The cells of the tubes sometimes contain small round transparent molecules, of a diameter varying from  $\frac{1}{1000}$  to  $\frac{1}{500}$  of a millimetre. The seat of these vegetations he ascertained to be in the cells of the epidermis. The true skin is compressed, not destroyed; and the bulbs and roots of the hairs are only secondarily affected. The disc of the capsule, which is not at the commencement perforated, opens by a small hole in the centre. This enlarges, and the plants push through it, so that, at a more advanced period, instead of there being a central depression in the capsule, there is a convexity, and its edges disappear. M. Gruby inoculated 30 phanerogamous plants, 24 silkworms, 6 reptiles, 4 birds, and 8 mammifera, but only induced the disease once, and then in a plant. The human arm was inoculated five times, but, inde-

pendent of a slight inflammation and suppuration, no effect was produced. Dr. Bennet some time after examined the crusts on the head of a boy who laboured under the disease, and immediately detected the cylindrical and ramified appearances described by M. Gruby. Dr. Bennett, on continuing his observations still further, satisfied himself that pustules are not essential to the disease, though frequently present. Hence will appear the error of classifying the *porrigo lupinosa* among the pustulæ. According to Dr. Bennett, desquamation of the cuticle always precedes the development of the disease. Dr. Bennett made several observations in order to ascertain the correctness of M. Gruby's statement, viz., that the plants grow in the substance of the epidermis. He found that the entire inferior surface of the capsule is formed of epidermic scales, thickly matted together. These are lined by an amorphous, finely-granulated matter, from which the plants appear to spring. Superiorly, however, the epidermic scales are not so dense. These observations indicate the probable mode in which these plants are deposited on the scalp. We have seen that the appearance of the peculiar *porrigo* capsule was preceded by a desquamation of the cuticle. Hence, it is more probable that the matters, from which the vegetations are developed, insinuate themselves between the crevices, and under the portion of epidermis thus partially separated, than that they spring up originally below, or in the substance of the cuticle. Dr. Bennett failed, as did also M. Gruby, in communicating the disease to other individuals, or from one part of the same individual to another, although it is generally conceived to be of a highly contagious nature.

“Dr. Bennett mentions that he has observed crusts upon the face of a living common house mouse, similar in every respect to those which constitute the *porrigo favosa* in man. The crusts were of a more irregular form, prominent in the centre, not forming distinct capsules or perforated by a hair. When examined microscopically, they presented the cylindrical tubes and sporules *en masse*, in every respect identical to those which grow on the scalp of man. It has been observed that the odour of the crusts of *porrigo favosa* is similar to that of mice, which makes it not a little singular, that the mycodermatous plant, constituting this disease, should be found growing on these animals. Whether the disease be peculiar to man and the rodentia, is a question yet to be answered.”—*Med. Chir. Rev.*, 1841.

The conclusions deduced from these fairly by Dr. Bennett are, 1st. “That these vegetations always arise in living animals previously diseased; 2d. That their presence indicates great depression of the vital powers and impairment of the nutritive functions; 3d. That the peculiar constitution favourable to their growth is the tubercular or scrofulous in the mammalia, birds, or fishes, and most probably in reptiles and insects; and 4th. That the therapeutic indications are—1. To invigorate the system, and 2. To apply locally such applications as tend to destroy vegetable life. Dr. Bennett has found more than once a vegetable structure in the black deposit, which collects on the teeth and gums of individuals in the last stage of typhus.”

human skin, in the state of eggs, are there hatched, live in the form of larvæ, and emerge at length in the shape of winged insects, as the *ostrus*, so common in sheep, oxen, and horses; finally, one species of the entozoa, the *filaria medicinis* is occasionally met with developed beneath the skin.<sup>1</sup>

#### PEDICULI.

1304. The existence and development of a very great number of pediculi or lice, in a particular region, or over the whole surface of the human body, is designated under the name of phthiriasis (φθιρίασις from φθίρω pediculis).

*Pediculi* are apterous parasitic insects, the flattened bodies of which are covered with a skin which is hard at the edges and transparent in the centre; they have a small distinct oval or triangular shaped head, supplied in the forepart with a fleshy excrescence, enclosing a small sucker, which appears to be simple; they have two short filiform antennæ, with five joints, and two small round eyes. The corslet, almost square, is rather narrow in front. They have six short thick feet, all of equal length, each consisting of a haunch of two pieces, of a thigh, a cylindrical leg, and a strong sealy, conical, arched hook at the extremity. The abdomen is round, oval, or oblong, lobulated or incised, and showing eight rings on the sides. It is provided with sixteen sensible stygmata, and with a scaly point at the posterior extremity in the male.

Swammerdam not having been able to discover male organs in any of the pediculi he dissected, and having as constantly met with an ovary, concluded that these insects were hermaphrodites. Leuwenhoeck afterwards succeeded in distinguishing the male from the female, and gave an exact representation of the organs which characterize the male. According to him, the males have a bent stylette which they carry in the abdomen, and with which they can pierce the skin; he even conceives that the great itchiness which these creatures occasion proceeds from the prick of this sting, the introduction of the sucker into the skin, according to him, scarcely producing any sensation. De Geer mentions his having observed a similar sting at the extremity of the abdomen in several pediculi. According to De Geer, the end of the abdomen is rounded off in the males, whilst in the females, which have no sting or piercer, it is notched.

Pediculi are oviparous, and the females, after the intercourse which fecundates them, deposit their eggs, known by the name of nits, upon the hair and clothes. The young are not long in emerging from the eggs; they change their skin several times, and after these changes are in a state to generate. To ascertain the periods of propagation, and the length of time required for the growth of these insects, Leuwenhoeck took two females, and placed them in a black silk stocking which he wore night and day. At the end of six days, each of them, without decreasing in size, had deposited fifty eggs; at the end of

<sup>1</sup> It has been supposed possible for other animals to exist in the human skin, and Etmüller has been quoted as the authority for this assertion; he informs us, in fact, that he has seen a peculiar disease in new-born children, produced by small worms lodged underneath the skin, which occasioned violent itching and irritation only to be subdued by the expulsion of these animals. According to his account, these pretended worms, which medical men have named cirrhes, or comedones, are of a coal-black colour; they have two antennæ, and a tail terminating in a tuft of hair. But in the present day, the observations of Etmüller, and those which have been more recently published upon the same subject, by M. Bassignot (*Histoire de la maladie connue sous le nom de crinons qui attaque les nouveau-nés à Seyne, en Provence; Mémoires de la Société Royale de Médecine, 1776*) are generally allowed to be inaccurate. Sebaceous deposits within the follicles of the skin have been mistaken for worms. The *furia infernalis* of Linnæus seems also to be an imaginary worm. The characters which have been assigned to it by this celebrated naturalist, are, in great part, applicable to the gordius and filaria.

The larvæ of the genus *musca*, and of several other genera, may be accidentally developed in the meatus auditorius of children who are neglected, on the surface of ulcers, &c. Other insects sometimes inflame the skin by their stings. The bug (*cimex lectularius*), by means of its trunk, sucks out the blood and throws an acrid fluid of a peculiar nature into the wound. The bite of this insect is followed by the development of a papular or tubercular elevation of a yellowish-red colour. The gnat (*culex pipiens*) produces still more painful stings, followed by small hard tumours also of a yellowish-red, accompanied with heat and violent itchiness. The rouget, or mowers mite (*acarum autumnalis*, Linn.), fastens itself to the skin, and produces the most insupportable itching, which is soon followed by small yellowish inflamed tubercles. These insects are destroyed by bathing the skin with pure alcohol or strong vinegar. Finally, other insects, bees, wasps, hornets, spiders, ants, &c., by puncturing the skin, occasion a greater or less degree of pain and irritation.

four and twenty days the young ones had produced others in such numbers, that in the course of two months these two females might have seen eighteen thousand of their descendants!

The three species of pediculi observed on the human body are known by the name of *pediculus humani capitis* (De Geer), *pediculus humani corporis* (De Geer), *pediculus pubis* (Linnæus). They all live upon blood, sucked through their trunk, which is not seen unless when in action.

1305. *Pediculus capitis*.—The body is of a grayish-brown, the lobes of the abdomen are rounded. Linnæus considers the *pediculus capitis* as a variety of the *pediculus corporis*, from which it differs in the skin being harder and darker, and the corslet and abdomen being edged on each side by a blackish-brown streak. M. Latreille also thinks that they may be considered as a single species. The *pediculus capitis* lives on the head, and, according to Willan, does not quit the hairy scalp spontaneously.

*Pediculi capitis* are transmitted from one individual to another. Want of cleanliness and diseases of the hairy scalp do not produce them. If they are often observed among the children of the poor, whose heads are not kept clean, and in those who have long fair hair; if persons who are negligent in removing the scurf which is formed by perspiration and the use of powder, or who are affected with chronic inflammation of the hairy scalp, favus, &c., are often troubled with these insects, and if they are frequently observed among convalescents from a variety of diseases, it is merely because the want of cleanliness insures their propagation, and renders their destruction more difficult, and because certain conditions are more favourable to their existence and increase than others. Some false notions, current among the lower classes, are very favourable to the production of *pediculi*: they imagine that persons affected with these insects are generally otherwise healthy, that they suck away the *bad blood*; and, finally, that the existence of a certain number of pediculi on the hairy scalp proves a kind of drain which must not be suppressed without the greatest care. (a)

The existence of *pediculi capitis* is announced by a greater or smaller amount of itchiness. When these insects are numerous, persons affected with them are constantly scratching the head; in children, the pruritus which follows the first itchiness is sometimes accompanied by loss of sleep, and great nervous irritability. *Pediculi* multiply to a disgusting degree under the scabs of favus, and in the neighbourhood of the ichorous exudation of eczema of the hairy scalp. But although very numerous, they never cause marasmus, and still less death. The instances of the *deaths occasioned by lice*, detailed or mentioned in the dissertations of George Franck, of Franckenau, and republished, without critical remarks, in the *Dictionnaire des Sciences Médicales*, and in the abridgment of the same, are, at the best, tales to frighten children, who are negligent of their hair.

*Pediculi capitis* may always be destroyed by combing the hair frequently, or by shaving the head, when the hair is covered with nits. The same end is also as fully accomplished by washing the head with an alkaline solution, in which some of the seeds of *staphysagria* are infused. Oil of lavender, or a decoction of the smaller centaury, has been likewise recommended as an application to the hairy scalp infected with pediculi, or powdered parsley seeds may be sprinkled among the hair, with the effect of destroying them; finally, the head may be lightly rubbed with a small quantity of weakened mercurial ointment. This last means has been said to have produced very serious effects in several children, such as coma, a state of great debility followed by convulsions, &c. I have used it repeatedly, always with success, and never with any ill consequences.

1306. *Pediculus corporis*.—The body white, broad, and flat, without spots, and the eyes black; the notches or lobes of the abdomen shorter and less distinct than in the *pediculus capitis*. This species

(a) Some individuals are more disposed than others to be infested with pediculi. Parent-Duchatelet informs us, in his elaborate work on Prostitution in Paris, that the heads of very few of the unfortunate women of the town, even of the better class, are free from pediculi. It is stated that the members of one of the first aristocratic houses in England have some difficulty in keeping themselves free from *pediculi corporis*. Curling's Lectures on the Entozoa.—(*Med. Gaz.*, 1837-8.)

exists on those parts of the body which are habitually covered, on the trunk and extremities, rarely on the head. Its nits are agglomerated, and generally deposited in the folds of the linen, and other parts of the clothes; of those who live amidst filth, particularly of such as wear flannel, and to whom a change of linen is a rarity. These insects often multiply in a disgusting manner among prisoners, galley-slaves, sailors, and the aged who live in poverty and wretchedness.

The name of *phthiriasis* or *morbus pedicularis*, has been applied to the development of this species in great numbers. The *morbus pedicularis* is always the consequence of the successive and multiplied reproduction of one or more of these insects, accidentally contracted.

This insect is found on the surface of the skin of the extremities, and particularly of the chest and axillæ, in the body linen, and on the clothes generally; the skin is not altered unless the *pediculi* are extremely numerous, and the individuals have been long affected with them. In this case, small papular, conical, and reddish elevations, and still more frequently, tubercular spots, and accidental pustules, are frequently seen on the surface. Scratches and excoriations are also frequently observed. But various other concomitant lesions may exist accidentally at the same time, such as prurigo, ecchymoses, &c. Such is the *morbus pedicularis* divested of the hypothetical and unfounded details with which its history is mixed up. As to the spontaneous generation of these insects, Aristotle, Theophrastus, and Avicenna have all admitted it; attributing the occurrence to a bad state of the body, to heat and putrefaction of the blood, &c.; but this was at a period when the prodigious fecundity of these animals was not known. Some modern writers have, nevertheless, adopted this old opinion, and have quoted the following cases in support of it: 1st. An innumerable quantity of *pediculi* are sometimes observed to be developed on the head of a young infant, without any appearance of eggs on the hairy scalp, and without either the mother or nurse being affected with *pediculi*. 2d. M. Mouronval assures us that several patients, affected with prurigo *pedicularis*, have come repeatedly to the Hôpital St. Louis to beg for advice and relief; simple baths were first administered to cleanse the skin, after which the patients were clothed in fresh linen, and put into a perfectly clean bed; but notwithstanding this, the shirts of these individuals were found covered, a few moments after, with small *pediculi*, which could only have proceeded from the skin. 3d. In this strange disease (*phthiriasis*), says Lieutaud, lice appear not only in prodigious quantities on the outside, but they also generate under the integuments, and even under the pericranium; and what is still more surprising, is that some have even been found on opening dead bodies, which, after having perforated the cranium and the two envelops of the brain, were actually lodged in the *substance of this organ itself*. In opposition to these various assertions, it may be alleged that Lieutaud's cases never occurred; that the fact quoted by M. Mouronval will only be conclusive after we are assured that there existed neither *pediculi* upon the body, nor nits upon the hairs, when the persons left the bath, which was not ascertained; and, finally, that M. Bremser's remark cannot be considered as decisive, unless it be proved that the infant had not contracted nits or *pediculi* in its contact with other persons, and that its clothes had not accidentally become infested, circumstances which would require such minute examination, as it would be exceedingly difficult to carry into execution. Nevertheless, I must confess, that at the end of any serious illness in children, I have often seen the head become covered, almost suddenly, with a great quantity of *pediculi*, and when those about them were not in any way affected in the same manner.

1307. Some writers assure us, that they have seen small tumours or little elevations on the skin, full of these animals. Forest, or Forestus, says that his father had seen a case of this kind, and he himself mentions two others. Rust states, that he was once called to a consultation, in behalf of a male child, thirteen years of age, labouring under a large tumour on the head, which had resisted every variety of remedy tried for its dispersion. This tumour was very much elevated above the surface, flabby, without any fluctuation, and presented no trace either of present or former inflammation, or lesion of the integuments of the cranium. The patient, who seemed cachectic, only complained of an insupportable itchiness in the inside of the tumour. This

tumour had appeared after the termination of a nervous fever, and in the space of eight months had increased considerably. An incision was now made into it, when it was found to contain an immense quantity of small white *pediculi*. It contained nothing else, and the patient soon got well. In these later times, Dr. Heberden has quoted a similar fact from Edward Wilmot. Bernard Valentine gives an account of a man, forty years of age, who experienced the most insupportable itchiness over the whole body, the skin of which was full of small tubercles. Some of these small tumours were opened, and found to contain neither blood, serum nor pus, but such an immense quantity of *pediculi* of different sizes, that the patient was nearly dying of fright. Can we reasonably suppose that had these tumours been carefully examined, they would have been found to consist of dilated cutaneous follicles, into which *pediculi* had penetrated?

The development of *pediculi corporis* has been spoken of as a very serious disease. Some modern writers have related, after the ancient traditions, that Herod, Sylla, Ennius, Philip II, of Spain, &c., died of the *morbus pedicularis*. An examination of the viscera of these illustrious men would probably have led to a very different conclusion. Still it is possible, that a great number of these insects infesting infants or aged persons already labouring under some other disease, might occasion such insupportable itchiness and loss of sleep, as would materially aggravate the evils under which they suffered. Others have thought that the spontaneous development of *pediculi* might sometimes be salutary. M. Fournier, in the *Dictionnaire des Sciences Médicales*, quotes the case of an old man affected with rheumatic gout of the right side, in whom a great number of *pediculi corporis* were developed, although there had been no neglect of cleanliness chargeable on the patient; the pains ceased on this occurrence, and returned after the disappearance of the *pediculi*.

1308. *Pediculi corporis* are easily destroyed by sulphureous water baths, sulphureo-alkaline frictions, sulphureous fumigations, or baths of the bichloride of mercury. An unguent composed of three parts of sulphuret of mercury, one part of hydrochlorate of ammonia and thirty-two of hog's lard, is also successfully used for this purpose. The clothes should be fumigated with the vapours of sulphur or of mercury.

A variety of other compounds have been recommended, into which the seeds of the staphysagria, Cocculus Indicus, tobacco, various salts and mercurial oxides enter as constituents. The effects of some of these medicaments should be carefully watched. Frictions with tobacco ointment, or an ointment containing the active principle of tobacco, have sometimes occasioned convulsions and vomitings, and mercurial inunction may produce salivation, disorder of the bowels, and other symptoms more or less serious.

Writers who have believed in the spontaneous generation of *pediculi* with a view to destroy the unknown cause which gives rise to the development of these insects, have recommended bleeding, bitters, purgatives, anti-scorbutics, pills of the protochloride of mercury, and a variety of other remedies, which may be injurious or useful, according to the nature of the disease with which the individuals are affected upon whom these *pediculi corporis* appear.

1309. *Pediculus pubis*, Linnæus, Fabricius, Geoffroy.—This species is rather smaller than the preceding ones, its body is rounder, flatter and more compressed; its corslet is very short, and almost blends with the abdomen, which presents posteriorly two projections in the shape of horns; the feet are curved underneath. These insects remain fixed in the same situation and attach themselves very firmly to the skin, above the level of which they scarcely rise. They are found at the roots of the hairs of the genital organs, of the beard, the eyebrows, the eyelids, and the axillæ; they also occasionally propagate on the trunk and extremities, when these are pretty thickly covered with hair, but it is very remarkable that they never fix themselves on the hairy scalp. The sting of this species, which is very sharp, has led some naturalists to denominate it *pediculus ferox*. It is known in France under the name of *morpion*, and in England under the title of *crab-louse*. *Pediculus pubis* occasion an insupportable itchiness. When they are numerous, the skin appears sprinkled over with small red spots, resembling drops of blood, which are said to be produced by the excrement of these insects. Persons affected with them often detach them from the skin with their nails, and papular elevations

frequently appear on the points which they occupied. This species propagates like the preceding ones, and increases with great rapidity. Frictions with mercurial ointment over the parts where the *pediculi pubis* appear, generally succeed in destroying them, without there being any occasion to shave off the hair to which the nits of these insects are attached.

Powdering the parts infested with calomel, also destroys them. Baths of the bichloride of mercury, sulphureous water-baths and sulphureous fumnigations are more expensive and less efficacious means of getting rid of these insects.

1310. Before concluding this article, I think it necessary to observe that symptoms similar to those produced by *pediculi* may be occasioned by *acarides*, an insect very closely allied to the *ixodes*, but capable, according to M. Bory Saint Vincent of forming a new class, characterized by a small sucker, accompanied with two feelers consisting of four joints. M. Bory Saint Vincent has observed these insects upon a woman of about forty years of age, who, after having experienced violent itchiness over the whole body, was very much astonished to see thousands of acarides on all the parts which she had scratched. (*Journ. des compl. Sciences Médicales*, tom. xix. p. 182.) In a case of *prurigo senilis*, Willan also observed an insect, which he says could not be classed either with the genus *pediculus* or *pulex*.

#### Historical Notices.

1311. The first accounts of *φθειρίασις*, or *morbus pedicularis*, are to be found in Aristotle, (*Opera*, cap. xxxi. lib. v.,) a disease under which, if Pliny is to be credited, Sylla, the dictator, sunk (Plinii secundi *Natur. Hist.*, fol. Lugduni, 1587, p. 273). Galen (*Definit. Med. Gaz.*, p. 96, introd. Isag. 116), Celsus (*De Medic.*, lib. vi. sect. vi. p. 15), and Paul of Ægina (*Opera*, lib. iii. page 34), speak of *phthiriasis* of the eyelashes, and all recommend the use of staphysagria. Galen also mentions the *morbus pedicularis*. Galeni (*Opera: de theriaca, ad Pisonem*, cap. 18). Schenck (*Observ. Medicinal*, in fol. lib. v. *De phthiriasi*), and Forestus (*Opera Omnia*, fol. *De phthiriasi*), have more recently attracted attention to the *morbus pedicularis*.

In these later times, Heberden (*Commentarii de morborum Historia et Curatione*, p. 278, 8vo. Londini, 1802), has quoted a case in which a number of tumours full of pediculi were observed. Fournier (*Art. Cas. Rares in Dict. des. Sc. Méd.*, t. iv. p. 252), gives several cases of the same kind; and Marchelli (*Memorie della Soc. Medic. di Genova*), has spoken of a woman upon whom six or seven hundred pediculi were destroyed daily! (a)

#### PULICES. FLEAS.<sup>1</sup>

1312. Fleas are apterous insects, the head and corslet of which are distinct, the mouth consisting of a beak or sucker. Two species have been observed on the human body: *Pulex irritans*, *pulex penetrans*.

1313. *Pulex irritans*, the common flea, according to Linnaeus, is an apterous insect, distinguished by its oval compressed body, covered with a pretty strong skin, and divided into twelve segments, by a small head, very much compressed, rounded superiorly, truncated, and ciliated anteriorly, and by two small eyes situated one on either side. Near the origin of the beak, we find a pair of pincers inserted, which are presumed to be antennæ; they are composed of four nearly cylindrical joints; the abdomen is very large; the extremities are strong, particularly the hind ones, calculated for leaping, and have large legs, and thighs, and tarsi consisting of five joints, the last of which termi-

(a) Full accounts of *pediculi humani*, under the subdivisions of *P. humanus vel capitis*, *P. pubis* and *P. subcutaneus vel corporis*, are given by M. Raspail (*Histoire Naturelle de la Santé et de la Maladie*, 1844, t. 2e, pp. 93-104). This writer intimates that many diseases, and some of internal organs may be produced by *pediculi*. He believes that plica has this origin.

<sup>1</sup> Duméril (C.). *Art. Puce* (*Dictionnaire des Sciences Naturelles*, 8vo., t. xlv. Paris, 1826, pl. 53, n. 3, A).

nates in two elongated hooks. The two fore legs are inserted almost immediately under the head.

1314. The bite of a flea occasions as insupportable a sensation as that of a bug. The small ecchymoses which the bites give rise to, differ from petechiæ in presenting a central point, the colour of which is deeper and does not disappear under pressure, like the rosy areola which surrounds it. These insects seem to show a particular preference to some persons, and the irritation caused by their bites may occasion serious nervous symptoms in children.

1315. *Pulex penetrans*, of Linnaeus<sup>2</sup> (the penetrating flea, chiko or jigger). The beak of this species is a third longer than its anterior haunches, which distinguishes it from the preceding one. The chiko is a real scourge to the inhabitants of the West India Islands, and South America. This insect has been described by Sloane<sup>3</sup> as occurring in Jamaica, by Marggraf, in Brasil, and by Catesby, in Carolina. The female makes its way under the skin of the inhabitants of these countries, more particularly under the nails of the toes, and towards the heel; and there establishes itself. The itching it occasions is slight at first, and in the commencement nothing is perceptible but a small blackish spot; by degrees, a little tumour of the size of a pea appears on the punctured part; it is reddish if the insect be superficially situated, but no change takes place in the colour of the skin if it have penetrated deeply; this small tumour is formed by a kind of bag containing a sanious pus and a great number of small, white, oval, oblong globules, which are the eggs of the insect. Left to itself the tumour bursts spontaneously, and gives rise to an ulcer over the surface of which the eggs spread and are hatched. These insects are not long in appearing in the surrounding parts, and create in their turn other ulcers, the cure of which is very difficult and sometimes impossible. In some rare cases in which the insects insinuate themselves into the skin of the back of the foot, the ulcers which are the consequence end in caries of the bones and the loss of the toes. Gangrene has even been known to take place from this cause, and we are further assured that death may be the result of a long continuance and extensive diffusion of this animal under the skin, negroes being often seen to perish in the colonies from this cause alone. For the rest, those only who are negligent of personal cleanliness are attacked by this insect, which seems to delight in hot, filthy, and ill-ventilated places.

1316. The treatment consists in dislodging the insect; a pin is the implement usually employed to raise the skin and lay bare the bag, which must be carefully detached without being burst; the only means of destroying the chiko being to get away the bag entire. The membrane only of the bag left behind is sufficient to produce erythematous inflammation and ulcers of a very bad description. The negroes are very expert in the operation of extracting these nests of the chiko; so much so that the surgeons of the country are never called upon to practice it. After the extraction, the little wound is dressed with tobacco, either in powder or decoction, or with a decoction of certain acrid plants of the country, with mercurial ointment, calomel, a solution of the nitrate of mercury, &c.

The treatment of the ulcers occasioned by this insect, if they are neglected, becomes exceedingly troublesome, and it is only after repeated incisions that patients can be freed from the mischiefs attending the continuous presence of these creatures under the skin. (a)

(a) The justice of the title of *pulex* to this insect, and of regarding it as akin to the common flea or *pulex irritans*, is denied by M. Raspail (*op. cit.*), who expends a good deal of erudite criticism on the subject. He arrives at the conclusion that the so called *pulex penetrans*, jigger or chiko, is really the *acarus Americanus vel Ægypticus*, and the same with the European *acarus reduvius* or *tique*, that infests dogs.

M. Raspail, after describing the effects of the irritation of this insect on the skin of the human subject, enlarges the picture so as to make the subsequent and prolonged afflux and hypertrophy of tissue, to

## ACARUS SCABIEL.

1317. M. Raspail, so distinguished for his admirable microscopic researches, has given so complete and faithful an account of this insect that I cannot do better than copy it here. "This insect, on a cursory view, appears white; with good eyes, a number of reddish-brown spots may be perceived covering a part of its body. There is no occasion for a magnifying glass to see it plainly running on a coloured surface. It is about half a millimetre in diameter. A simple lens suffices to enable us to count the feet, distinguish the mouth, and recognize the various details which De Geer has indicated. When the insect crawls, and it is seen through a microscope, it appears flattened, and in the transparent parts it presents curved and parallel streaks which give it the appearance of the scale of a fish. Examined with a glass of the same power, the forefeet and the head are seen to be susceptible of being concealed under the body, by being curled underneath it, in the same manner as the forelegs and head of a turtle are drawn under its shell. The conformation of the dorsal surface of this insect is favourable to this action, as it overhangs the whole of the body, and advances like a shield or roof over the forefeet and head. The posterior portion of the body of this animal, examined particularly, presents eight hairs of unequal lengths, the shortest being situated towards the anus. Four of these hairs belong to the four posterior feet, and the four others are inserted two on each side of the anus, on as many small tubercles which are not distinguishable unless forced out by pressure with the point of a needle. On the disc of this dorsal surface a series or system of shining points is perceived. On looking at the animal in profile, the large white spot of the centre is found to consist of a protuberance considerably elevated; the anterior and the posterior surface are alike raised, and each of the small curves of the back is surmounted by a stiff transparent hair. The four rows of points which descend towards the anus, and towards the head, present the longest hairs. The contour of the body presents lobes of different forms according to the motions of the animal and the positions which it takes. As for the streaks which we have already mentioned, they cover the whole surface of the body. It was an error to imagine that they were only simple folds of the skin; they form a great cellular network, the cells of which are linear and hollow, and the interstices, which I entitle vascular, are in relief. This network resists sharp instruments powerfully; so powerfully, indeed, that it would be difficult for the observer, with the best inclination in the world, to transfix the insect with the point of a needle, when he was extracting it; and it is even very difficult, with the assistance of the lens and appropriate dissecting instruments, to seize and crush or divide it; it slides and bounds under the instrument, and the stiff hairs which cover its back do not a little serve to increase the difficulty of anatomizing it. Not only is the body then found to possess considerable toughness, but the feet and oval appendage, which, being rendered diaphanous by the refraction of the light, appeared to be of an extremely delicate texture, are discovered to be scaly and horny, and do not yield under the instrument.

Such are the general and particular aspects of this insect when it crawls and presents its back to the eye of the observer. But when it is turned over, and the lower surface of its body is examined, its organization is found so much more complicated as to require a more particular study. The two pairs of forelegs and the head are then clearly seen to be implanted in so many sheaths into which, however, it is impossible for them to recede. These sheaths form a sort of plastrum of a singular appearance.

The head is inserted within a notch or angle, the summit of which is prolonged upon the thorax in a line of a golden red. The head is extremely simple in its form, of a purplish colour, and curving downwards to where it ends in a sucker, which does not appear to me to be formed of any apparent system of mandibular forceps. Examined in acetic acid, two transparent vesicles appear on each side of the head, which may be naturally presumed to be the two eyes; on the

nucha two pairs of points are seen, each surmounted with a hair. These hairs, when they pass the curved head, appear to be of unequal length, because two are inserted on the posterior pair, and two on the anterior pair of points.

The edges of the sheath of the two feet nearest the head extend in two reddish lines, and approach each other at the level of the line which comes from the tail of the creature. The edges of the sheaths of the other two legs unite in the form of red lines at the convexity of those lines of which we have spoken, a distribution resembling in some sort a fan. The legs are composed of four joints and an oblique basilar piece which appears like a triangle, with its hypothenuse turned towards the posterior part of the body. Each of these articulations is covered with hairs, of which only those on the sides are visible. The last joint is covered with very short prickles, and armed beneath with a stiff hair, which is terminated by a flexible cavity, capable of producing a vacuum, like the soft glutinous pads of certain animals much higher in the scale, such as the tree frog; these pads enable the insect to fix itself in any position. The joints are not very distinct, and can only be counted after long examination. These five anterior members are half covered, as I said before, by the projection of the dorsal surface of the body.

On the belly two pairs of other organs are seen, which De Geer considered as four hairs enlarged at their bases and attached to the belly. These four supposed hairs are the four hind legs, which although shorter than the forelegs, possess the same essential organization, only they are without the apparatus, or accompaniment adapted for progression, which I shall designate under the name of *ambulacrum*. Except this trifling circumstance all that is observed in the fore feet is found in them. 1st. The reddish line which borders the sheath, the opening of the sheath, the hypothenuse, and the four articulations. Here the *ambulacra* are replaced by very long hairs. Upon the whole, the hairs of the hind feet which are nearest the head, are more developed than those of the two most remote. When seen with the lens, this arrangement of the feet looks very like De Geer's figure, and the red line bordering the sheath appears to be a hair which swells into a red vesicle in the region of the foot, and is produced in the form of a white hair at the top of the vesicle.

The anus sometimes appears projecting and sometimes hidden, but to see it very plainly it is only necessary to let the insect dry, when the dermis, on account of its hardness, retains its shape, the abdomen shrinks, and the direction of the anus is plainly seen through the transparent dermis. This animal externally is as white as snow, except the feet and the sucker; but if seen by refracted light it appears yellow, like all the white tissues of animals. This happens from the decomposition of the rays of light which pass through the organic substance, a decomposition in virtue of which the least refrangible rays, such as the yellow, alone reach the eye.

Although the hairs of the forelegs and head of this insect are directed forwards, it is easy to see that having the power of bending its feet and sucker underneath, these hairs can prove no obstacle to its progress through the skin. But the structure which facilitates this operation, is the presence of the hard papillæ of the back, which being directed backwards, offers such resistance in that direction, as prevents the creature from receding; above all it is assisted by the hard scaly case of the trunk which forms a covering like the shell of the tortoise. I think I have already remarked that the ventral is streaked in the same manner as the dorsal surface.

1318. M. Gras has described with much care the furrows or covered ways (cuniculi) already indicated by Bonomo, Casal, and Adams, and at the extremity of which the *acar* *scabiei* is generally found. In fact, if the vesicles of scabies in the hands, and in some cases in the feet, are examined with care, it will be seen that several of them present on their summits or on some part of their surface a small blackish spot; this sometimes extends in the form of a semicircle, and is found to be situated on a small whitish point. On other vesicles a blackish or whitish and sometimes a sinuous punctuated line is seen departing from this point, and traversing almost the whole surface of the vesicle; in this case, when the epidermis which is raised by the serum is removed, and examined with a lens, the punctuated line is found to be formed in its substance; with the assistance of the light of the sun, a small brownish point will be seen at the extremity of the

which it gives rise, a modification of disease analogous to, if not identical with, elephantiasis, or Barbadoes leg, Pian, and *Mal Rouge*.

cuniculus which is farthest removed from the vesicle, and on raising the epidermis in this place, the acarus can be extracted. It is worthy of remark that there is no communication between this *cuniculus*, and the cavity of the vesicle, and that it is always easy to remove the acarus without causing any discharge of serum.

M. Gras never saw two *cuniculi* begin in the same vesicle, although these covered ways frequently intersect each other. Sometimes the *cuniculi* are not seen near all the vesicles; in many individuals affected with scabies they are not even to be met with readily except on the hands; the burrows generally extend from two to four lines from the vesicles. M. Gras having placed an acarus on one of his fingers, the insect took twenty days to trace a burrow of two lines in length; another insect was only three days in making a *cuniculus* of the same extent.

There is no relation between the number of vesicles and burrows. In some persons affected with scabies, burrows are seen without vesicles in their neighbourhood; but at one end of these burrows, a small point of skin, which has lost its epidermis, and appears surrounded by a minute edging of this substance detached, is frequently observed; in other places, even such a trace of a vesicle does not exist, as occurred to M. Gras, who, having placed acari on different places in the skin, first observed *cuniculi* formed by the insects, and vesicles only some time afterwards and at a certain distance from them.

The insect may be extracted by means of a pin, by introducing the point obliquely into the epidermis, and turning it back; the acarus is often thus discovered at once, which, so long as it is not wetted with the serum of the vesicle, seems to attach itself with great ease to the point of the pin. This insect is at first motionless, and it is not until after three or four minutes that it is seen to move its legs and begin to walk with rapidity. In a temperature of from fifteen to eighteen degrees, these insects may be kept alive three or four days after their extraction.

Acari are very seldom found alive in persons affected with scabies after they have been for two or three days under treatment; and yet this disease is seldom cured before the tenth and sometimes even the fifteenth day. The acarus has been sought for in vain in individuals affected with other diseases of the skin,—prurigo, eczema, lichen, &c.

1319. In the article on scabies, I have mentioned the principal works relative to the history and particular study of this insect (§ 371), but I think it proper again to quote the work of M. Raspail and that of M. Gras, whose observations I have here copied. Raspail. *Mém. Comparatif sur l'Histoire Naturelle de l'Insecte de la Gale*, fig. 8vo. Paris, 1834.—Gras. *Recherches sur l'Acarus ou Scarcopte de la Gale de l'homme*, 8vo. Paris, 1834. (a)

#### FILIARIA MEDINENSIS. GUINEA WORM, &c.

1320. Under the name of *filaria*, a genus of the *entozoa* is indicated, the principal characters of which I shall here particularize: a cylindrical filiform and very long body, decreasing in a very slight degree only towards the extremities, which are blunt; a very small articular mouth, terminal as is the anus also, in all probability; the male organ short, somewhat rounded, and situated before the point of the tail; the intestinal canal very distinct, and extending the whole length of the body. The *filaria* inhabits the cellular tissue of animals of all classes.

1321. The most celebrated of all the species of the *filaria* has been observed in the human subject. It is known to naturalists by the name of *filaria medinensis*, (b) *dracunculus* or *Guinea worm*. The body of this species of *filaria* is of a dirty white, which becomes yellow in alcohol; its size, nearly equal in its whole extent, varies from that of a thick fiddle-string to that of a straw. The length of the *filaria medinensis* varies between nine and forty-two inches

(a) M. Raspail, in the work already quoted, (in note to § 1311,) tome Ire, pp. 441–475, gives a detailed and an amusing history of the progress of observation and opinion, respecting the *acarus scabiei*, together with engravings of the imaginary and the real insect.

(b) A name given to this worm by Avicenna, after the city of Medina, in the environs of which he had most frequently seen it.

(Heath), a foot, a cubit, and more (Kæmpfer), three feet and a half, Rhenish measure (Gründler), more than two ells (Kunsmüller), eight to ten feet (Gallandat), and even eight ells (Férmin). The head is furnished with a kind of sucker, formed by the enlargement of the lip surrounding the mouth, the orifice of which is very small. The tail is terminated by an inflected hook. The *filaria medinensis* bears the greatest resemblance to the *filaria of the monkey*.

According to the recent researches of Jacobson, certain *filaria* at least are composed, not of one single individual, but of an assemblage of individuals, living under or within the same skin. M. Jacobson received an Arab into his hospital, who had a tumour near the outer ankle, which was discovered to be occasioned by a *dracunculus*; this, after several fruitless attempts, was extracted by the ordinary process. A second tumour having appeared on the other ankle, it was laid open, and the knife having divided a portion of the worm longitudinally, a purulent-looking matter issued from the opening, which, on being examined with a microscope, presented a crowd of small elongated filiform worms, with the head somewhat enlarged, and a short tail, much thinner than the body. Upon extracting the whole of this *dracunculus*, all its parts were found to present the same appearance. That which had been extracted from the first tumours was ascertained, on examination, to exhibit precisely the same structure.

M. de Blainville presented a portion of the internal substance of this worm, collected by M. Jacobson, to the Academy of Sciences. Seen through a microscope, it was almost entirely formed of small animals, in perfect accordance with the description given by that talented anatomist. M. de Blainville thinks that it would be interesting to ascertain whether all *dracunculi* presented the same peculiar organization (*Gazette Méd.*, 1834, p. 216). (a)

1322. The history of this entozoon presents a very remarkable peculiarity, for which it is impossible to account satisfactorily at the present day. The inhabitants of the torrid zone alone are almost ever affected with it. The principal observations which have been made on this animal, have been collected in Arabia-Petrea, on the banks of the Persian Gulf, of the Caspian Sea, and of the Ganges, in Upper Egypt, in Abyssinia, in Guinea, &c. I do not believe that it has been developed in the human subject in Europe. (b)

(a) M. Raspail (*op. cit.*), denies the accuracy of this statement of Mr. Jacobson. The *filaria* consists, the former tells us, almost entirely of a very long ovary; the head and thoracic region seeming to be one of its extremities. The intestinal canal, which traverses the whole body from end to end, being very minute and easily broken, we can understand how Jacobson should have believed that this long body was only a sac filled with *vermiculi*; for, as the *filaria* is both viviparous and oviparous, it is easy to see, at a certain period, the small worm through the transparent envelopes of the ovum or egg. And again, very seldom does it happen that the *filaria* can be extracted from the body in which it is imbedded, without its head and tail being torn off under the effort of traction; and then the ovary is left, seeming to the eye of the examiner to be a tube filled with eggs.

(b) The following succinct summary of the localities and subjects of *filaria medinensis*, and the symptoms and mode of treatment when it is imbedded beneath the skin, is derived from Mr. Curling's Lectures on the Entozoa, already referred to.

*Locality and Subjects of Filaria*.—"It occurs at all ages and in both sexes, and appears to be endemic in the tropical regions of Asia and Africa, where it appears generally in the hottest seasons. It is by no means confined to the natives; many facts tend to show that it may be communicated from one individual to another; and Lind and other writers are of opinion that Europeans, on visiting the countries where it exists, become affected with it by contact with the negroes. In America it is said to make its appearance almost exclusively amongst the negroes, and chiefly in those who are newly arrived from Africa. We occasionally meet with it in this country, in individuals who have recently returned from the tropics. There is a specimen in the Museum of the College of Surgeons, twenty-two inches in length, which was extracted from the leg of a boy who was a patient of the late Sir W. Blizard, at this hospital. We have also a worm in the museum, removed by Mr. Headington, who was formerly surgeon of this hospital, from the leg of a sailor, where it had been

The filaria medinensis has been most generally observed in the subcutaneous cellular tissue of the human body, particularly of the lower limbs. Of one hundred and eighty-one cases collected by Sir

imbedded for two years; and there was another patient in the hospital at the same time, likewise affected in this way. From some observations by Sir James Macgrigor, it would appear that the disorder originating in these worms prevails at times in an epidemic form. Thus he mentions that some troops having embarked, after a residence of two months at Bombay, were attacked whilst at sea so generally, that out of three hundred and sixty, as many as one hundred and sixty-one became affected with it. Clot Bey, a French surgeon, in the service of the Pacha of Egypt, mentions that he has seen as many as a hundred patients, labouring under Guinea worm, in hospital at one time. Little seems to be known which can account for the development of this parasite, though authors have speculated abundantly on the subject. It has been noticed, however, that it occurs much less frequently amongst the officers than the common soldiers, and those who occasionally lie on the ground, or go about with their feet and arms naked."

*Symptoms.*—"The Guinea worm may remain imbedded beneath the skin for many months, without occasioning any inconvenience, but sooner or later it excites irritation and inflammation in the structures around, which vary in severity according to the constitution of the individual, and the situation and size of the worm. The symptoms commence in a formicating sensation or uneasiness under the skin, accompanied with a superficial cord-like elevation on the surface. A phlyzaceous vesicle or pustule forms, which bursting, gives exit at a circular aperture, either immediately or after suppurating for a day or two, to the head of the worm. These local symptoms are preceded usually by slight derangement of the system generally. When situated about the fingers or toes, the worm is often productive of much suffering, and is with difficulty got rid of. When deeply seated it sometimes causes considerable fever, great swelling, and tedious abscesses and sinuses, giving out a serous ill-conditioned discharge for many months without the worm making its appearance.

"The treatment consists in the cautious and gradual extraction of the worm, special care being taken to avoid breaking it across, as this accident is liable to be followed by an aggravation of the inflammation, and the formation of sinuses in its course, together with great constitutional disturbance. These unfavourable effects are attributed, by Hunter, to the contact of dead animal matter, with a large extent of living surface, to which it now bears the relation of a foreign body; such violent symptoms being rarely seen so long as the dracunculus is alive and uninjured. When the worm protrudes, it should be laid hold of and gently drawn out from its resting-place as far as possible. The part removed should then be secured at the aperture with a strip of plaster, or tied to a piece of stick, and the traction may be repeated once or twice in twenty-four hours until the entire worm is brought away—a process often requiring many days, or even a month, for its completion. Some surgeons recommend cutting down upon the middle of the animals, and by pulling simultaneously at both ends, shortening the period requisite for the removal of the dracunculus—a plan which is practised by the native Indians. When the worm is got rid of, the sinus usually closes readily. The use of internal remedies and external applications do not appear to be of any essential service. Sir James Macgrigor found that the extension of this affection amongst the troops was checked by requiring great attention in regard to cleanliness, and separating the soldiers troubled with these worms from those that were free from them."

M. Sigaud (*op. cit.*, pp. 133–35), represents the filaria medinensis to be common among the negroes of Brazil. He mentions cases in which the worm was extracted of the length of seven feet; and also a case in which violent inflammation had seized on the whole of the right leg, and gangrene, even, appeared in spots. Free incisions were practised and cataplasms of camphor and flour of manioc were applied to the parts, while tonics were administered internally. The cause of all these formidable lesions was then found to be a filaria, which, with some difficulty, was in part extracted. Cicatrization, aided by various dressings, the chief of which was the root of the *milhomens*, began about the twenty-seventh day. But, ere long the negro com-

J. Macgrigor, it is calculated that in one hundred and twenty-four of them, this worm was situated in the feet, in thirty-three in the legs, in eleven in the thighs, in two in the scrotum, and in two in the hands. Kämpfer found it in the hollow of the ham and in the scrotum; Peré has seen it in the head, the neck and the trunk; Bajon assures us that he has twice seen it under the mucous membrane of the ball of the eye, &c.; Chardin pretends that the filaria medinensis almost always occurs singly, while Bajon and Bosmann assure us that it is not uncommon to meet with several of them in one patient at the same time.

It seems to be an established fact, that this animal is never developed except on the human body. Læfser, who lived many years in those parts of Africa where the inhabitants are troubled with it, never heard that it had, on any occasion, been observed in water; and Hind, who has also carefully examined the water of these countries, never detected either these worms or their eggs in it. The contrary opinion has arisen from this species of filaria, having been taken for a true *gordius*, which is supposed to possess the power of making its way, and living underneath the skin.

The great size which the filariæ, extracted from the human body, sometimes acquire, would lead one to imagine that these animals do not occasion the phlegmon which proclaims their existence, until some weeks, or even months, after their formation. This inflammation of the cellular tissue soon ends in suppuration; and upon the spontaneous or artificial opening of the abscess, one or more inches of the filaria generally protrude.

This animal is extracted by being repeatedly and very gently drawn out. The imperfect extraction of the filaria is said to be followed by very serious symptoms.

1323. There is much difficulty in France in procuring the filaria medinensis to examine its organization. I have seen one very well preserved in the collection of the Jardin du Roi. It is about three and twenty inches long, from the head to the tail, and one line in diameter throughout. It is generally flattened, and the two terminal openings are very distinct. M. Henri Pétoz, chief apothecary to the Hôpital de la Charité, possesses another of these animals, which was extracted from the foot of a negro of Guinea. This worm is about twenty-five inches long; it is yellowish, like cat-gut, which probably arises from its having been so long preserved, dried, and rolled on a small piece of wood. One of the extremities, the tail, is hooked, and near it, under the microscope, a small tubercle is seen, in the centre of which is an opening. The other extremity, examined by a microscope, magnifying twenty-five times, appeared unequal, irregular, and jagged. The head had probably been broken or crushed. Finally, M. de Blanville says (Grundler. *Traduction Française de l'ouvrage de Bremser sur les vers intestinaux*), that he possesses a filaria medinensis, which was sent to him by M. Delorme, the author of some very interesting observations on this entozoon (*Journal de Physique, Chimie, &c.*, August, 1818). (a)

plained of fresh pains, as intense as those under which he had formerly suffered and in the same spot. On careful examination, a new inflammation was found, the centre of which was in the form of a flattened tubercle of a pale colour. This was opened, and the remainder of the worm was seen and gradually withdrawn; after which the inflammation soon subsided, and the leg was perfectly healed.

(a) The opportunity denied to M. Rayer has been afforded to M. Maisonneuve, of Paris, who has published his observations in the *Archiv. Gen. de Méd.*, of which we give a summary as follows.

"In October, 1843, he received into his wards, at the Hospital of St. Antoine, a man named Edé, aged twenty-eight, who had, five months previously, returned from Senegal, where he had served as a soldier two years and a half. About a month before he entered the hospital, he perceived on his left foot, for the first time, a small tumour, which gave rise to a dull pain in the vicinity of the articulation, and was accompanied by considerable itching, for which he in vain tried poultices, rest, and various other plans of treatment. M. Maisonneuve was surprised to see a vigorous man enter an hospital for what appeared nothing more than a very small phlegmonous tumour on the level of the posterior extremity of the fourth metatarsal bone, and merely made a small incision, afterwards ordering a poultice. On examining the wound the following day, he observed a

1324. Several writers have confounded the *filiaria medinensis* with the *Gordius aquaticus*. This mistake was the more likely to occur from the circumstance of the body of the *Gordius* being in the form of a thread, as well as that of the *filiaria*, but the former differs from the latter, in its body presenting the transverse folds of the annelida, to which natural order it belongs, inhabiting like them soft waters, slimy places, subject to inundations, &c., whilst the *filiaria* are true entozoa. In addition to this, all the *gordii* examined by M. de Blainville, presented the anterior extremity of the body, divided in the form of pincers, which is not the case in the *filiaria*. Besides, in combating the opinion of Joerdens, who thought that the *Gordius aquaticus* might make its way under the skin of the human body, M. Bosc has very judiciously remarked, that the organization of this species of *Gordius* renders it incapable of piercing the integuments, and that it has never been seen in the subcutaneous cellular tissue of the human subject. After having examined some specimens, belonging to this species of *Gordius*, which my friend Doctor Asselin and I had collected in the ditches of the forest of Meudon, we became satisfied of the accuracy of the observations of M. Bosc. Finally, it is known that Pallas no where

kind of white filament, which he seized with his fingers; it gave way, but broke when he had drawn out about six inches. On ascertaining from the patient that he had lately inhabited Senegal, it occurred to M. Maisonneuve that it might be a guinea-worm, and he then examined the man more attentively. In the vicinity of the furunculous tumour there was a slight degree of œdema, which extended to the malleoli; pressure over this region was painful. At the superior and external part of the same leg, just below the head of the fibula, there was another small tumour, very similar to the first. It was indolent, merely gave rise to slight itching, and had only been perceived by the patient about fifteen days previously. From this tumour there passed a kind of flexuous, irregular cord, which he at first thought was a varicose vein; after turning round the anterior part of the leg, it lost itself in the calf; its consistence was hard, like that of whipcord. It was evidently a second worm. The man was muscular, and in the full vigour of youth. He had never suffered any thing of the kind whilst in Senegal, nor had his white companions, although it was common among the negroes. In the course of the fortnight which followed the man's admission, several phlegmonous tumours formed round the external and internal malleolus, and on being incised, exposed different portions of the *filiaria*. It was entirely extracted, but not without some trouble, as it broke repeatedly. One day, on pressing the superior furuncular tumour, a few drops of a white fluid, like whey, escaped. This fluid was examined with the microscope, and found to contain myriads of small cylindrical worms, with thin, pointed tails. They were amazingly active in their motions, and on being examined in water, were not found to present any tentacula or appendages of any description. Some of them remained alive several days. The head of the *filiaria* showing itself at the tumour, M. Maisonneuve seized it with his fingers, but it broke. He then took up a fold of the skin over its course, and by a transverse incision, exposed several circumvolutions of the worm. It was situated in the lamellar subcutaneous cellular tissue; he dissected it out with care, passing a sound underneath, and was thus able to extract all the superior portions. It was about as thick as a crowquill, and very like the *vas deferens* near the epididymis. On exercising traction by the part exposed, it broke, and a second incision and dissection were resorted to. The remainder of the worm was found curled up on itself in the cellular tissue, like the superior part, and was obtained in the same way; a small piece of the caudal extremity was left, but extracted the following day by the patient himself.

"M. Maisonneuve remarks that this case is very interesting, as it establishes a point in natural history which has been much debated—viz., the existence of the *filiaria* as a distinct species of animal, capable of propagating itself whilst in the human economy. As long, in all probability, as the *dracunculus* merely increases in size, its presence, says M. Maisonneuve, gives rise to scarcely any local disturbance, but when the period of reproducing arrives, it makes an effort to perforate the skin, and thus occasions a furuncular tumour. It is singular that these parasitical animals should thus discharge their young externally."—*Lancet*, Feb. 8th, 1842.

met with so great a number of *Gordii aquatici* as in the lake of Waldei; but he could not learn that this worm had ever been known to make its way under the skin of any of the persons who had bathed in this lake.

#### Historical Notices.

1325. The *dracunculus* was known to the ancients: "quemadmodum, in quodam Arabiæ loco (ut aient) in tibiis hominum dracunculi vocati nascuntur, nervosa natura, colore crassitudinque lumbricis similes" (Galen Opera, fol., class. 4, de locis affectis., lib. 6). Aetius has given a very good description of it, and an account of its treatment after Leonides (*Tetrabl.* iv. sermo xi. in fol. 1549, p. 800). Avicenna (liber quartus; de venâ medeni), speaks also of having seen it. Schenck (*Obs. Medic.*, lib. v. de *dracunculis Ethiopiæ et Indiæ propriis*), has collected a number of facts relative to the history of the *filiaria*. In these later times, new, *Gonneau ou Veine de Médine et sur l'usage du sublimé corrosif dans cette maladie* (*Journ. de Méd.*, Janvier, 1760); Macgrigor, (Sir James,) medical sketches of the expedition to Egypt from India, 8vo. London, 1804; Paton, cases of Guinea worm, with observations, (*Edinb. Med. and Surg. Journ.*, t. xi.); Scott (Will.), and Kennedy (Alexander), Remarks on the *Dracunculus* (*Edinb. Med. and Surg. Journ.*, t. xvii. p. 96); Grant (Robert), extracts from a correspondence on the *filiaria medinensis* (*Edinb. Med. and Surg. Journ.*, t. xxxv. p. 122). Two cases of the extraction of several *dracunculi* performed in France, have been related by M. Brulatour (*Journ. de chimie médicale*, t. vi. p. 624). Grunbler, in his treatise, *de venâ medinensi*, has given an original representation of the *filiaria medinensis*, which has been republished in several works, and in particular in the *Encyclopédie Méthodique*, t. xxxix. fig. 3.

#### ÆSTRUS.

1326. *Æstri* are dipterous insects characterized by the almost complete absence of a mouth, which has caused them to be designated by M. Duméril *astomata*. Their larvæ deposited under the skin of the human body, and more frequently under that of the ox, occasion small circumscribed and painful inflammations.

1327. The species of *æstri* which live under the skin of animals have been described with much accuracy by Mr. Clark (*Trans. of the Linnean Society of London*). Mr. Say (*Journal of the Academy of Natural Sciences of Philadelphia*, vol. ii. pp. 353–60), thinks, with Linnæus, that there really exists a species of *æstrus*, the larvæ of which inhabit the human body; an opinion which is discountenanced by Fabricius, and other modern entomologists, but which Mr. Say founds on the following observations, contained in a letter to Dr. Harlan from Dr. Brick, who had extracted the larva, afterwards submitted by Mr. Say, and described by him in the *Journal of the Academy*. Dr. Brick writes:—"After a very sultry day's march, and being very much fatigued, I went to bathe in the Chama, a small stream emptying in the lagoon of Maracaibo. Not long after coming out of the water, I received a sting from some insect, in the left leg, over the upper and fore part of the tibia; it was several days attended with a considerable degree of itching, but without any pain, and I continued on my journey some few days longer without experiencing much inconvenience, except during several periods of perhaps two or three minutes continuance, when an acute pain came on suddenly, and was severe whilst it continued, and then as suddenly subsided. On my arrival and during my continuance at El Rosario de Cucuta, I walked with difficulty; there was a considerable tumefaction over the tibia, which had the appearance of an ordinary bile (phlegmon); in the centre there was a small black speck; the usual applications were used without any success, and the tumour became more irritated and inflamed, and thus it remained for some days, attended at times with a most acute pain, which for a few minutes was almost intolerable.

"In returning to Maracaibo, I had to descend the Cottatumba in an open boat, without any shelter, and being wet to the skin by the cold rains which fell every night, I suffered much, and was almost constantly tormented by the tumour, which became more painful at those particular periods than usual; during this passage, which lasted

for twelve days, I was induced to scarify it, and had recourse to the usual topical applications, but without success. At times I imagined that I felt something moving, and suspected that there was something alive beneath the skin.

"After my return to Maracaibo I became scarcely able to walk, and was in a manner confined to my quarters. In this situation I continued two weeks longer, the tumour having begun to discharge, and without any diminution of the painful periods.

"Being now nearly worried out, it occurred to me to try a poultice of tobacco, which was used for several nights, having previously scarified the tumour; during the day, I frequently dusted it with ashes of segars: as an ingredient I used rum instead of water in making the poultice. On the fourth morning after this remedy, I felt considerable relief, and on the fifth, with a forceps, I drew out the worm which you have now in your possession, and which was then dead.

"In a few days the sore assumed a healthy look, and in ten days was perfectly healed up—although, at times, I yet experience a heavy pain in the part from whence the worm has been taken. It had traveled on the periosteum along the tibia for at least two inches. The severe pain which I experienced for those periods, I attribute to the irritation of some of the branches of the nerves distributed to the parts by the worm in its progress. Respecting this worm there are different opinions among the Spaniards and Creoles. *Ouche* is the name it is called by some, who say it is produced by a worm which crawls on the body from the ground, and penetrating the skin, increases in size. Others maintain that they are produced from the sting of a winged insect which they call *Zancudo*;<sup>1</sup> others again call the insect *Husano*; for my part I am rather inclined to think that they are produced from the sting of a winged insect which deposits its egg.

"N. B. Should it even be proved that the form of the anterior part of this larva is owing to the violence used in extracting it, of which there is no appearance, still it will stand as distinct from other known species."

1328. Mr. Say thinks that this larva, which was sent to Dr. Harlan by Dr. Brick, belonged to the *æstrus* genus. He describes as follows:—"The form of this larva is clavate, the posterior moiety of the whole length being dilated and somewhat depressed; the segments of this portion are armed with transverse series of small, black, horny tubercles, dilated at their bases, near their tips rather suddenly diminishing to a filiform curved hook, pointing forwards and with an acute termination; these series are six in number on the back and sides, placed in pairs, and three in number on the abdomen; near the posterior termination of the body are numerous minute tubercles of the same character with the others, excepting that they conform to no regular series; the anterior moiety of the body is entirely glabrous, cylindrical, or rather elongate conic, of a much smaller diameter than the posterior portion, and truncate at the tip; the lips at the posterior termination of the body are short, and the intervening fissure of but little width.

"Total length eleven-twentieths; greatest width more than three-twentieths of an inch."

1329. Mr. Say compares this larva to that of the *æstrus* in oxen, horses, sheep, and to that of the hemorrhoidal *æstrus*, several of the characters of which it presents, but still it exhibits distinctive ones of its own. (a)

M. de Humboldt has seen in South America, Indians whose abdomens were covered with small tumours produced, as he presumed, by the larvæ of the *æstrus*. Finally, M. Howship read a paper to the Medical and Chirurgical Society of London, on the 26th Nov., 1832, on the *æstrus of the human body* in which is contained an account of two new cases, one of an *æstrus* found in the cellular tissue of the shoulder of a soldier at Surinam; the other of an *æstrus* in the cellular tissue of the scrotum of a young man of Santa Anna, in Columbia.-(*Gaz. Méd. de Paris*, 1834, p. 71.)(b)

(a) I have replaced the imperfect and in some respects erroneous extract from Mr. Say's paper, in the text, by the introduction of the main parts of it from the Journal of the Academy of Natural Sciences.

(b) M. Raspail, who is disposed to attribute so many diseases to

<sup>1</sup> "The word *Zancudo* is used by the South American Spaniards to denote several species of *culex*."—S.

## FIRST GROUP.

## INTUMESCENTIÆ.

1330. This group comprises several diseases with which the skin is not primarily affected, but which occasion hypertrophy of its different layers. These diseases, sometimes preceded or accompanied by fever at the commencement, are almost always followed by permanent *intumescence* or enlargement of the parts affected.

## ELEPHANTIASIS ARABICA.

1331. Certain *enlargements* of the limbs, scrotum, labia majora, face, &c., usually accompanied by hypertrophy of the skin, distinct from phlegmon, from œdema and from bloody tumours, have long been and are still described or designated under the name of *elephantiasis arabica*, or Arabian elephantiasis.

1332. *Symptoms*.—Elephantiasis Arabica generally attacks the lower limbs; one limb only is most frequently affected, but both may be implicated either at the same time or successively (Alard., obs. 1. 3). Hendy has described a variety of this disease under the name of *Barbadoes leg*: M. Alibert designates it by that of *lepre élephantine tuberculeuse*.

In a great number of cases this enlargement of the lower extremities is announced in an acute manner by a more or less severe pain in the groin and ham, following the course of the vena saphena, and principal trunks of the lymphatic vessels, and next by the appearance of a *red line*, or hard, knotty, tense cord, resembling a chain of small subcutaneous tumours, extending from the bend of the groin to the knee or ankle, (Hendy, cases 2. 4. 9,) or from the ankle to the groin (case 8); or still otherwise, by an attack of erysipelas. In almost all cases, the skin assumes an erythematous hue, and the subcutaneous cellular tissue becomes the seat of considerable tumefaction. The neighbouring joints are stiff and contracted; frequently from the commencement, there are long-continued shivering fits, great thirst, uneasiness, restlessness, violent retching, vomiting, occasionally delirium, then intense heat, accompanied with palpitation of the heart, followed by general or partial sweating, and the cessation of the febrile symptoms. In the course of one or more months these phenomena return in the shape of paroxysms at shorter or longer intervals, which may vary in number from three (Hendy, case 17), to fourteen in the course of a year (Hendy, case 16), or may only recur at the end of seven years (Hendy, case 19). These fits, the number and duration of which can neither be foreseen nor calculated, are followed by a progressive increase in the size of the limb, which would appear at first to be owing, in a great measure, to the deposition of a certain quantity of serum or coagulable lymph within the cellular tissue. The limb afterwards becomes hard and no longer retains the impression of the finger. The lymphatic ganglions of the groin and ham, often very much increased in size, are sometimes otherwise apparently healthy and indolent. In this second stage of the disease, it exists without any further inconvenience than that which the deformed state of the limb necessarily occasions. It sometimes assumes such extraordinary shapes, and becomes so entirely out of proportion to the other parts, that it is impossible to form an idea of the extent of alteration undergone without having seen some cases, or the drawings of the disease which have been published. In one case the tumour is full and uniform like a well-filled bag or bladder; in another, it is in divisions as if each successive fit had formed and left its own particular swelling.

After the first attacks, the skin is usually pliant, and does not exhibit any change of colour; vessels sometimes appear creeping beneath it, and give it a brownish hue; by degrees, however, it becomes hard, particularly in the neighbourhood of the ankle joint, and is covered with elevations and small veins; the epidermis then often becomes

insect and entozoic origin, asserts his belief that the cure of cancerous fungus of the uterus, in which extirpation was performed by Recamier and Marjolin in 1825, was caused by larvæ of the *æstrus*.

thickened as in ichthyosis. Finally, chaps and fissures are sometimes formed on the limb, which now becomes excessively deformed. The knee-joint occasionally becomes the seat of very obstinate chronic inflammation in these cases. Such anomalous developments are not always preceded by the symptoms of acute inflammation of the vessels and lymphatic glands, or of the veins of the inner part of the lower limbs, mentioned in almost all the recent cases of the glandular disease of Barbadoes related by Hendy, and in many others, in which it had been of long standing (cases 14, 15, 17, 18, 21). In fact, these enlargements sometimes occur after ulcers of the legs (Andral), repeated attacks of erysipelas, of lichen *agrius*, or *eczema rubrum*. The knotty, hard and tense cord is not then seen, as in the woman Berton (Alard, obs. 1). This system was not perceived by M. Bouillaud (*Archives générales de médecine*, t. vi. p. 56), in a woman whose lower extremities, enormously enlarged and as hard as a stone, had become like those of an elephant. The intumescence in this case, in fact, followed the obliteration of the crural veins and the vena cava. I have given the history of a patient in the first edition of this work, in whom the anomalous development of one of the lower extremities coincided with a varicose state of the veins of the thigh.

1333. *Anatomical researches*.—Despite these enlargements of the lower extremities, the distended skin may retain its natural thickness, and almost its natural colour; but hypertrophy more frequently takes place, at least in some parts, and there it bears a close resemblance to a fibrinous deposit, or the buffy coat of the blood; the epidermis covering it is also generally very much thickened. Mr. Chevalier (Med. and Chirurg. Transactions, vol. ix. p. 63), found the papillæ of the skin exceedingly enlarged, lengthened, and projecting from the surface of the dermis; on the points where these papillæ were less developed, the epidermis was thinner; the corion was so much hypertrophied, that in some places it was half an inch thick, and presented the granular appearance which is observed in large quadrupeds. On its inner surface it adhered to the indurated cellular tissue with which it was evidently blended. In other respects it was neither injected nor altered in its colour.

In the body of a woman who, fifteen years previously, had suffered from an ulcer in the right leg, which had increased to an enormous size, and the skin of which was very hard, rough, and of a dark brown colour, and in some places absolutely black, like that of the hand of a negro, M. Andral found the subcutaneous and intermuscular cellular tissue sensibly hypertrophied and hardened, more and more so as it lay nearer the dermis; this had also increased considerably in thickness, and in several places could not be separated from the indurated cellular tissue, each seeming to be but different degrees of the same organization. The papillary body laying over the corion was greatly developed, evidently distinct from the dermis, and appearing to stand in the same relation to it as the villi do to the intestinal mucous membrane. Situated over the papillary body, again, and between it and the epidermis, there were three very distinct layers; the innermost of the three penetrating between the eminences of the papillary body, receiving no vessels, and consisting of a fibro-cellular tissue (*couche albide profonde* of Gaultier, *couche épidermique* of Dutrochet); the second, situated more externally, composed of extremely delicate blackish filaments, interwoven in the true sense of the word, forming a network which was exactly similar to the coloured rete of the negro; finally, a third, quite close to the epidermis, and, in particular places, forming only a white line similar to the epidermic layer of the papillæ; but thicker in others, and hardened as though formed by a series of superposed scales; this was certainly the *couche albide superficielle* of Gaultier, the *couche cornée* of Dutrochet (*Archives générales de médecine*, March, 1823).

I have made similar observations on the structure of hypertrophied skin in the first edition of this work (vol. ii. p. 560). M. Gaide and I have since repeated these anatomical researches, and he has published the results (*Cases of the individuals named Allard and Fournier*). After having incised the skin in the direction of its thickness, the following layers were discovered, reckoning them from the more internal to the more superficial strata. 1st. Small lobules of adipose tissue, connected together by a healthy laminated tissue, forming a subcutaneous layer. 2d. Above this was placed the corion, represented by a transverse band of a pale yellow colour, evidently hyper-

trophied, the arcolæ of which were less distinct than in the natural state; it was, besides, loaded with a great quantity of serum, which was easily made to flow out by compressing it between the fingers. From its inner surface it sent off whitish fibrous prolongations, which penetrated some depth into the subcutaneous cellular tissue. 3d. Above the corion a second layer was seen, composed of parallel fibres, running from the outer surface of the corion towards the epidermis. This second layer, evidently formed by the papillæ elongated, and of a ruddy violet colour, was of unequal thickness in several parts, and varied from two to three lines and a half in length. These two first layers of the skin were rendered distinct one from the other, both by the opposite directions taken by their fibres, and by a transverse line which resulted from their difference in colour. Between the parallel fibres of the papillary layer small vessels might be distinguished by the naked eye; these were, of course, more distinctly perceived when examined under the magnifying glass. The superficial surface of this second layer presented small eminences, mostly lenticular, separated from one another by deep furrows, evidently formed by the most elongated papillæ, whilst the smaller ones, united in the same line, gave rise to the formation of the wrinkles of which I have spoken. By maceration, the papillæ which formed these elevations became free, and appeared, when examined under water, like the pile of velvet or plush. Above the papillæ a third layer exists, distinct from the epidermis which covers it; it is that which has been designated under the name of the *lamina albida seu cornea*. In detaching this third layer, very delicate filaments are seen tending towards little whitish bodies, situated, and, as it were, attached to the inner surface of the *lamina albida* (follicles): these small bodies, variously disposed, either singly and scattered, united in parallel series, or agglomerated in the form of larger or smaller patches, all or almost all came away with the *lamina albida* to which they adhered. Some of these follicles are perfectly round; others are longer, and terminate in a point at one of their extremities in the form of tears; others, again, still longer, appear cylindrical; some present, in their centre, or on their outer aspects, a blackish point, which would seem to be their orifice. The epidermic layer, disposed like the preceding, in the form of a membrane, and, like it, transparent, where it is not formed of accumulated squamæ, is also in contact, on its inner surface, with small follicles similar to the preceding ones. United in general in the form of patches, these were more particularly apparent on the parts which correspond to the squamæ. This disposition of the layers is always seen. From the inner surface of the epidermis small prolongations are sent off, which surround the hairs to their bulbous extremities, and are very distinct from the follicles.

1334. In elephantiasis *Arabica*, the subcutaneous cellular tissue has been found harder in proportion as it was nearer to the dermis. The adipose tissue has been known to become enlarged in a very extraordinary manner. I have also found the cellular tissue infiltrated as it is in dropsies of long standing. M. Fabre has seen the subcutaneous cellular tissue converted into a thick, hard, almost fibro-cartilaginous layer, presenting, in several places, small ossified plates, adhering so closely to the aponeurosis of the leg, and to the nerves and vessels which traverse it, that it was impossible to separate them. The sub-aponeurotic and intermuscular cellular tissue participated in the same alterations, but in a less degree. In a woman, who died in the Hôpital de la Charité in 1820, whose lower limbs were affected with elephantiasis, M. Andral found under the skin, and in the place of the muscles of this limb, which were reduced to some thin discoloured shreds, an enormous mass of hard, condensed cellular tissue, with cavities here and there filled with serum, and partaking, in more than one place, of all the qualities of cartilage. (*Precis d'anatomie pathologique*, t. i. p. 277.)

1335. Hendy has found the lymphatic glands hardened, or in a state of suppuration, and much larger than they are in their natural state. The absorbing vessels were dilated, and their coats so much weakened as to be incapable of standing injection. I never observed these large absorbing vessels in any of the cases of elephantiasis *Arabica* which I have dissected. M. Fabre says that he found it quite impossible to discover these vessels in the midst of degenerated subcutaneous cellular tissue. I have frequently found inguinal glands of much larger size than they are in a healthy state; but in scrofulous

subjects, the same morbid development is observed, without dropsy or any morbid increase in the limb having taken place. In the body of Allard, whose case M. Gaide has published, the lymphatic glands were not found to be larger than those of several other bodies which we examined for the sake of comparison on the same day; the glands of the left groin only were of a deep red, whilst those of the right side were of a milky whiteness. The vessels which were distributed to these glands were not larger than they are in the healthy state. In another patient who died of elephantiasis of both of the lower extremities (case of Fournier), the lymphatic vessels situated on the back of the left foot, and inner edge of the great toe, were as small and delicate as in the healthy state. The glands of the popliteal region had undergone no alteration; but from the left groin to the point where the aorta sends off the renal artery, a string of lymphatic glands existed, each of which was almost of the size of an almond; some of the glands of the groin were red, or reddish, others were white, and easily crushed between the fingers; those lying over the femoral artery, all those which extended from thence along the outer side of the iliac vein, and in the front of the *psaos* muscle, were white, crushing easily between the fingers, and discharging a whitish fluid like pus, or softened cerebriform matter. Besides this string of altered glands, we discovered others in the cavity of the lesser pelvis beneath the common iliac vein, forming, by their union, a sort of glandular subperitoneal layer, which extended over the internal surface of the ischium. The lymphatic vessels which were distributed to the glands of the groin were not larger than in the healthy state; and although the chain of glands of which I have spoken adhered to the iliac vein, this vessel did not appear to be evidently compressed by it. M. Bourgeoise ascertained that the lymphatic glands of the right leg were not larger than in the healthy state; the lymphatic glands of the ham presented no alteration; the inguinal and pelvic glands, not nearly so large or so numerous as those of the opposite side, disposed in a band round the iliac vessels, penetrated the smaller pelvis; in other respects they presented the same anatomical characters as those of the left side.

1336. In the *compte rendu* of M. Allard's work, and in a case since published (*Archives Générales de Médecine*, v. ii. p. 215 and 372), M. Bouillaud called the attention of the profession to the obliteration or obstruction of veins, as an occurrence, the influence of which he had already pointed out in causing the development of local dropsical affections. Since the publication of these researches I have had an opportunity of observing the contraction of one of the *venæ saphenæ*, and the obliteration of the other, in a case of elephantiasis of both legs. (*Mémoire de M. Gaide; obs. d'Allard.*) In the left leg the *vena saphena*, laid bare along its whole extent, appeared in the form of a cylindrical cord of a yellowish-white colour, and not transparent, about a third less in size than the same vein in its natural state; the cavity of this vein was found almost obliterated at the point of junction between its middle and lower third; the vessel having been cut across in this place, a central point was distinguished upon each of the cut extremities into which a fine wire of the diameter of that which is usually inserted into silver catheters could be introduced, though not without difficulty; the calibre of this vessel had become, in some sort, capillary, through an extent of about two inches; its sides being double their usual thickness; the vein cut across transversely in any point where it was contracted, continued gaping in the same manner as an artery. The femoral vein towards its junction with the *vena saphena*, contained clots of recent formation; most of the other veins of this extremity presented no alteration. The *vena saphena* of the left leg contained fibrinous clots of old formation, and adhering by their surface to the internal membrane of the vessel; the calibre of this vessel was not contracted, but its sides, like that of the right *vena saphena*, were thickened, and resembled those of an artery. I ought to add, that in estimating the thickness of the walls of these vessels, the difference which naturally exists between those of the lower extremities and those of the upper was taken into account, and that to prevent all mistake I took an opportunity of comparing the thickness of the particular veins examined in several subjects.

In the case of elephantiasis of the leg, published by M. Fabre, the *vena saphena* laid bare from one end to the other, could not be traced in the middle part of the leg; it was only found at the distance of

about four finger-breadths below this point; a very fine probe introduced into the upper and lower part of the vein led to two shut sacs. This vein in the remainder of its course was so much contracted, as only to allow the passage of a small silver stilette with great difficulty along it. Its sides were hypertrophied, and like those of an artery. The external *saphena*, except that it was nowhere obliterated, presented the same appearances; the anterior tibial and fibular veins contained blood. The posterior tibial vein was obliterated in a part of its course. No obstacle to the course of the blood existed in the popliteal, femoral, or external iliac veins, &c.

1337. Henly found the small arteries of parts affected with elephantiasis larger than they are in a healthy state. In two cases seen by M. Gaide, at the Hôpital St. Antoine, the arteries of the extremities presented no alteration. In a case, the particulars of which are related by M. Fabre, the anterior tibial and fibular arteries were ossified; they contained a little blood; the posterior tibial vein was converted into a cylindrical bony stem into which the blood no longer penetrated; the femoral and popliteal arteries were also equally ossified; similar ossifications were found in the arteries of the other extremity.

1338. In a particular case which Nægle examined, he found the tibial nerve increased in size, presenting on its surface and in its interior round and oval-shaped nodosities, forming so many small cysts which contained a clear fluid, limpid in some places, and turbid in others. In three cases of elephantiasis *Arabica* which I have dissected with great care, the nerves presented no alteration. In M. Fabre's case the great sciatic nerve, after having preserved its natural size to the middle of the thigh, afterwards increased continually in its dimensions till it reached the ham, where it was of such magnitude that its several branches were each much larger than the trunk which sent them off. In the thickness of the external popliteal nerve a gelatinous hydatiform mass was found, of a pale red colour and the size of a small almond, pretty firm in its consistence, and having the medullary fibrils of the nerve parted and applied around it. The branches of the external and internal popliteal nerves were themselves so much increased in bulk that the tibial nerve, the cutaneous muscular branch and the anterior tibial were each four times their natural size, and presented several enlargements. These nerves, although very hard, still preserved pretty evident traces of their peculiar organization. M. Ferrus met with a similar disposition of the nerves in the leg of an old woman affected with elephantiasis.

1339. Hendy commonly found the muscles softened and blanched. I have also seen them less deeply coloured than in the healthy state; in a patient of M. Fabre's, several of the muscles were increased, others decreased in size; each of them was converted into a fatty substance. They were very hard, and creaked under the scalpel; the *solæus* muscle presented this degeneration in a greater degree than any of the rest; here and there a kind of streak of bony matter appeared, which seemed to occupy the spaces between the muscles, and some of which were connected with certain bony excrescences that rose from the surface of the periosteum of the tibia.

1340. In the cases of elephantiasis of the lower limbs, which I have had the opportunity of examining anatomically, the bones had undergone no change. But in several patients, and among others, in a woman whom I attended in the Hôpital St. Antoine, the tibia of the diseased leg was three times the size of that of the opposite side; in M. Fabre's patient, too, the inter-osseous ligament of the leg only existed for the space of about an inch in the situation where the anterior tibial vessels pass through it; no further vestiges of it were seen; it was replaced by an osseous uneven lamina covered with asperities, and a line in thickness in some places. This bony lamina adhered so intimately to the tibia and fibula, that these two bones, thus soldered together in their whole extent, really formed no more than one. The surfaces of the lower peroneo-tibial articulation were so completely united that no trace of division between them could be discovered, even after more than three months of maceration. The circumference of the tibia was almost the double of that which it is in its natural state; that of the fibula in the middle was fully more than triple. These bones, thus closely united, were covered with a prodigious number of shorter or longer asperities, bedded in the soft parts, their edges being prolonged in the form of prominent ridges, twisted in various ways, so as to represent in some sort a series of canals crossed

by vessels and nerves, which ramified upon their surface. The upper surface of the bones of the foot presented similar ridges to those on the tibia and fibula. The density of the tissue of the tibia was such that it could only be sawed across with very great difficulty; in colour and compactness of texture it resembled ivory. The bony surfaces of the tibio-tarsal articulation were healthy; none of the hard or soft parts of the plantar aspect of the foot participated in these alterations. Messrs. Ferrus and Cruveilhier have observed similar morbid appearances, and M. Larrey, in his description of elephantiasis, speaks of violent pains felt along the course of the bones.

1341. With respect to lesions of the viscera accompanying or coinciding with elephantiasis *Arabica* in the lower extremities, the following is what I observed in the body of the man Fournier: the larynx, the trachea and bronchi, were natural; each of the pleuræ contained from eight to ten ounces of serum. The left lung was crepitating and loaded with serum which flowed out when pressed between the fingers; there was no trace of sanguineous engorgement in this lung, but on the posterior part of the lung of the right side there was, and the whole mass of this organ felt firmer and resisted pressure more powerfully than that of the left side.

The pericardium was in a healthy state; the heart, of the natural size, contained some fibrinous clots in the right cavities; the thoracic aorta was healthy; the cavity of the abdomen contained a small quantity of transparent serum. The internal surface of the stomach was divided into two portions by a deep line of demarkation, which separated the anterior exactly from the posterior part; in the former, the mucous membrane was healthy; the latter was, on the contrary, almost without any trace of mucous membrane, and of a dead white; its surface was covered with bluish vessels which projected from it, and contained a larger or smaller quantity of blood, so as to give this region a blue and red marbled appearance. The mucous membrane terminated abruptly in a sharply cut edge in the pyloric region, whilst towards the cardia it was continuous with the mucous membrane in a state of health; in some parts of this region the softened mucous membrane had a grayish aspect, which contrasted on the one side with the alteration which I have met, just described, and on the other with the healthy portion of the organ. The small and large intestines presented numerous vascular ramifications, separated from each other by parts in which the softened mucous membrane appeared to have lost some portion of its substance. The mesenteric glands presented no particular appearance, the liver was enlarged, and its yellow substance pretty abundant; the finger could with difficulty be pushed into its substance.

The kidneys, larger than in the healthy state, presented a more decided alteration on the left than on the right side; their whole substance, but particularly the cortical part, was of a morbid yellowish-white, very different from the usual colour of these organs. The brain and its membranes had undergone no alteration.

In another case, of a woman named Mary Allard, the peritoneum was covered with numerous granulations over almost its whole extent, particularly where it formed the epiploon; the portion of this membrane covering the intestinal canal was very much injected. The cavity of the lower pelvis was partly filled with a sero-purulent effusion; some whitish lines appeared on the stomach, over which the mucous membrane was softened, and very sensibly diminished in thickness. A similar alteration had taken place in several parts of the small intestine. In the large intestines, and particularly in the descending colon, small, round ulcers were met with, surrounded by the mucous membrane, blanched and of a dead white. In the situation of the sigmoid flexure of the colon, the subperitoneal cellular tissue was loaded with a profusion of purulent matter; large sinuses existed here, but without communicating with the intestine; this alteration extended a considerable way into the cellular tissue of the lower pelvis; the other viscera of the abdomen appeared to be in a healthy state. (a)

(a) Dr. Musgrave (*Edinb. Med. and Surg. Journ.*, No. 902), terms the disease *migratory inflammation of the lymphatic system*. He tells us: "Whatever may be its original seat, the patient is never secure, while the constitutional disturbance subsists, from a sudden retrocession to some vital organ. I have seen it in the same case translated

1342. Elephantiasis *Arabica* seldom attacks the superior extremities. M. Allard, however, quotes four cases of the disease occurring in the arms. In one (case 7) the hard and permanent swelling of the left arm occurred after the application of a blister. In another (*op. cit.*, p. 190), the right arm increased to such a size that it weighed two hundred Genoese pounds, forty of which consisted of serum; the swellings of the arm and forearm resembled a distended bladder or skin; the arteries, the veins and the nerves had undergone no alteration; but the lymphatic vessels were very much dilated and loaded with lymph. The third is a case of Fabricius Hildanus. The fourth is extracted from Hendy, who relates several others of the same description, in which the disease appeared in a very acute form, by a sort of numbness in the shoulder and arm, the enlargement of a gland in the axilla (case 13) or elbow (case 5) and a red line running over the inner part of the arm and forearm. (b)

I have myself observed three cases of elephantiasis of the upper extremity, but the progress of the disease in all was chronic. One occurred in a woman who had had the right breast taken off for a cancerous affection of the mammary gland, and in whom the lymphatic glands, become scirrhus, compressed the axillary vein (first edition, viii. p. 630); the second case I met with has been published by M.

from the scrotum to the head, from thence, after some hours, descend with the rapidity of lightning to the abdomen; again migrate to the chest, to return, perhaps, to the encephalon and prove fatal there; or, under more favourable circumstances, resume its comparatively harmless situation, and run its subsequent course, as if nothing untoward had occurred; and, while occupying the different cavities, giving rise to the ordinary symptoms of acute inflammation of that particular viscus which it had selected for its temporary abode."

(b) A parallel case is related by Dr. Sanderson, of Oxfordshire (*Lancet*, 1838-9). The narrative is interesting, and runs as follows:

"Mrs. H., aged 49, of spare habit, lymphatic temperament, and healthy constitution. Ten years ago, perceived a small tumour in the right mamma, the size of a broad bean, movable, unattended with pain or discoloration of the part. No constitutional disturbance; gradually increased to the size of a walnut, still unaccompanied by pain, but occasionally felt in the breast a slight tingling sensation. Plasters and steaming appear to have been the only remedies used by her former medical attendant, after which the surface of the breast became red, and eventually the skin gave way. No matter evacuated, but an irritable sore produced; the diseased portion, the size of a large cork, (said to have been carcinomatous, but doubtful as to its real character,) was removed by an operation five years ago. The wound has never entirely healed, but continues to this time, exhibiting an ill-conditioned appearance, and discharging a thin sanious matter. Six months after the operation, three or four glands in the axilla became enlarged and painful, and some time afterwards experienced a general sense of numbness to pass down the arm until it reached the hand, when the use of the limb appeared at once to be lost. The arm next began to swell, and a dragging, twisting pain to be felt along it; the integuments on the back part of the hand especially began to expand, and gradually to develop the extraordinary circumscribed mass of disease it at present exhibits, overhanging and projecting, as it does, several inches beyond the fingers, which seem, as it were, imbedded in it.

"The head obliged to be supported in the direction of the affected side, from the contraction of the muscles, and the natural inclination of the body to bend towards the diseased limb.

"The arm is completely covered with a thick brownish incrustation, or a sort of scaly efflorescence; and springing up in different parts of this crust, are five or six tubercles of a dusky-red colour, slightly sensible to the touch, varying in size from a pea to that of a cherry.

"There is a large massy tumour extending upwards from the dorsum of the hand, in figure and size much resembling a round quartern loaf, or what is generally called an oven or batch-cake; the surface, smooth, red, and shining, sensible to the touch, hard and firm, from time to time exhibiting a slight disposition to form a like efflorescence to that on the arm, but only in limited points, where there have first been small ulcerations and a discharge of serosity.

"The fingers are much expanded, flattened, and nearly lost in the

Gaude; the subclavian, axillary and brachial veins were here filled with a fibrinous clot of long standing, adhering to the inner membrane of these vessels, and of a yellowish-gray in the centre. In the third, which was detailed by M. Bonnet, of Poitiers, and in which the left forearm was the part affected, we found the basilic vein hard, and filled with a coagulum which adhered closely to its inner membrane; this hard and solid clot was blanched or of a grayish colour, intermixed with red striæ.

1343. The history of elephantiasis occurring in other regions of the body, is less complete; elephantiasis of the scrotum is almost the only case which has been made the subject of correct anatomical research. Elephantiasis of the hairy scalp is very rare. M. Ricord has given two cases of it in the *Revue Médicale*, vol. ix. p. 13.

1344. Elephantiasis of the face sometimes only attacks it on one side; such was the case with the patient whose history forms the subject of M. Alard's ninth case, and in whom the elephantiasis would seem to have been complicated with eczema of the ear. Willier's (Alard, case 2) is a remarkable case of elephantiasis of the face: after committing a debauch at table, this patient experienced a violent pain in the left cheek and below the zygomatic arch: this pain soon extended under the chin; the submaxillary glands enlarged and felt painful; the face swelled and became erythematous; and he experienced nausea and slight shivering fits. At the end of

tumefaction, with the exception of the little finger, which is nearly absorbed, being reduced to a mere skin. 'These parts (the fingers), have a moistened or sodden appearance, from a constant oozing of a serous fluid, proceeding from the under surface of the tumour.

"The circumference of this enormous enlargement is, at the base, 29 inches, that of the upper arm 19 inches, and that of the lower arm 15 inches.

"The most remarkable fact connected with this interesting case is, that, during all this morbid action, carried on for a period of ten years in the breast, and in these parts, the general health has been uniformly good up to the present time; appetite excellent; digestion perfect; tongue clean; bowels regular; pulse 75; no fever, nor any other constitutional disorder.

"It seems difficult to account for this extraordinary morbid formation, unless we suppose that the irritation excited in the breast, in the first instance, produced a diseased action in the lymphatic vessels and glands, from the axilla downwards, which, by repeated effusions of serous or gelatinous matter poured into the cellular membrane under the thickened skin, and upon the cuticular surface, have produced the present tumid and scaly condition of the limb. My friend, Mr. Rye, who is attending the case with me, and who intends taking a drawing of the limb, in its present state, agrees with me in thinking the disease, in character and appearance, more like that which, at the present day, is termed *elephantiasis* (the elephantiasis of this country), than any other with which we are acquainted. The case has been regarded by us as one of considerable interest, inasmuch as we are not aware of there being another exactly similar placed on record.

"The uniformly good health enjoyed by the patient, the curious alteration of the whole cuticular surface, and the extraordinary magnitude and aspect of the limb in general, and the hand, in particular, invest the history of the case under consideration with a high degree of interest and importance. Our present narrative, however, must be incomplete until an opportunity is afforded of following the disease to its termination, and of examining the pathological character of the parts involved in this peculiar morbid action. For this reason we refrain, at present, from encroaching further on your columns until the above deficiency can be supplied.

"I may just add that I have been informed by the practitioner who saw the disease in its early stages, that it then assumed very much the character of erysipelas, especially on that part of the skin covering the back of the hand; in some points appearing red and vesicating, in others pouring upon the surface a serous fluid; and, again, in others forming a slight incrustation, which afterwards desquamated; and that a constant repetition and succession of these processes were carried on, during which time the whole limb was rapidly acquiring an increased magnitude."

six months, another attack, after which the patient perceived that the face continued puffed; this attack was followed by several others, and the face became larger and larger. In similar cases tumefaction may arrive at such a height that Schenck speaks of a man whose head exceeded that of an ox in size; the lower part of the face was entirely covered by the nose, which had to be raised to enable this unhappy being to breathe (*Obs. Méd. Rar. Nov.*, &c., lib. i. p. 12). I have seen one case only of elephantiasis of the face which supervened after repeated attacks of erysipelas.

1345. This disease causes the breasts to increase to such a size, that they are obliged to be supported by bandages passed around the neck. Salmutius (Cent. 2 obs. 89), speaks of a woman whose breasts increased to such a size that they hung down to her knees. She had, at the same time, glandular tumours as large as the head of a fœtus, under the axillæ. M. Borel, physician in Castres, also quotes the case of a woman whose breasts became so large that they were obliged to be supported by straps which passed over the shoulders and neck.

1346. M. Alard relates as a case of elephantiasis, that of a lady of Berlin (*Ephem. Nat. Cur.*, 3 anno. 2, p. 71, 1694), who had an abdominal tumour, the lower part of which reached to the knees. This tumour, situated under the skin, outside of the cavity of the peritoneum, was formed of a congeries of small pouches, agglomerated, and adhering to one another, like the swimming bladders of some large fish. Seven of these cells, adhering very closely together, formed the circumference of this tumour, and an eighth occupied the centre. Each of these cells was itself divided into several small compartments, which enclosed a clear and limpid fluid, like the white of egg, but of greater consistence in some, and in several similar to the boiled white of an egg. The contents of others again, were yellowish, greenish, or reddish. On the peritoneum being opened, no vestige of disease was found in the abdominal cavity. No sensible alteration had taken place in the veins, which were only found to be a little out of place.

M. Delpech also quotes a case of elephantiasis of the walls of the abdomen, observed in a young woman, four-and-twenty years of age, born at Toulouse, who had three conical tumours on the abdomen, adhering to the sides of this cavity, near the hypogastrium and umbilicus, two on the right side, and the third on the left. These tumours were of the structure of those enlargements which constitute *andrum*; that is to say, a cellular tissue, the cells or areolæ of which are of great magnitude, separated from one another by very extensive and semi-opaque laminæ, covered with very much dilated lymphatic vessels, and some few sanguineous vessels, of extreme tenuity, and but little ramified; the intestines were filled with a serum, half liquid, half solid, and rendered almost opaque by a considerable portion of albumen.

1347. Next to the lower limbs, the scrotum is the part of the body which is most frequently attacked with elephantiasis *Arabica*; this part and the penis often acquire an enormous size when affected with the disease. This alteration has been improperly designated by Larrey under the name of *sarcocèle d'Égypte*; by Prosper Alpinus under that of *hernia carnosæ*; and by Kæmpfer, under that of *endemic hydrocele of Malabar*. M. Alard relates three cases of the disease from Hendy (obs. 16), from Gilbert (obs. 5), and from the *Ephemerides Curiosorum Naturæ* (obs. 108, p. 212). M. Dumeril has seen a remarkable case of the affection in a man upon whom all the resources which art possessed had been lavished in vain. M. Delpech relates two cases of it, one of which afforded him the opportunity of performing an extraordinary operation. This last patient, who was thirty-five years of age, had been afflicted with his infirmity for ten years. The skin of the scrotum had become excessively hard, thickened, tuberculated, and intersected with deep wrinkles; the enlargement, pasty at first, had afterwards acquired a greater consistence, and became hard and very heavy. The tumour formed by the scrotum weighed, when it had attained its maximum size, about sixty pounds; under or within this shapeless mass, the penis and the testicles were buried; it seemed to be divided into three unequal masses, two lateral and one anterior, where a sort of umbilicus was seen, through which the urine passed. This patient did not experience the erysipelatous affections, accompanied with fever, shiverings,

vomitings, &c., observed by Kämpfer (*Amanit. Erotic. fasc. 3*, obs. 8, p. 557), Hendy, and Gilbert, in similar cases.

Several other inquirers have ascertained that the disease is not always accompanied by these phenomena; and in the patient operated upon by M. Delpech, the same alterations of the skin and cellular tissue which are observed in elephantiasis of the limbs, were found; the organs of generation were healthy.

In another individual, who was operated upon by M. Larrey, one of the testicles was found to be healthy, the other smaller than in its natural state (*Campagnes*, t. ii. obs. 1, p. 122). In a third case, which has been republished by M. Alard, independently of the alteration in the skin and cellular tissue of the scrotum, it was discovered, after death, that the testicles were *inflamed like the rest of the parts*. The right testicle, after having been stripped of the tunica vaginalis, was not less than a goose's egg in size. It was divided into three compartments: a gelatinous and thick matter infiltrated the upper and lower parts, and the middle was occupied by a substance nearly the size of a walnut, into which the vasa efferentia emptied themselves, without appearing to have undergone much alteration. The tunica albuginea was much thicker than in the healthy state, and contained a pale fluid, lodged in small divisions like those of a lemon. On opening the tunica vaginalis of the left side, two quarts of serous and almost colourless fluid were discharged; the same state of things was found on the opposite side. Upon removing the integuments covering the penis, which were three fingers thick, this organ was found to be of its natural size, or even smaller than it should have been; the corpora cavernosa could not be inflated as they usually may. All the rest of the body was healthy, except the right kidney, the ulceration of which had no doubt caused the patient's death. Finally, according to Hendy, the disease peculiar to Barbadoes may attack the testicles and the inguinal glands at the same time (case 10).

Elephantiasis *Arabica* may also be complicated with scrotal hernia, of greater or less magnitude, as it was in the case of a man, named Lajoux, of Toulouse, the details of which the *Société de Médecine* of that city has published in its transactions. The following case, detailed by M. Fabre, is another instance of the same kind, occurring in an old man seventy-three years of age, who was affected with elephantiasis of the scrotum, and with double inguinal hernia. When this patient was fasting, the upper part of the tumour gave a clear sound on being struck, whilst in the lower part the sound was dull; after eating, however, the dullness extended along the whole of the right side of the tumour, and the sound remained clear in the upper part of the left side. It was enough for the patient, whilst fasting, to drink a certain quantity of liquid, to cause the sound immediately to become dull on the right side. M. Fabre concluded, and with reason, that the stomach was displaced in this case, and formed a hernia on the right side.

1348. I saw, some years ago, under the care of M. Dupuytren, in the Hôtel Dieu, a woman of the town, in whom elephantiasis *Arabica* was developed in the labia majora, which were of an enormous size. Similar cases have been collected by Gilbert (Alard, case 2), Larrey (*Campagnes d'Egypte*, t. ii. p. 127), and by Talrieu (Delpech, *mem. cit.*).

Elephantiasis *Arabica* may also be developed on the verge of the anus, a case which Bayle was the first to observe.

1349. Upon dissection, this enlargement of the cellular tissue does not present any appearance similar to scirrhus in whatever part it is incised. No scirrhus induration or cerebriform matter is discovered, but merely a kind of very hard œdema, a cellular tissue, full of a colourless fluid, which can be at all events partially squeezed out by strong pressure. The enlargement is hardly ever confined to the verge of the anus; it generally extends to a greater or less distance into the cellular tissue of the buttocks, where it terminates gradually (*Dict. des Sciences Médic.*, t. iii. p. 609).

1350. M. Alard gives a curious case as one of elephantiasis of *one side of the body*, but it is deficient in essential details, (*op. cit.*, p. 219).

Finally, certain anomalous enlargements of the tongue, of the uvula, of the submucous cellular tissue of the intestines, and of the subserous cellular tissue of the epiploons, have been assimilated by some writers

to Arabian elephantiasis, and will be described hereafter (see Glossocèle). (a)

(a) The following description of Brazilian elephantiasis, with its frequent complications, is derived from an instructive volume (*Medical Topography of Brazil and Uruguay, with Incidental Remarks*, Philadelphia, 1845), by Dr. G. R. B. Horner, of the United States Navy:

"Elephantiasis exists in every form and degree: spares no sex, age, nor condition; pays no respect to natives or foreigners; affects the poor and rich: harasses servant and master; affects the plebeian and patrician. The poor and labouring classes, however, are most annoyed by this disease; and the negro population, both the slaves and free portion, have a full share. The persons most affected with elephantiasis, strictly speaking, and according to the derivation of the name, are those who live miserably, or are obliged to make much use of their feet, and have them frequently, and for a long time, exposed to the sun without shoes or any thing else to protect them. One of the best evidences of this fact was, that I knew a sailor to bring on a violent inflammation and swelling of his feet, similar to elephantiasis, from such exposure. Had the irritation been kept up, I have little doubt a chronic affection would have been induced, and a permanent enlargement taken place. I have observed, also, that the labouring class of people, particularly men who stand or walk much, and women who are in the habit of washing clothes and immersing their hands in hot water or other warm fluids, have them or their forearms affected.

"Of the pathology of elephantiasis, it may be well for me to make a few remarks, and first of its causes. The chief remote ones at Rio are, without doubt, the heat and moisture of the climate, rendered more injurious by the miasmata and impurities without and within the crowded city, situated chiefly in valleys overhung by high mountains, and divided by hills. That these are the most efficient causes is proved by the acknowledged fact, that since John VI came from Portugal, lived at Rio, and drained, cleaned, and otherwise freed the city of noxious substances, the disease has declined considerably. The luxury and indolence of the people, and the general relaxation of their systems, from climate and other debilitating agents, may likewise be mentioned as remote causes. The exciting are, heat directly applied to the parts, and different irritating things put upon or lodged in them. Of the latter, chigues may be called the most common and efficient among the slaves and other people who are in the habit of leaving their feet uncovered. Erysipelas is one of the exciting causes, according to one of the most respectable native physicians; and when this attacks the scrotum, it becomes enlarged very rapidly: but this erysipelas is probably brought about by the same causes, primary and secondary; and as it affects the same tissues—the tegumentary and cellular—it may be looked upon as a mere premonitory symptom of ordinary elephantiasis, or that attended with increase of substance in the parts diseased. That attended with a decrease of it is called Greek elephantiasis or leprosy—as said when I spoke of my visit to the hospital appropriated to it, and is of a less acute kind—is slower in its progress—and though the parts are seldom much enlarged, without doubt is owing to the same causes in most instances. The chief difference in the two forms of the disorder consists in the action of the absorbents and capillaries. These, in common elephantiasis, excrete and add to the parts; but in the leprosy kind, the former take up and carry off, first the cellular, serous, fibrous, and other soft tissues, and then the osseous. That this is the true difference, is satisfactorily proved by what is to be seen in the patients affected in the hospital; where the same person, nay, the same part of the body, is affected with both kinds of the disease. For instance, the legs may be seen enlarged—the lips most unnaturally increased, while the toes and nose are wasting away, if not already totally absorbed. That this phenomenon should occur, is not more unaccountable than the formation of a fibrous, cancerous, or other tumour, while in the same person an ulcer should be devouring the soft tissues, or a caries be destroying the hardest bones.

"Of the two forms of elephantiasis, it is not easy to say which

1351. *Causes*.—Individuals affected with Arabian elephantiasis may suffer from a variety of acute and chronic diseases, either before or after the occurrence of the intumescence, which sometimes appears after repeated attacks of eczema. Mentzell and Bayle have seen gout coincide with Arabian elephantiasis; patients affected with elephantiasis *Græca* (see elephantiasis *Græca*), have sometimes presented, not only œdema of the lower limbs, which is common, but the true, hard, and bulky enlargement of Arabian elephantiasis also. Upon the whole, then, several alterations of the veins (varices, phlebitis, contraction, obliteration, &c., &c.), and various forms of inflammation of the skin (erysipelas, eczema, liehen, ulcers), are the diseases which are the most frequently observed before the development of Arabian elephantiasis, or during its course.

Elephantiasis Arabica shows itself above all in those parts of the body in which the venous circulation is slower than usual;—in the lower extremities, and in the scrotum in men. This disease is neither contagious nor hereditary. It is seen in persons of all ages, most frequently in adults, more rarely in the aged, and in children. Chausier presented to the society of the Faculty of Medicine of Paris, on the 1st of March, 1810, the leg of a still-born infant, on which two deep constrictions, and a considerable tumefaction of the back of the foot, very similar to elephantiasis, were seen. Out of thirty cases of this disease which I have met with in Paris, more than half had occurred without any appreciable external cause. There is not, perhaps, a department in France in which this singular affection has not been observed. Delpech assures us that he has seen numerous cases in Roussillon, particularly in the neighbourhood of Elne. According to Casal, it is very common in the Asturias. (*Hist. Natur. y médic. de el Principado de Astur.*, pp. 321, 323.) I am not aware that any other observations have been made either in England or on the Continent, with the view of ascertaining whether particular topographical

occasions the most inconvenience to the sufferers: for one lops off his members, the other enlarges them to an enormous extent—and both deprive of the means of obtaining a livelihood; one by a deficiency, the other by an excess. A seamstress and shoemaker lose their fingers by one form of the disorder; a footman and porter have their legs and scrotum so much increased by the other, that the former can only stand, and the latter has as much as he can carry about his own person. A belle, ambitious of having the smallest of feet—the most delicate of ankles—has them converted into stumps, or such heavy clubs, that all elasticity of gait is destroyed; and so far from dancing well, cannot walk with common grace. A beau, desirous of displaying his finely-formed features, and causing every belle to look with admiration at his noble Roman nose—his expressively dark eyes—has the former converted into a genuine pug, or insignificant Grecian; and only one of the latter is left to view the ruins of the once sublime bridge, and the extinction of its fiery fellow orbit.

“Cases of scrotal elephantiasis are nearly as numerous, if not quite as much so, as those of the feet; and the first attain the greatest magnitude of any other form. One or more instances have occurred where it was so large that a wheelbarrow was requisite to carry it; and two cases I saw of it were about four feet in circumference. One of them was that of a negro in the Miseracordia; another, that of a late officer of customs, who resides in the Rua dos Bazotes, or Busson’s street, which takes its name from the number of such persons residing on it. Dom Francisco H. C—— had been afflicted with the complaint only three years, and he, nevertheless, had the scrotum formed into a vast tumour of nearly the natural shape of the part. The skin was quite firm, smooth, of a reddish-white colour, and felt soft, but was firm and elastic; the prepuce spread out six or eight inches around, and divided into irregular lobes, semitransparent, fungous, and entirely concealing the glans. This was embedded in the mass. His feet and legs, just above the ankles, were correspondingly enlarged. The first were too big for shoes, and protected by moccasins; the second were bottle-shaped, and a linen sac, supported by straps, held the unwieldy scrotum. Dom Francisco is no longer able to obtain a livelihood by labour, and receives alms privately. His age is fifty-six years; and as his chin and face are becoming affected more and more, he must expect to spend the rest of his life in misery beneath the weight of his irremediable disease.”—pp. 106–8.

conditions or other circumstances have really a marked influence on the development of this disease. In the island of Barbadoes its frequency is attributed to the sudden impression of cold, to the extreme coolness of the nights, and to the currents of air which blow through all the houses. We are assured that this disease is endemic in some regions of the torrid zone, and it is principally seen on the left bank of the Ganges, in Egypt, Nubia, &c., countries which are continually under influences nearly of the same kind. (a)

1352. *Diagnosis*.—When Arabian elephantiasis is announced by febrile symptoms, accompanied with pains along the course of the veins, vessels and lymphatic glands of a limb, it presents almost the same characters as certain œdemas observed in puerperal women, in whom the principal veins of the extremities have been found obstructed by fibrinous clots. (Rayer; article *Œdema*. *Diction. de Médecine* in 21 volumes.) When the skin has become uneven or tubercular in Arabian elephantiasis, the alteration which takes place is somewhat similar to that which is seen in elephantiasis *Græca*, but in the latter the inequalities or tubercles follow spots of a tawny colour, and do not constitute its principal outward character; whilst in Arabian elephantiasis the lesser swellings and tuberculations are accidental, only appear during the last stages of this disease, and are always accompanied by other lesions of the parts under the skin. The point in brief which it is of the greatest consequence to ascertain in cases of elephantiasis Arabica, is whether the tumefaction of the parts affected, be produced by indurated cellular tissue, impregnated with serum and hypertrophied, by adipose tissue, or by an anomalous development of the skin, muscles, and other tissues which enter as component parts into the organization of the limbs or parts affected, whether the vessels and lymphatic glands be inflamed or not, and whether the enlargement be the result or not of some obstruction to the course of the blood occasioned by compression, dilation, contraction or obliteration of one or several of the veins.

1353. *Prognosis*.—According to Dr. Hendy, in some rare cases, elephantiasis Arabica has been known to get well spontaneously. A man affected with elephantiasis of the scrotum, after having had several attacks, was awakened one morning by an uncomfortable dampness round the thighs; this proved to be water which had been effused through a crack in the diseased skin. About six ounces of the fluid were collected in a basin. A few months after this the patient had another recurrence of a similar evacuation from the scrotum,

(a) The following succinct account of the geographical distribution of elephantiasis Arabica, is given by Dr. Scott, in the *Cyclopædia of Practical Medicine*.—“This disease is in a remarkable degree endemic in the island of Barbadoes, on the southwest coast of Ceylon, in the neighbourhood of Cochin, on the Malabar coast, in some parts of Japan, in Egypt, and in Abyssinia. It occurs not unfrequently in almost all of the West India islands and British settlements of South America; in the Polynesian Isles; and in the provinces of Castile and the Asturias in Spain. Sporadic cases occur over Europe generally, and perhaps in all parts of the world.

“Persons liable to this disease.—In Barbadoes elephant leg was, until about the year 1704, confined to the black population. A white inhabitant was attacked in that year; and before the year 1760, when he died, the disease was common among the white population. In general, it would appear that imported Europeans are not liable to the disease unless they reside for a considerable time in the island. It is perhaps owing to this circumstance that soldiers are very rarely affected with it.<sup>1</sup>

“In Ceylon the disease is confined to the indigenous inhabitants, including the half-caste and Creoles. Imported inhabitants, comprehending Europeans, Africans, Malays, or natives of the peninsula of India, may be said to be exempted from its influence. There is only one instance known of a native of Europe having become affected; and in his case the disease did not appear before he had been a resident at Point de Galle between thirty and forty years.

“Soldiers and other imported Europeans are not liable to it at Cochin.”

<sup>1</sup> Dr. Hendy states that horses are liable to the disease in Barbadoes, and that it had been reported to him that dogs, horned cattle, and poultry, were sometimes affected with it.

after which this part was reduced almost to its natural size. (Hendy, case 22).

1354. *Treatment*.—The inflammatory symptoms observed in the first stage of elephantiasis Arabica, should be treated by emollient applications, tepid baths and bleeding; the fears which have been entertained against bleeding are unfounded. I have employed it with success in the paroxysms, the length and intensity of which it certainly moderates. In the chronic stages of the disease, bleeding has been followed by momentary relief at least, when the patient has complained of a feeling of painful distension of the parts affected. I have also seen very happy effects produced by local bleedings, from the groin, the hollow of the ham, the axillæ, &c. The part affected, placed as constantly as possible in a position that facilitates the return of the blood towards the heart, should be covered with emollient cataplasms, or wrapped in flannels steeped in soothing and narcotic decoctions. If the enlargement is developed on one of the lower extremities, the patient should keep his bed for several weeks. (a)

Emetics and purgatives have been administered at this period with various success; I rarely make use of them myself. The antispasmodic effects of the sublimed oxide of zinc in doses of eight grains a day, have been much spoken of. Hendy assures us that this remedy allays the sickness and uneasiness which patients experience in the periodical exacerbations of elephantiasis. Several physicians of the island of Barbadoes, struck with the frequency of the vomitings during the paroxysm, have thought it necessary to encourage the sickness, and even to provoke vomiting by the exhibition of emetics. Dr. Hendy objects to this practice.

In women, pregnancy is a very unfavourable circumstance. A young woman, of Havre, having married against my advice, became pregnant three times; after each pregnancy the right leg, which was affected with elephantiasis, became more and more enlarged.

A great number of patients have been cured by compression, either alone or combined with other means. This method was completely successful in the hands of Bayle and M. Alard, in one of their patients who had been affected with elephantiasis for twelve years. A strong man was employed to press the leg of the patient every morning in all directions, during three quarters of an hour or an hour, after which a roller was firmly applied from the toes to the knee. M. Lisfranc has also been very successful in these cases by the judicious combination of scarifications, compression and local bleedings. I have myself obtained unhelped-for cures by this method. It is more especially applicable in cases of elephantiasis of the limbs, consisting of simple hypertrophy of the cellular tissue without infiltration of serum. If it does not succeed completely when the tumefaction is partly owing to anomalous development of the muscles and bony tissue, it determines at all events the absorption of a certain quantity of fat and serum, and this is a result which we are always happy to obtain. Compression alone is found to suffice in a majority of cases; scarifications seem now to be rarely used; when it is thought necessary to have recourse to them, they should be made at such a distance from each other as shall prevent the inflamed circles, which are or may be formed around them, from meeting. The inflammation produced in an extremity by twenty or thirty scarifications of from half an inch to an inch in length, is not in general considerable; if it should increase to any degree of intensity, local and general bleedings must be had recourse to in combination with emollient and cold narcotic applications. It will be necessary to wait until the first scarifications are healed before others are made; several practitioners have recommended blisters and issues to the parts affected with elephantiasis. I have tried the effect of flying blisters. The trials which have been made with arsenical preparations upon patients labouring under elephantiasis, but without any evident advantage, should not be repeated. (b)

(a) We must regard Arabian elephantiasis as a constitutional disease with febrile action and phlogosis, which, if not checked, ends in a deposit in some organ or limb. The treatment recommended by Rhazes, of general blood-letting with emetics, laxatives, diet and rest, is the best. It is that adopted by M. Rayer and also by Dr. Musgrave, who also used to apply leeches and fomentations to the limb, and administered calomel until the mouth was affected.

(b) Instances have been quite recently related (*Brit. & For. Med.*

Patients who have been affected with elephantiasis should continue to wear a laced stocking, or a tight bandage after recovery, particularly when several of the veins of the extremity are in a varicose state. (a)

1355. Harassed and worn out by the enormous weight of the parts affected, many patients have insisted upon amputation as a last resource for an incurable disease. M. Alard assures us that those who have survived such an operation have become affected with elephantiasis in other parts of the body, or that they seldom failed to sink after one or more attacks of an inflammatory affection of the viscera, to which they seemed to become liable. A woman who, from the age of fifteen years, had suffered frequent attacks of the Barbadoes malady, was so much incommoded by the size of the affected limb that she begged it might be amputated. This was done; but a short time afterwards she had so violent an attack of the disease on the other leg that she sunk under it (Hendy, case 24). A woman, named Mary Pecout, whose case I have related in the first edition of this work, underwent amputation of the right thigh, in the month of March, 1823, after having been affected with Arabian elephantiasis from the age of seven years. In January, 1825, the disease attacked the right arm, and was treated successfully by M. Lisfranc by local bleedings, scarifications, and blisters. To these unsuccessful cases of amputation, Delpach opposes that in which M. Delmas, chief prosecutor of the faculty of Montpellier, amputated the arm under circumstances exactly similar, and without its being followed by any relapse. A patient operated upon by M. Larrey for elephantiasis of the scrotum, was in a fair way of recovery when this celebrated surgeon left him to proceed to Alexandria. Authier, operated upon by Delpach, on the 11th of September, 1820, left the hospital of Montpellier in the early part of February, 1821, apparently in good health, but with a slight cough. On his arrival at Perpignan he was pale and completely blanched in appearance; his pulse was extremely small. He died on the 23d of the same month of inflammation of the liver, of the peritoneum, of the right hypochondrium, and of the pleura of the same side. M. Talrich operated with success, in 1811, on a young woman affected with elephantiasis of the sexual organs. Nægele has been equally successful in the amputation of a leg in a case of elephantiasis. The question, therefore, as to the propriety or impropriety of amputation is not entirely settled. (b)

#### Historical Notices.

1356. The first pretty accurate ideas in regard to this disease are to be found in Rhazés (cum Serapio, Averrhoë, edit. G. Franks), 1533, in Haly-Abas, and in Avicenna (*Libri de re medicâ omnes*, in fol., Venetiis, 1564, vol. i. p. 952, *elephantia*), and it is on this account that the disease we are discussing received the name of *elephantiasis Arabica* or *Arabian elephantiasis*. The disease has been since noticed by Forestus (*Opera*, lib. xxiv. p. 453), by Mercuriali (*De morbis cutaneis*, lib. ii. cap. v.), and by Kæmpfer (*Amœnit. Exot.* fasc. 3, p. 58).

*Rev.*, April 1845), of cures of elephantiasis by the use of the Carlsbad waters. Iodine, in solution, with salines, merits a full trial in conjunction with its external use in the form of ointment of iodide of potassium, or of liniment holding this salt in solution. The vapour bath is also a useful adjunct.

(a) Change of climate, or at least of locality, should be recommended.

(b) A case of elephantiasis of the scrotum occurring in a negro boy, nineteen years of age, on the island of St. Croix, is related by Dr. W. H. Ruan (*Amer. Journ. Med. Sciences*, vol. vi.), in which he amputated the diseased part. The operation was performed on the 8th of November 1828, and on the 26th of January following, the youth returned to his work on the plantation. The communication was made by Dr. Ruan, in February 1830, leaving the inference that to that date all had gone well in this case. The disease had begun in early boyhood with erysipelatous inflammation of the scrotum, penis, and surrounding skin and cellular substance.

Doctor G. R. B. Horner (*op. cit.*), says that this operation has been repeatedly performed at Rio de Janeiro, "and it is said with success in some cases."

Elephantiasis Arabica has been observed in Egypt, by Prosper Alpinus (*Medicina Methodica*, Lugd. Batav., 1719), and by the medical officers of the French army that invaded Egypt (Larrey, *Relation hist. et chir. de l'expédition d'Egypt*, in 8vo. Paris, 1812, 1817). J. Heudy (*On the glandular disease of Barbadoes*, translated into French by Alard, in *Mém. de la Société Médicale d'émul.*, t. iv. p. 44), studied it among the natives of Barbadoes. M. Alard, who has published a learned essay on this disease (*De l'inflammation des Vaisseaux absorbans, lymphatiques dermoïdes et sous cutanés, (éléphantiasis des Arabes)*, new edition, in 8vo. fig. Paris, 1824), thought that the anomalous developments which characterize it were constantly preceded by inflammation of the lymphatic vessels and glands. (a) The cases of M. Bouillaud (*Observations d'éléphantiasis des Arabes*, *Archives Générales de Médecine*, t. vi. p. 567), and some others published subsequently in the first edition of this work, and detailed under my own eye, by M. Gaide (*Observations sur l'éléphantiasis des Arabes*, inserted in the *Archives Générales de Médecine*, t. vii. p. 553), would lead us to imagine that varicose states, and contractions, and obliterations of the veins, as also eczematous and erysipelatous inflammations, were in many cases not less efficient causes of these intumescences. The researches of M. Fabre may be consulted with advantage (*Observations de l'éléphantiasis des Arabes*. *Revue Méd.*, Oct., 1830), and a case of Arabian elephantiasis, by Martini and Horack, published under the title of *Obs. rarioris degenerationis cutis in cruribus elephantiasis simulantibus*, Lipsiæ, in 4to., 1828, as also the various cases which have been published on elephantiasis of the hairy scalp (Ricord, *Revue Méd.*, t. ix. p. 13), of the arm (Hensler, *Histor. brachii partumidi*, in Haller, *Disputat. Chirurg.*, vol. v.; Ludoff, *Casus elephantiasis in brachio observata*, in 4to., Erford, 1703, in 4to.), of the scrotum and penis (Tallrich, *Revue Méd.*, t. i. p. 180; Wadd, *cases of diseased prepuce*, 4to., London), on the pathological anatomy of the skin in elephantiasis, by M. Andral (*Revue Méd.*, t. xiii. p. 224), and on the treatment of this disease, by Lemasson (*Influence salutaire d'un erysipèle sur une éléphantiasis des Arabes*. *Journ. hebdomadaire 2de série*, t. iv. p. 408), on elephantiasis cured by antiphlogistics (*Revue Méd.*, 2de série, t. iv. p. 489), and some cases of amputation published by Nægele (*Archives Gén. de méd.*, t. xiii. p. 126), and by Clot (*Gazette des hôpitaux*, 1833, p. 388), are all interesting, and all deserve to be consulted. (b)

(a) The monograph of M. Alard is both learned and comprehensive. After giving the anatomy, physiology and pathology of the absorbents, the author examines the state of the knowledge of elephantiasis among the ancients and the Arabians. He next indicates the regions in which it is met with, and analyzes the description of it by different writers. Then follow cases occurring in Europe, the precise seat of the disease, the textural and organic changes to which it gives rise, its symptoms, causes and treatment. Several good engravings are attached to the work.

(b) M. Sigaud (*op. cit.*, 1844), tells us that this disease is endemic in parts of Brazil, where it is called the erysipelas of Rio de Janeiro. It is also called elephantiasis leprosy, and Foot of St. Thomas.

Doctor Pennock, on "Observations on Elephantiasis" (*Amer. Journ. Med. Sciences*, vol. xiv.), details a case of elephantiasis of the Arabs complicated with frambæsia, which terminated fatally, and of which the post-mortem appearances are described. It will interest, we are sure, the reader, and hence is transcribed for his benefit.

"Barbier, aged twenty, by profession a joiner, entered the Hôpital St. Louis, service of M. Biéti, in the autumn of 1833. In the month of December, I collected the following facts respecting his case.

"He was born in the Department of Haute-Saône; has never been in tropical climates, but has always lived in France, and his parents were free of all cutaneous disease. His nourishment has always been good. During the first years of childhood until he was nine years of age, he enjoyed good health; from that period until the age of seventeen he was affected with a succession of abscesses in the groins, on the neck, arms, and at the external extremity of the left clavicle. From the appearances of the cicatrices, there is no doubt but that these abscesses were scrofulous. They are of a brown colour, almost livid, intermixed with white, of an irregular form, and an uneven surface.

"The present affection commenced two years ago, immediately

above the great toe of the right foot, by a slight elevation and discoloration of the skin, attended with local pain and some fever; these symptoms were followed by a small, soft, projecting tumour of a red colour which bled upon the slightest touch.

"Six months afterwards the patient contracted a blenorragia, which ceased in a month under the treatment of injections of infusion of marsh-mallow, drinking the decoction of sarsaparilla and the liquor of Van Swieten. No secondary symptoms followed, but the cutaneous affection was subsequently augmented; since that time he has not had any venereal symptoms. The disease extended itself by the successive formation of the spongy tissue from the toes to the superior part of the thigh. It presents, according to its degree, four principal forms.

"First. A small, indolent, subcutaneous tubercle of the size of a pea, causing a slight elevation of the skin. This is the commencement.

"Second. Convex elevations exactly circular rising from one to four lines above the skin, surrounded by a brown circle varying in diameter from a quarter of an inch to one and a half inches, of a red colour, soft, spongy, analogous to the fungus of wounds, and bearing some resemblance to raspberries lying side by side, and exuding a red serosity.

"Third. Masses formed by the union of the above, but of irregular forms of variable size, covering the leg and the inferior part of the thigh. The greater part of these tubercles have the same appearance as those which are isolated. Where the healing process has commenced, the surface is drier, less elevated, and not so irregular. At the superior and inferior part of the leg the vegetations have the forms of small fleshy tongues, imbricated, resembling the crest of the cock.

"Fourth. Cicatrices, which are sometimes large, smooth, of a white colour, slightly elevated above the healthy skin; sometimes the fungosities seem to have dried up without changing form, and have assumed a brown, livid appearance.

"The union of all these alterations has changed the form of the limb, and gives it the appearance of the elephantiasis of the Arabs. The circumference of the superior two-thirds of the diseased leg is one inch more than that of the corresponding part of the other: the inferior third is one inch and three-quarters more than the left. The limb is the seat of excessive itching, and when cauterization is attempted by the per-nitrate of mercury, the patient suffers excruciating pain. With the exception of the cutaneous affection, his general health appeared good during the winter of 1833-4. Treatment—Infusion of hops for habitual drink, with 3ij sub-carb. soda, per oij.; alkaline baths daily, and cauterization with per-nitrate of mercury (*nitrique acide de mercure*).

"April and May.—After the first of April, excessive diarrhœa commenced, attended with extreme prostration of strength; the tongue was red, dry; thirst extreme; abdomen slightly painful upon pressure; the pulse frequent (88), and feeble; his usual cheerfulness forsook him, his mind became depressed, and he complained bitterly of his situation. The diarrhœa was arrested at intervals by regulating his diet, and by opiates and astringents, but was renewed by the imprudent excess of the patient. During this time the vegetations, (fungosities,) and the tissue of the cicatrices ulcerated, and the diseased limb was covered with extremely painful ulcers, very irregular in their forms, their edges perpendicular, and internally of a grayish colour. The slightest pressure upon them produced an exudation of very fetid pus. With these symptoms the patient died on the second of June.

"Autopsy thirty hours after death.—The skin on every part of the diseased limb was thickened, and with the cellular tissue beneath was from one-fourth of an inch to an inch and a half thick. On the cicatrized points the epidermis was smooth, and beneath this the entire thickness of the cellular and adipose substance, with the exception of a few isolated masses of adeps, was replaced by a white, fibrous, aponeurotic tissue, which was firmly attached to and blended with the dermis. In the points in which cicatrization had not commenced, the epidermis appeared detached from the dermoid mucous tissue, which was red, thickened, slightly uneven, (*mamelonné*), bearing some resemblance to the intestinal mucous membrane, and could be raised without dissection from the subjacent adipose layer. In the middle of the thigh between the sartorius and rectus femoris muscles, was an abscess of the size of a goose-egg, containing a white tenacious pus; and on a level with the internal malleolus, all the cellular tissue, for the space of two inches, was changed into a sanious

## BARBADOES LEG.

1357. In the month of February, 1755, a fever prevailed in the island of Barbadoes, characterized by a cold stage of four or five hours duration, a hot fit, &c., headache, and frequently severe pains in the back. This fever was sometimes ephemeral, and occasionally lasted no more than four or five days; it, however, much more generally continued longer, and then there supervened inflammation of the leg similar to that which accompanies the fever of elephantiasis, but without swelling of the lymphatic glands, and without any hard cord in the limb. The inflamed part was of a vivid red; small phlyctenæ arose here and there over its surface, as in erysipelas, and desquamation took place after the cessation of the inflammatory symptoms.

An epidemic of the same description recurred during the month of February, 1757, but marked by several important varieties, which were probably ascribable to the excessive heat of the weather upon this occasion. The fever was now accompanied with pain in the stomach, nausea, cough, and sometimes with delirium and coma. The local affection was exhibited in the feet, legs or arms of either side, but never of both sides at once, and was distinguished by the same redness and swelling as in elephantiasis; the swelling, moreover, increased after the fever had ceased. During the next month many persons were no otherwise affected than with a troublesome cough, which ceased as soon as the tumour appeared on the arm or hand. The disease continued with this phasis till the month of June, when it assumed new features: the heat became more considerable, the thirst greater, the pains in the back and limbs much greater than at first, and the tumours or swellings were apt to fall into suppuration, instead of being resolved, as they were through the preceding stages of the disease. (Hendy, James. *A treatise on the glandular disease of Barbadoes*, 8vo. London, 1784.) Hillary, W. (*Obs. on the air and the concomitant epidem. diseases in the Island of Barbadoes*, 8vo. London, 1759.) (a)

## ANDRUM AND PERICAL.—PEDARTHIORACE AND ENDEMIC HYDROCELE.

1358. These are two affections analogous in their nature to Arabian elephantiasis, which prevail endemically on the coast of Malabar, in

mass of a slate-gray colour, and of a fœtid odour. At the external healthy parts of the leg, the adipose substance was two lines in thickness, soft, and of a clear light-yellow colour; in the diseased parts, on the contrary, it was an inch thick, and separated into masses by a white tissue. This tissue was firm, resistant, and was penetrated with difficulty by the scalpel; the cells formed by the interlacing of its fibres contained, beside the adeps, a great quantity of serous and gelatinous fluid. In the parts which were highly diseased, the skin was entirely destroyed, and the ulceration extended to the adipose layer; on the internal and superior part of the leg, and beneath the aponeurotic fascia, was an abscess of the size of a hen's egg, containing greenish pus, and partly lined with a false membrane. The tunics of the internal saphena vein were thickened, and when cut across, the cut extremity remained open like an artery. The tendons, bones and periosteum were healthy.

"*Thorax*.—A small group of tubercles were found at the summit of the right lung. Near these was a cavity traversed by fibrous bands, and was evidently a cicatrized tuberculous cavern. The rest of the lungs crepitant, and floated when thrown on water.

"*Heart*.—The heart was soft, and the parietes of the ventricles thin.

"*Abdomen*.—The liver was much enlarged; it not only occupied the epigastric region, but extended into the left hypochondriac; the volume of the left lobe was almost equal to that of the right, its entire weight eight pounds. Externally and internally it was yellower than usual. The gall-bladder contained a greenish bile; its ducts were unobstructed. The mucous membrane of the stomach, and the intestines, in their entire extent, had its normal colour and consistence. There was neither redness nor softening, nor induration of this tissue."

(a) There was no call for separating Barbadoes leg from elephantiasis in the preceding section, since the former is merely the latter disease endemic in Barbadoes,—as it is in so many other places. See note *antè* to § 1351.

the island of Ceylon and Japan. The one attacks the foot (*perical*), the other the scrotum (*andrum*).

1359. *Perical*, or febrile foot, is very common among the natives of Cochin. Young persons are attacked more frequently than adults, and these oftener than the aged. A very general opinion is, that the Christians, among whom the disease is very common, bring it from the Coromandel coast. The disease attacks one or other of the lower extremities; very rarely both at once, and always occurs on the lowest part.

Those affected with it have an attack of phlegmonous inflammation every month, which vanishes after a few days, but leaves a swelling which degenerates so that the extremity becomes triple, quadruple and more, its former size. It is uneven, œdematous, hard, of a scirrhus appearance, and often the seat of ulcers which discharge a serous-looking fluid. The swelling generally extends to the toes, rarely ascends above the calf of the leg, and never affects the knee. It is occasionally also observed in the thigh, which, however, may be simply infiltrated from the scrotum when this is the part affected, as it is in the endemic hydrocele. Although the tumefied part be hard, and have a brownish and deformed appearance, it never becomes gangrenous, and is not dangerous. It is only painful at the epoch of the periodic inflammation, and is troublesome solely from its weight. When the affection becomes inveterate, the limb is apt to be covered with a number of small ulcers, which render the infirmity more unbearable.

1360. *Andrum*, or endemic hydrocele, begins with an erysipelatous affection of the scrotum, which is renewed every month at the time of the new moon, and leaves a swelling behind it which is caused by the effusion of a quantity of serous fluid, the quantity of which increases from day to day, and distends the part to such a degree that it has at length to be evacuated by punctures and scarifications. This fluid is either thin and limpid, or viscid; it is always reddish in colour, and differs in its qualities according to the temperaments of patients. The disease attacks the natives and Europeans; a residence of a few years is enough to render any one subject to an attack. It is incurable in the country; but it is neither dangerous nor very troublesome. Still it sometimes happens that the testis is implicated and becomes scirrhus. If patients leave the country, the tumefaction abates gradually, unless it be complicated with sarcocele, a disease for which there is no remedy (Kæmpfer, *Amœnit. Exoticæ*, 4to., Lemgo, 1712).

## SENKI.

1361. Senki is the name given by the natives of Japan to a disease which is very common among them, so common, indeed, that among ten adults, it is difficult to find one who has not been affected with it at one time or another. Strangers, too, after a short residence in the country, are liable to the disease. It begins with pain in the belly, and spasms, particularly in the abdominal muscles, when a sense of suffocation supervenes, from the tension which then occurs between the region of the pubes and that of the false ribs and ensiform cartilage. The disease is sometimes fatal. When it abates, swellings are observed to occur here and there over the whole surface of the body; among men it often produces an enormous enlargement of the eyebrows; among females, the labia majora are beset with a congeries of tubercular or fig-like enlargements. Enlargements of these parts in the two sexes are common in Japan, and may supervene without appearing to be consequences of colic (Kæmpfer, *op. cit.*, p. 552).

## MOUTH CANKER [LABRA-SULCATA (a)], OR CHEILOCAECIE OF IRELAND.

1362. Boot describes a disease as prevailing in Ireland and even in England among children of four or five years old, characterized by a *tumefaction of the lips*, which become hard, and by projecting from the gums and teeth, give the countenance a hideous and unnatural expression. Occasionally they are divided by a deep chap or fissure into two parts, as it were, from whence there flows a sanious-looking

(a) *Labri—sulcium* in the text.

fluid, which dries up into a crust. The upper lip alone presents this anomalous enlargement in some cases, and when both are affected, the upper is always so in a much greater degree than the lower. This disease is *mouth-canker*, *labra sulcata*, or *cheilocace*. It is very generally accompanied with ulcers in the mouth, on the palate, tongue, and gums. The best treatment, we are told, is to purge patients freely with calomel, and infusion of senna, to make them drink an infusion of fumitory, rumex, patientia, and endive; to apply leeches to the lips and temples, and even to recur to general blood-letting if they be strong. The lips should be kept moistened from time to time with a decoction of honeysuckle, &c., or with a solution of sulphate of zinc, and then rubbed over with a liniment of the acetate of plumbi and oil. A blister may be applied to the arm, if the disease be obstinate, and decoction of sarsaparilla, cinchona, &c., prescribed for all drink (Boot); Arnaud (*Obs. Med. de affectibus omissis*, 12mo: Lond., 1649):

Mercurialis and Bonetus (*Sepulchret. anat.*, lib. i. sect. 21, obs. 17), also speak of this disease, upon the nature and characters of which there still hangs great obscurity. I have frequently observed a *hard and indolent tumefaction of the lips* in children of scrofulous constitution. (a)

## SECOND GROUP.

### ENDEMIC TUMOURS.

1363. This group includes tumours which are only known to occur in certain countries.

#### ALEPPO PUSTULES (BOULTON D'ALEP.).

1364. *Symptoms*.—The Aleppo pustule or spot is a disease endemic in Aleppo and several towns of Syria, which attacks almost all and sundry once in their lives. It is characterized by one or several pustules of tardy growth, which get well after having ulcerated, but leave ugly cicatrices behind them. It is denominated *habbet el seneh* (spot or pustule of a year), in Arabian, because a year is required for it to run through the whole of its stages, that is to say, to be evolved, to suppurate, and cicatrize. It begins in the shape of a small prominence of a lenticular shape, without heat, pruritus or pain. This increases insensibly to the end of the fourth or fifth month, when it may have acquired from about six lines to several inches in diameter, and be found to project about three lines. At this time it becomes the seat of acute pain, the severity of which, however, varies according to the place of the affection. Its surface becomes covered with a whitish moist incrustation, which, when very firm, is either detached completely, or only cracks in different places, and allows a quantity of purulent matter, white or of a yellow colour, and inodorous at first, which is formed slowly in the interior of the tuberculation, to escape. When the crust falls off, the surface it covered is found uneven, granulating, and of the colour of raw meat; the place is surrounded with a red areola. The crust falls off entirely or in pieces at intervals; when it remains long adherent, the discharge becomes thick, of a dark colour, and extremely fetid. The period of suppuration lasts five or six months, and ends in the formation of a dry and adhering crust, which is complete by the end of the year when the disease has been left to itself, and the patient is in other respects well. The affected part, when first exposed, is at first of a vivid red, then becomes of a reddish-brown, and by and by approaches nearly to the natural colour of the skin.

1365. All parts of the cutaneous surface may become the seat of the Aleppo pustule, but it is most generally developed on the face and extremities. The inhabitants of Aleppo have it more frequently on the face than on any other part. This is the mark which distin-

guishes them from the rest of the Syrians. Foreigners, on the contrary, are seldom attacked with it on the face. When the pustule appears on the joints, over bony projections, and on regions which are but indifferently covered with soft parts, it occasions very severe pain. M. Guilhou relates a case of this disease occurring on the scrotum in a Frenchman; such an event is very rare.

The inhabitants of Aleppo distinguish two species of this disease by the very objectionable names of *male* pustules, and *female* pustules. The former are *single*, whilst the latter occur in numbers together. Round several of the principal pustules, others of smaller size and in greater or smaller numbers, are frequently clustered; these may be so numerous, that the whole body becomes ulcerated by them. M. Guilhou once saw a Frenchman who had seventy-eight principal pustules, each surrounded by smaller ones in such numbers that the eruption at first sight had the appearance of confluent small-pox. The loss of substance which the pustule occasions is sufficient proof that the whole substance of the skin is implicated. This eruption constantly leaves an indelible cicatrice which is as various in its form as the ulcers which precede it; it is depressed, with the edges more or less oblique, sometimes rather deep, but in general superficial. The cicatrice is either smooth or rough, rarely brownish, more frequently white.

1366. *Causes*.—This disease is endemic to Aleppo and its environs. M. Gilhou assures us that a similar eruption prevails in Bagdad, on the banks of the Tigris, and of the Euphrates, and in all the villages on the road from Bagdad to Aleppo, such as Mossal, Diarbekir, Medira, and Orfa. At Aleppo, foreigners and natives, without distinction of race, sex, temperament, or profession, are affected by it. It rarely attacks infants at the breast; it is generally at the age of two or three years that it is developed. There is not a single instance of a child born in Aleppo, having reached the age of two years without having been affected with this disease. The time at which it attacks strangers is variable. It is very rarely that they suffer from the eruption till after a residence of some months. It is also often years before it shows itself; but it is the general opinion at Aleppo that it is enough to have passed some days in that city for the disease to be developed sooner or later, in whatever country the individual may afterwards happen to reside. Several facts in confirmation of this statement have been adduced. The Aleppo pustule is not contagious; it only attacks individuals once in the course of their lives.

1367. *Prognosis*.—This disease is never fatal, but the face may be horribly disfigured by it, particularly when it is situated in the neighbourhood of the eyes, mouth or nose, &c. The ulcers often partially destroy the eyelids, and the alæ of the nose; they divide the lips, cause gaps in the external ears, and always leave frightful cicatrices behind them. In fact, the cicatrices which the Aleppo pustule leaves, are the worst and most dreaded effects of the disease.

1368. *Treatment*.—The various curative means tried in this disease have seldom appeared to exert any beneficial influence. It would indeed seem advisable to confine all treatment to the use of soothing washes, to great attention to cleanliness, and to keeping the ulcers from exposure to the air; still the ceratum minii camphoratum, or cerate of Nuremberg and the actual cautery, appear to have been employed with advantage before the period of suppuration, during the third or fourth month.

#### Historical Notices.

1369. We are indebted for the principal documents we possess on the Aleppo pustule to Russel [Alex.] (Natural History of Aleppo, and the Neighbouring Country, 2 vols. 4to.), to Dr. Hasselquist (*Iter Palestinum* (in Swedish), Stockholm, 1757, 8vo.), to Volney (*Voyage en Egypte et en Syrie*, 1787), to Bo (*Mémoire sur le bouton d'Alep*, addressed to the Royal Society of Medicine, *Journal de Médecine de Roux Destillats*, vol. lviii. p. 411), to M. Alibert, who has himself seen the disease in two individuals who had lived at Aleppo, and has published several cases collected there by one of his pupils, (*sur la pyrophlyctide endémique ou pustule d'Alep*, *Revue Médicale*, Juillet, 1820, p. 62), finally to M. Disant (*Gazette Médicale*, Paris, 1832, 4to., p. 556), and to M. P. J. B. Guilhou, who have seen the disease

(a) This disease of the lips is to be regarded as a part, merely, of canker or gangrene of the mouth.—*Gangrenous Stomatitis*. See Bell & Stokes's *Lectures*, vol. i.

in the countries themselves where it prevails, during a journey made through Syria, in 1829 (*Essai sur le bouton d'Alcp.* Diss. inaug. Paris, 1833, 4to.).

## TARA OF SIBERIA.

1370. Gmelin, during his travels in Siberia, in 1740, 1741, 1742, 1743, observed a contagious epidemic, which generally prevails during the months of June and July, in the city of Tara, and on the banks of the river Irtysh. This disease shows itself at first by a species of pustule of a pale colour, and hard to the touch, which appears on different parts of the body. In the course of four or five days these pustules attain the size of the fist, without changing colour or becoming less hard. The patient then experiences great weakness, with excessive thirst, loss of appetite, drowsiness, vertigo, præcordial anxiety, difficulty of breathing, fetid breath, paleness of the face, excruciating internal pains, inexpressible anguish, and, if a copious sweat does not break out, death is inevitable from the ninth to the eleventh day.

The treatment which is considered to be infallible is always undertaken by a Cossack, who kneads the tumour all around until the blood flows from it, or he plunges a needle into it until the patient complains of the pain of the operation. He then applies a cataplasm of chewed tobacco and sal-ammoniac, which is renewed three or four times in the course of twenty-four hours, and in the space of six or seven days the cure is accomplished. No other drink than warm *quaas* or *quass*, a liquor made of leaven or flour fermented in water, is generally allowed during this interval, though chicken broth with horseradish stewed in it, is occasionally prescribed instead. Milk, meat, fish and dry vegetables are interdicted.

The parenchyma of these tumours is said to be a spongy bluish kind of flesh. Gmelin treated these tumours by opening them and powdering their interior with the red precipitate of mercury, whilst he prescribed calomel internally.

Horses contract this disease; the tumours are treated in these animals by the application of the actual cautery. (Gmelin, *Travels in Siberia*, from 1733 to 1743. Göttingen, 1731-52, 4 vols. 8vo. fig., in German.)

## THIRD GROUP.

## ELEPHANTOID DISEASES.

1371. In this third group several endemic diseases which are evidently varieties of Greek elephantiasis [*the tubercular lepra of the middle ages*], and others which evidently bear a greater analogy to elephantiasis than to syphilis, with which they have sometimes been assimilated.

## THE MAL ROUGE DE CAYENNE.

1372. Under the name of the *Mal Rouge de Cayenne*, Bajon and Bergeron have described Greek elephantiasis, or *tubercular lepra*, which is more common in this island than in any other in the French colonies. See Dazille (*Obs. sur les maladies des nègres*, 8vo. Paris, 1742, t. i. p. 300), Bajon (*Mémoires pour servir à l'histoire de Cayenne et de la Guyane Française*. Paris, 1777, 1778, in 8vo. 2 vols.), the *Rapport des commissaires de la société royale de médecine sur le mal rouge de Cayenne ou élephantiasis*. 8vo. Paris, 1786, and Bergeron's treatise (*Mal rouge observé à Cayenne*. Diss. inaug. Paris, 1823).

## RADESYPGE.

1373. *Radesyge* is a Norwegian term, synonymous with the Latin phrase *morbus atrox*, by which the physicians of the country have

designated a disease of the skin which is looked upon by some as a species of syphilis, and by others as a variety of elephantiasis; the latter opinion, according to the descriptions we have of the symptoms, seems to me the more probable of the two.

*Radesyge* shows itself in the cold and foggy season, by a feeling of weight over the whole body, lassitude of the limbs, and itchiness of the skin. Patients afflicted with this malady fly every kind of occupation; they experience a stiffness in the joints, and headache in the frontal region, accompanied with a sense of tightness in the chest, and dyspnoea. The face has a pale, livid, leaden colour, followed by plethoric redness, and running at the nose, which renders the passage of the air into the nasal fossæ difficult. The nose becomes red and swelled, the voice hoarse, the uvula elongated, and wandering pains in the limbs supervene, which subside towards morning after a very copious, viscid, and rather fetid perspiration. Some months, or some years afterwards, a dry, whitish, mealy, or furfuraceous eruption forms on the surface of the integuments, the scales of which fall off and are replaced by thicker ones which render the skin uneven, hard, and rugous. At other times an extensive discharging eruption is thrown out, which occasions most distressing pruritus. Some patients present an eruption of small spots of various colours and the size of flea-bites, at first, on the face and then over the whole body, which appear and recede alternately, particularly under the influence of a damp atmosphere. These spots are mostly insensible, and may be pricked with a needle without causing the least pain. When they ulcerate a viscid matter runs from them, and they soon become covered with scabs or scales; a serous ichor often flows from them which inflames and ulcerates the neighbouring parts with which it comes in contact. These eruptions are accompanied or followed by coppery or lead-coloured tubercles, which are evolved, first on the face and afterwards over the whole body. By degrees the skin of the forehead thickens and wrinkles, the eyelids tumefy, the cheeks swell and assume a deep red colour, the lips, swelled and stretched out, give an unnatural size to the mouth. The external ear is folded and convoluted, the eyes are surrounded by a red circle, the look becomes oblique and menacing, in one word, the face is so hideous that it inspires universal disgust and horror. The tubercles, once formed, present scales, scabs, and ulcers, on their summits. On examining the posterior fauces tubercles are seen on the uvula, tonsils, and velum palati, to which foul ulcers succeed. These ulcers have callous, hard, uneven edges, from which a reddish and fetid matter is discharged, which dries up into reddish or brownish crusts. The skin situated between the ulcers is also often intersected with ridges or crevices, and the hair with which it is covered falls out. The violent pains in the limbs decrease, and sometimes cease entirely, as soon as the skin is affected. Arrived at this pitch, the disease still continues to advance. The ulcers, after having destroyed the integuments and soft parts, extend their ravages to the bones; the discharge is now extremely copious and of a most unbearable odour. Flaps of fungous flesh are detached from the bottom of the ulcers, caries attacks the bony palate, vomer and ossa nasi, the voice changes and becomes weak, articulation is difficult, the hair of the head and of all the other parts of the body, eyebrows, &c., falls off; sometimes even the phalanges of the fingers drop. Patients are at the same time said to have a most voracious appetite, and unquenchable thirst. These phenomena are regarded as the forerunners of approaching death. This happens when the strength is entirely exhausted by night sweats and colliquative diarrhoea.

As to the treatment of *radesyge*, much the same course has been recommended as that followed in elephantiasis, or in cases of syphilitic affection, according as it has been held analogous to the first or to the second of these diseases.

## Historical Notices.

1370. Dr. Ludwig Hunefeld, in his work on *radesyge* or Scandinavian syphiloid (*Die Radesyge oder Scandinavische Syphiloid*. Leipzig, 1828, Extract. in *Bull. des sc. médic. de Férussac*, t. xviii. p. 387; t. xx. p. 410), has given an account of the principal researches made into the nature of the disease. Consult Holst (*Morbus quem radesyge vocant, quinam sit, quanquam ratione e Scandinavia tollendus*, 8vo. Christianiæ, 1817), Munk, (*Mémoire sur le radesyge*, *Act de l'Ac. Roy.*

*des sc. de Stockholm*, 1815). Arbo (*Afhandl. om radesygens Kjen-detegn.*, &c., Copenhagen, 1793), and Voug (Jac.) (*Diss. inaug. sistens, obs. in exanthema arcticum vulgo radesyge dictum*. Gryphix, 1811, &c.)

## LEPRA OF HOLSTEIN. (SPEDALSKEDE.)

1374. Doctor Struve assigns the following characters to this disease: the face swelled, sallow, and shining; loss of the hair, eyebrows and eyelashes; swelling and change of colour in the nose; the tongue tubercular; the lips swelled and hard; alteration of the voice, and difficulty of breathing. Struve looks upon the lepra of Holstein and radesyge as the same, or as mere varieties of the same affection; he assimilates them to the lepra of the middle ages. Struve (*Ueber die aussatzartige Krankheit Holstein's, allgemein daselbst die Marsch-Krankheit genannt*, 8vo. 1820. Extract, in *Edinb. Med. and Surg. Journ.*, vol. xviii. p. 92).

## LEPRA TAURICA.

*Disease of the Crimea, or Lepra of the Cossacks.*

1375. Pallas, Gautier and Von Martius have described, under this name, a disease which prevails extensively among the inhabitants of the Crimea, and which was introduced, as is said, by the Russian troops engaged in the war with Persia.

According to Martius, the lepra taurica, with or without fever, is announced by the appearance of a great number of livid spots, or flat, indolent tubercles on the face, trunk and extremities, principally on the radial side of the wrist. At a later period (according to Martius, in the following year), the spots increase in number and size, and become of a blackish or brown colour; every part of the body except the skin of the hands, and the bends of the joints, may become covered with these spots; at this period the spots are not painful; the voice is occasionally hoarse, and the patient is restless and depressed. Still later (about the third year), a feeling of itchiness arises in the parts of the skin affected, similar to that occasioned by the bites of ants. The tubercles now become true flattened tumours, some of which are indolent, whilst others are the seat of intolerable itchiness. The shape of the body and face alters; the face swells; the lymphatic glands tumefy; and at this stage of the disease great weakness of the internal organs and considerable prostration are observed. In the fourth year great pain in the limbs, and particularly in the joints, comes on; the sleep and appetite, which, up to this time, were unaffected, fail; the strength decreases by degrees; the spots and tumours assume a reddish-brown hue, become hard, rough, and covered with squamæ. Scirrhus lumps are seen under the skin of the face and extremities, and under the tongue. In the *fifth year* the swellings begin to give way, and, particularly on the feet, are followed by ulcers of bad character, from which a fetid sanies is discharged, or which are covered with thick scabs. These ulcers have been seen to involve the loss of all the points of the fingers in succession. Tormented by a sense of insupportable heat in other parts, the patients, by scratching, give rise to ulcers, even of a more serious nature than the first. The manner in which the natives treat these ulcers, further, renders the slightest wounds of the greatest consequence. Finally (sixth year), the cheeks, lips, velum palati, and tongue, are corroded by ulcers, which often form on the inside of the nose, and in the trachea, when they occasion great interruption to the breathing. The nails, by this time, have generally been lost or are much altered. The viscera become more and more diseased, and death at length concludes the patient's misery. (Martin's Henricus, *de lepra taurica, specimen medico-practicum*, 8vo. Lipsiæ, 1806.)

## LEPRA ANÆSTHESIACA OF INDIA.

1376. Robinson gives the characters of this disease in the following terms:

One or two circumscribed spots or patches of a deeper colour than

that of the skin around them, appear on the feet or hands, and sometimes on the trunk and face; these spots are neither prominent nor depressed; they are shining and wrinkled; the wrinkles do not run into the surrounding healthy skin. The spots extend slowly until the skin of the legs and arms, and, by degrees, that of the whole body, when the disease is so extensive, is totally deprived of feeling. No perspiration takes place from the surfaces affected, neither are they itchy nor painful, and it very seldom happens that they are swollen. In a more advanced stage of the disease the pulse becomes very slow, (fifty to sixty pulsations in a minute,) and soft without being small; constipation of the bowels follows; the toes and fingers are benumbed as though with cold, shining, slightly swelled, and somewhat stiff. The patient is indolent, slow in understanding the questions put to him, and seems to be constantly half asleep. The soles of the feet, and palms of the hands present hard and dry cracks; a furfuraceous matter is deposited under the nails, which raises them, and occasions the skin around them to ulcerate. The legs and forearms swell; the skin is everywhere rough and chapped; at the same time ulcers form on the metacarpal and metatarsal articulations of the fingers and toes, in the line of flexion, and in the corresponding parts of the articulations of the trunk, without any evident tumefaction or pain; pieces of skin, half an inch in length, become gangrenous and fall off, leaving the pale and flaccid muscles bare; these, in their turn, mortify, and by and by are also cast off. Different joints may be thus attacked, and destroyed in succession, by the slow but uninterrupted progress of this terrible disease, which renders those who are affected with it objects of horror to all who approach them. The pains in this affection are not insupportable; the appetite is unaffected, and patients, horribly mutilated, sometimes live long, without appearing to be disgusted with life. They are finally carried off by dysentery and diarrhœa. Robinson assures us that, although *tubercular elephantiasis* sometimes shows itself during the course of *elephantiasis anæsthesiaca*, it is not necessarily consequent on it. (*Transact. of the Medic. and Chirurg. Society of London*, vol. 10.)

## JEWISH LEPROSY (SARAA).

1377. Moses (xiii. and xiv. chap. of Leviticus), in his laws concerning leprosy (Saraa), points out the signs or marks by which the Jewish priests might recognize it. Dom Calmet has given the following summary of these: the first indication is an outward tumour; the second is a pustule or abscess; the third a whitish or red and shining spot, to which the epithets *white*, *brilliant* are often applied. Whoever presented one or more of these marks, was shut up for seven or fourteen days. The certain signs of leprosy were, first, a whitish, reddish, and shining spot; second, the hair pale and red on the same place; third, the part more deeply sunk than the rest of the skin.

A simple white spot was not sufficient to cause a man to be declared a leper; it was necessary that this should grow and increase. When the whole body was white from the head to the feet, it was a *pure leprosy*; and when the flesh was covered with white tumours, and the hair, on the parts where these were seen, had changed colour and become white, it was an *inveterate leprosy*, and rooted in the skin.

If, in a cicatrice or in a place which had been burned, a white tumour or a whitish spot was seen, shining or red, more depressed than the surrounding parts, and the hair of which had become fair or pale, it was a mark of a *true leprosy*. Finally, when any place was seen in the head of man or woman, more sunk than the rest, if the spot increased, it was leprosy, whether the hair changed colour or not. On the head of a bald person, spots, either whiter or redder and more shining than the surrounding parts, indicated leprosy.

1378. The Jewish leprosy has been assimilated with several other diseases. Bartholinus, J. Leclerc, and others associate it with tubercular elephantiasis; Hillary and Adams think that it was nothing more than the frambœsia of Africa; Bateman believes it to correspond with the *leuce* of the Greeks, with the *baras* of the Arabians, and with the third species of *vitiligo* of Celsus; Lorry and several others regard it as a distinct disease; but at the present day, possessing these scanty accounts only, it is evidently impossible to form any thing like a definite and just idea of the nature of this disease.

*Historical Notices.*

1379. On the Jewish leprosy, consult Mead (*Medica Sacra*, London, 1749), Dom. Calmet (*Diss. ou recherches sur la nature et les effets de la lèpre dans la Sainte Bible*, Latin et Français, Svo. 1820, t. iii. p. 19); Oussel (*Diss. Philologico-medica de leprâ cutis Hebræorum*), Schilling (*de Leprâ*, p. 63), and Boussille-Chamseru (*Recherches sur le véritable caractère de la lèpre des Hébreux*. Mém. de la Soc. Méd. d'Emulation, t. iii. p. 335).

## MALUM MORTUUM.

1380. The *malum mortuum* observed in the middle ages, has been described by Théodoric and Joannes de Vigo. "Quædam infirmitas nascitur circa tibias et brachia, quæ *mal mortuo* appellatur. Sunt enim ulcera livida et sicca modicæ saniei generativa, quandoque fiunt de purâ melancholiâ naturali; quandoque e melancholiâ cum admissione phlegmatis salsi; si illud, cognoscitur per nigras pustulas sine pruritu; si hoc, livescit locus cum pruritu e mordicationibus" (Théodoric, *Chirurg.*, lib. iii. c. 49). "Malum mortuum est squalida scabies maligna et corrupta in brachiis, coxis et tibiis, faciens pustulas crustosas cum saniositate subtus ad instar lupini . . . Sumitur per viam contagionis. . . In signis, curis et causis plurimum confert cum morbo gallico; quæ uni conferunt, alteri conferre videntur . . . Pustulæ sunt aliquantulum extra cutim elevatae cum colore mori semimaturi . . . scarificatione profunda usque ad os parvum aut nihil patiens sentire videtur (De Vigo, *Tract. in arte Chirurg.*, etc., c. v. p. 3).

The *malum mortuum* has been assimilated with gangrenous elephantiasis and elephantiasis anæsthesiaca.

M. Alibert (note on the *genus spiloptaxia*, *malum mortuum* of some pathologists, *Revue Médicale*, 1829, vol. iv. 169), has given the details of a case of disease which he met with in the course of his practice, and which he believes to be similar to the *malum mortuum* of the middle ages.

## FOURTH GROUP.

## SYPHILOID DISEASES.

This group comprises epidemic syphilitic, and other analogous diseases.

## DISEASE OF THE DISTRICT OF CHAVANNE-LURE.

(*Département de la Haute Saône.*)

1381. M. Flamand writes as follows, on the 6th of October, 1829: "I have now satisfied myself that a disease having the reputation of being contagious, has existed in the district of Chavanne for the last eighteen months; up to this time from twenty to five-and-twenty persons, and probably even more, have been affected with it; for the inhabitants, from a sense of false shame, being unwilling to confess that they are its subjects, several have undoubtedly eluded my researches, and those of the mayor of the place. It begins with sensations of general weakness, followed by pain, more or less acute in its character, in the limbs, which increases during the night, and which the patients compare to that of rheumatism. These pains continue, in different cases, from a fortnight to four or five months, and successively attack several of the articulations. Afterwards an inflammatory swelling takes place on the lips, which become covered on the inside with whitish aphthæ, and which crack, acquiring twice and even three times their usual size. The inflammation soon shows itself in the throat, attacks the uvula, the tonsils, and the velum palati, and occasions an extinction of voice, which, in some persons, is almost complete. As soon as these inflammatory symptoms appear, the pains

in the limbs diminish, and entirely cease as they increase. In some persons a pustular eruption breaks out over the whole body, but more particularly upon the head. The pustules are accompanied with intolerable itchiness, which, however, ceases on their bursting and discharging a little purulent matter. These pustules are rather large, and of a livid red colour; they leave marks on the skin, traces of which are seen long afterwards. One individual had the pustules on the head only, and in another the symptoms of the disease were accompanied by a tedious ophthalmia, and a considerable flow of tears; this second stage lasts several months, and even a year.

In two-thirds of the persons who have been affected, the disease appeared to me to get well spontaneously; others still retain some of the symptoms. It has not, as yet, been fatal to any one. A man, named Pierre François Goudey, twenty-eight years of age, was the first who was attacked; it is now twenty-eight months ago. The first symptoms were general weakness, and disinclination to work, then pains in the limbs, which lasted about two months; afterwards, inflammatory and aphthous swellings of the lips and inside of the mouth, for nine months; at the same time inflammation occurred in the posterior fauces, and an extinction of the voice supervened, which lasted for three months; an inflammatory affection also appeared on the scrotum, which the patient attributed to the rubbing of his drawers of coarse new linen cloth. No vestiges now remain of the disease, nor of any of its symptoms. Goudey communicated the affection under which he laboured to his three young children, all of whom suffered from the swelled and aphthous state of the lips; one only from the inflammatory symptoms of the throat, and the hoarseness. His wife, with whom he cohabited, was the only individual of the family who did not catch the infection from him, which would seem to indicate that the union of the sexes is a means very little apt to communicate this disease, although it is regarded as a peculiar modification of syphilis. Goudey having been made prisoner, and detained for three days, by a troop of Austrians, at Montbéliard, at the time of the second invasion, pretends that he contracted the disease by drinking out of the same glass immediately after a soldier of that nation, who, he said, had the disease on the lips. It was not until some time after his return home, that Goudey felt the first symptoms of his malady. Elizabeth Goudey, fourteen years of age, assures me that she caught the infection from the children of the above-named Goudey, her relations, from having eaten with them; she experienced the pains in the limbs, swelling of the lips, inflammation of the throat, and loss of voice. Her brother, Claude François Goudey, about fifteen years of age, contracted the disease some time after his sister, and experienced the same symptoms, with ophthalmia, in addition, which lasted several months; the eyelids, indeed, are still slightly injected, and the eyes watery. The wife of Jean Baptiste Goudey thinks she caught the disease from Elizabeth Goudey, from her being so frequently in the house, and going often there to her meals. The disease showed itself in her by very intense pains in the limbs. These pains began in the lower limbs, and attacked, successively, the shoulders, elbows and wrists, and lasted about five months. She had had a general pustular eruption, though the head was the part more particularly affected; the marks of this still exist in the shape of spots of a livid red. Her lips were not inflamed, but she had aphthæ on the tongue, and inflammation of the throat, which, as well as the hoarseness, was still complained of. The husband of this woman took the disease six months after her; he only suffered from pains in the limbs for a fortnight; his throat is in a high state of inflammation, and this is accompanied by an almost complete extinction of voice. The inhabitants of Chavanne are persuaded that this disease is particularly propagated through the medium of the implements used in taking food, which is the more likely to be the case, as it is known that country people make use of these one after another without any attention to cleanliness. The following cases seem to strengthen these opinions . . . . .

"Since the month of March I have had those individuals under my care who still showed any of the symptoms of the disease; I recommended the use of the warm bath, and of tonics, and mercurial preparations, particularly the liquor of Van Swieten, internally. I had the satisfaction of finding that this treatment succeeded, and of seeing the disease entirely disappear from Chavanne, without having

been communicated to the adjoining districts." (*Journal Compl. du Dict. des Sci. Med.*, t. v. p. 134.)

## DISEASE OF THE BAY OF ST. PAUL. (CANADA.)

1382. Between the years 1776 and 1780, a disease which has been designated under the names of the *disease of the Bay of Saint Paul*, *le mal de chicot*, *le mal des éboulemens*, appeared in Canada, particularly in the Bay of St. Paul. According to Dr. Bowman,<sup>1</sup> who was sent by Governor Hamilton, to investigate the nature of the disease, it was announced by the appearance of a number of small pustules on the lips, tongue, and inside of the mouth. These pustules, which resembled small aphthæ, advanced rapidly; and children have been seen whose tongues were almost entirely destroyed by them. The whitish and puriform matter they contain communicates the infection to those who touch it. Patients are tormented with nocturnal pains in the bones, but these generally subside when ulcers appear on the skin and in the interior of the mouth; cervical, axillary and inguinal buboes are often met with; at a more advanced stage, the body becomes covered with pruriginous tetters, which soon disappear. The bones of the nose, palate, cranium, pelvis, thighs, arms, and hands, become affected with nodes and caries; all the functions become greatly disordered; the senses are disturbed, the patients die a prey to the most acute sufferings. Some individuals, however, are so robust that they stand out against this complication of infirmities for many years, dragging on a most miserable life; entire limbs have been sometimes known to sphacelate and fall off. This frightful disease spares no one, but it seems to rage with peculiar virulence among children. It is, above all, by the sexual act, that it is communicated or transmitted from one individual to another.

Decoctions of the roots of *patientia*, of *actium lappa*, and *sarsaparilla*, are the remedies usually employed to arrest its progress. A decoction of a species of fir, or beer, made with a decoction of the branches and bark of the pine of Canada (*Pinus Canadensis*) has also been approved. The inhabitants of some parts of Canada, and among others, those of the Bay of Saint Paul, where the disease spread extensively, pretend that it was brought among them by the English. The peculiarity most worthy of remark connected with the history of this disease is, that it rarely attacks the organs of generation, and that it may be contracted without any actual intercourse with individuals affected with it, even without touching them immediately.

Swediaur observes that Dr. Bowman's description, however imperfect it may be, recalls to his mind the account which the writers of the fifteenth century have given of syphilis. The similarity to scherlievo is still more striking.

## DISEASE OF FIUME, OR SCHERLIEVO.

1383. This epidemic disease, the origin of which was attributed to four sailors, who were supposed to have brought it from Turkey, appeared in 1800, in the districts Scherlievo, Gronemico, Fiume, &c. It was supposed by others, again, to have been imported in 1790 from Kukulianova, by a peasant named Kumzut. A short time after his return, his father and mother were affected by it, and afterwards propagated it in Scherlievo, &c. The disease spread with so much rapidity in 1801 in the provinces of Buccari, Fiume, Viccodal, and Fuccini, that in a population of from fourteen to fifteen thousand individuals, it was calculated that more than four thousand five hundred were affected with it. Messrs. Percy and Laurent assure us that a commission of physicians appointed in Sept. 1801, found more than thirteen thousand persons affected with this disease, out of a population of thirty-eight thousand. It reappeared in 1808 and 1809, raging especially in Scherlievo, where it seemed to be kept up by the filth of the lower orders of the people, whose damp cabins are shared with their domestic animals.

1384. *Symptoms*.—This disease usually commences with lassitude

<sup>1</sup> These details are from Swediaur, who seems to have mistaken the name of Bowman for that of Beaumont, and that of Hamilton for that of Haldiman (Adams, obs. on *Morb. Poisons*, p. 194).

of the limbs, and pains in the bones of the arms, thighs, and spine, which increase during the night; the voice soon becomes hoarse, and deglutition difficult; the face is flushed; the velum palati, the uvula, the tonsils, and sometimes the pharynx and larynx are red. Soon after, a species of aphthæ burst, and discharge an ichor, which erodes the neighbouring parts; small ulcers are formed, which unite and create a sore of various dimensions, but always of a round shape, of an ashy colour, and with hard, raised, and dark red edges. These ulcers, which are in some cases evolved with great rapidity, cover the uvula, the tonsils, the velum palati, and the surface of the cheeks and lips; caries affects the bones of the nose, when pus of unbearable fetidness is discharged; the voice changes more and more, and is at last entirely lost. The exostoses which had appeared from the beginning, occasionally but rarely shrink and vanish, along with the pains which accompany them, as soon as a pustular eruption is evolved upon the skin. Dr. Lambini, however, relates four cases, which prove that the pains in the bones became more violent, notwithstanding the treatment employed, and lasted throughout the whole course of the disease.

When scherlievo commences by a pustular eruption, M. Boué says that it is announced by violent itchiness, which lessens as the eruption comes to an end. The pustules are of a coppery colour, round, and of various extent. They most frequently appear on the forehead and hairy scalp, but they are also seen on the inner surface of the thighs, legs, and arms, and round the anus and genital organs. An acrid ichor sometimes flows from them, which inflames the skin; at other times this discharge dries and forms scabs; the disease often remains stationary in this state. After the scabs have fallen off, the skin retains marks of a coppery hue, which it is difficult to remove.

Scherlievo has been known to begin with various sized blotches of a coppery colour, in the centre of which ulcers are seen, from which a matter is poured out, that by drying forms scabs similar to those which cover the pustules. These blotches are generally surrounded by an areola of a coppery hue, and give the patient a most hideous aspect. It is related as a fact worthy of notice that the genital organs in women are more frequently the seat of this disease than those of men. Doctor Cambicri, among the immense number of cases which came under his notice, only found one of gonorrhœa which came on after the desiccation of the pustules of the skin, and which disappeared as soon as the eruption was restored. As for the ulcers which so frequently erode the scrotum they always appear as secondary to the general infection.

1385. *Causes*.—The transmission of scherlievo is seldom the consequence of sexual intercourse, but is the effect of simple intermediate contact; the clothes, table utensils, such as glasses, spoons, forks, napkins, &c., and an atmosphere charged with the breath of those infected, are all sufficient to sow the seeds of it. Children have been known to bring the disease with them into the world, or to have it communicated by the nurses who suckled them. It hardly ever appears by buboes in the groins, or enlargements of any of the other lymphatic glands.

1387. *Prognosis and treatment*.—When this disease appears in the form of pustules, spots or ulcers in the mouth, it yields readily to antivenereal remedies. The prognosis is more unfavourable when patients have been weakened by fruitless treatment, or by previous complaints; when the ulcers have reached, and occasioned caries of the bones, or when the patients are debauched, indulging in intemperance and neglect of personal cleanliness. The treatment of scherlievo does not, in any particular, differ from that of syphilis. I have been assured that the bichloride of mercury, given in the syrup of Cuisinier, (comp. of senna and sarsaparilla), has always proved the most effectual means of subduing it; and that, when caries had attacked the bones, the treatment might be concluded with advantage by ten or twelve mercurial frictions. Opium combined with mercury is employed with complete success against the pains in the bones. The protochloride of mercury, mixed in the cerate with which the ulcerated pustules are dressed, and the solution of corrosive sublimate diluted used as a gargle or wash to the ulcers of the mouth, always expedite the cure.

Messrs. Percy and Laurent have proposed the establishment of a Lazaretto, and the disinfection of the dwellings and clothes of the poorer classes by chemical agency, as a means of getting rid of the

disease of scherlievo entirely (Percy and Laurent. *Dict. des Sci. Méd.*, art. *Mal de Fièvre*). But if, as all seems to authorize us in believing, scherlievo be only syphilis under another name, this recommendation would require to be modified.

#### Historical Notices.

1388. Scherlievo has been particularly studied by Cambieri, Massieh, Hensler, J. P. Frank and Bagnieris, whose observations have been analyzed in a report read to the *Soc. de Méd.*, 6th Aug. 1811. (*Journal de Médecine et de Chirurgie*, t. xlii. p. 1.) M. Boué, in his inaugural dissertation, has related several cases of scherlievo (*Essai sur la maladie de scherlievo*, 4to. Paris, 1814). Eyerel has given a good description of the disease in his continuation of J. P. Frank's work, *De curandis hom. morb.* M. Amdée de Moulon has very recently published his *Nouvelles Observations sur la nature et le traitement du Scherlievo*, 8vo. Milan, 1834.

#### FACALDINE.

1389. Under this name is designated a variety of syphilis, which is said to have been introduced, in 1786, into the village of Facaldo, in the province of Bellune, bordering on the Tyrol, by a female mendicant labouring under *venereal itch*, and ulcers and warts on the vulva. The following characters are assigned to facaldine: Seabious eruption, of a syphilitic nature, which attacks adults and children, ulcers in the throat and nasal fossæ, destruction of the nose, serpiginous ulcers, which erode the skin in various directions; gummy tumours, are seldom seen; pains in the bones occur very rarely, and exostoses hardly ever. In adults blenorrhagic discharges take place from, and ulcers occur on the genital organs; buboes, and several species of exerescences, are also frequent occurrences. Cure by means of mercurial medicines.

Mareolini has related a case and given a representation of facaldine, which he considers as a variety of scherlievo. Mareolini, *Mémoire Médico-Chirurgique*. Milano, 1829, p. 18. See, besides, Zucchinielli, *Ann. Univers. di Medicina*. Milano.

#### MORBUS BRUNNO-GALLICUS (MORAVIA).

1390. An epidemic appeared in Brünn, in 1578, which in the space of two or three months, attacked forty persons in the city, and almost a hundred in the suburbs; a considerable number of the country people were also affected. This disease presented symptoms similar to those of syphilis. The disease was generally supposed to have been propagated by baths, and the practice of cupping, which is in common use among the inhabitants.

Thomas Jordan, the historian of this epidemic, thus describes its characters. "Interim insuetâ quâdam ignaviâ, seu torpore gravati: pigri, segnes, inertes ad consueta munia obeunda, animo quoque abjecto, tristes vultu, cum nec mens neque manus et pedes officium facerent, veluti umbræ, non homines, passim oberrantes conspiciabantur. Nativus faciei color in pallidum; vigor ipse oculorum in torvum, circulo fusco sicut mulieribus menstruatis deformem, subito immutatus: frons exporrectior in caperatam et nubilam degeneraverat. Manifestum tum se prodidit indicium. Vestigia cucurbitularum turgentia, extemplo ardor invasit immensus et immedicabilis, quem fedi abscessus et ulcera exsepere putrida, sanie taboque fluitantia; circum-circa pustulæ, palmum quoque latæ, achoribus floridæ, quibus dehiscentibus acu aut medicamina discissis, profluxit pituita tenuis, serosa, marcida, sanieque mucosa: aliis etiam acris et erodens: tum caro cucurbitæ ambitu circumsepta, corrosa, putrescens, tetrum ut è telephiis ac phagedænicis ulceribus invexit fœtorem. Ubi admiratione dignum initio, quod è tot affixis cucurbitis, cum alii decem plus minus, tres quoque tantum nonnulli apponi jussissent, una duntaxat, aut ad summum duæ (socrui Laurentiæ sartoris è quindecim, tres) ex iis omnibus in fœdam transiverint vomica. Nonnullis universum corpus pustulis compersum, facies informis, triste, supercilium, horrendus vultus, dorsum, pectus, abdomen, pedes, loci a summo ad imum por-

riginosa scabie, crustaceis ulceribus supra cutem paulum elevatis, duorum cruciatorum nummum, vel unguis pollicis amplitudine, ambitu rubente, candidâ superficie (ut tinea quam barbari vocant) polluta, et deturpata, cernere erat. Manabant hæc quoque pingui liquore, mucore lento, qui non pus, sed saniem referret luridam. Imò, scabie sublatâ et sanatâ, maculæ atræ, diversæque ab impetiginibus, aut vitiliginibus, plumbei et fusci coloris, remanserunt. Progressu morbi, in capite calli concrevere, qui summo cum dolore et ejullatu rupti vel dissecti, melleum quippiam, resinosum et tenax, seu ex coniferis arboribus laticem extillare videmus, lentum inquam et viseidum, marescentis pituitæ argumentum, exudabant. Abscessus hi sordidi verèque cacoëthes, postquam magnâ difficultate expurgati, et non minore carne rursus productâ, coaluissent, novum prorupit symptoma. Universi corporis artus, brachia, scapulæ, cubitus, humeri, suræ, tibiæ, pedes imi, puncturis quibusdam quasi aculeis, intensissimè vellebantur, ac si ferris discinderentur, aut forcipibus ignitis laniarentur (sic ægri sensum doloris exprimebant) potissimum ubi tibia maximè excarnis, lacertorum non fulta thoris, à solo periosteo vestitur. . . . 'Nulla tamen quies, perpetua vociferatio, lachrymæ, gemitus, indesinenter torquentibus doloribus, nocte potissimum, cum fessa membra sopore dulci reficiuntur, illis noctes pervigiles, ob cruciatum vehementiam,' &c.

Various remedies were tried for this disease; but the following method seems to have been generally successful. After having bled the plethoric patients, and exhibited some purgative medicine, decoctions of guaiacum, turpeth mineral in pills, and the expressed juices of wild endive and fumitory were administered, whilst the ulcers were dressed with mercurial ointment.

#### Historical Notices.

1391. Consult Thomas Jordan (*Brunno-gallicus, seu luis novæ in Moraviâ exorta descriptio*, Franckfort, 1577, 8vo., ibid., 1783, 8vo.); Joannis Sporischii, *tractatus*, and Cratonis *Epistolæ*, lib. ii. I have not been able to procure these last two works, which are quoted by Schenck, who has republished Jordan's memoir (Schenck, *Obs. Medicar. Rarior.*, p. 792, lib. de Brunno-Gallico).

#### AMBOYNA PUSTULE, OR AMBOYNA POX.

1392. J. Bontius (*Medicina Indorum*, 4to., Lugd. Batav., 1718; *De tophis, gummatis ac exulcerationibus endemicis in insula Amboyna ac Moluccis præcipue quas nostratas Amboyne pocken vocant*), gives the following description of a disease, endemic in the island of Amboyna.

"Endemius, seu popularis quidam morbus in Amboyna, ac Moluccis insulis præcipue oritur, qui symptomatis suis admodum similis est morbo venereo. Sed in his inter se differunt quod hic sine congressu venereo quoque nasci solet. Erumpunt in facie, brachiis, ac cruribus tophi, seu tumores, duri primum ac seirrhosi ac tam crebi per universum corpus, quam elavi ac verrucæ oriuntur in manibus ac pedibus in patria; si vero eos ulcerari contingat, materiam lentam, ac gummosam à se reddunt, attamen tam acrem, ac mordacem, ut profunda, ac cava ulcera inde oriuntur, cum labiis callosis, ac inversis; fœdum ac deformem malum, et cum luc venerea conveniens, nisi quod hic tanti doloris non adsint, nec caries in ossibus tam facile oriatur, nisi per curantis incuriam. Hic affectus originem trahit, primum ex peculiari cæli et soli istius genio; tum ex aëre, vaporibus salsis, è mari undique ascendentibus infecto; cibis præterea crassis, ac melancholicis et pituitosis, ut sunt pisces marini, quorum hic magna captura est, quibus incolæ assidue escuntur, quod reliquæ annonæ sit satis indiga regio. Magnum etiam momentum huic malo adfert usus placentarum, quas vici panis, per totum istum tractum edunt, ac ab incolis *sago* vocatur, et est è corticibus arborum excussa farina. Ad hæc confert potus importunus liquoris cujusdam saguër vocati, qui ferre eodem modo ex arbore elicitur, quo è palma indica seu coquos arbore liquor iste, quem incolæ Towac, Lusitani Vinho de Palma vocant. Hic immoderate sumptus non secus ac vinum et cervisia inebriat; caput ac nervos infestat, hinc etiam in his insulis crebrior est ista paralyseos species, quam *Berberi* supra diximus appellari. Quantum ad curem attinet, ea, si recens sit hoc malum, non ad modum difficilis est. Sin inveteratum, jam mo-

lestior est curatio. Porro iisdem forme remediis cedit, quibus lues venerea, obstructions lienis, leuco-phlegmatia, ac ipse hydrops, et ceteri chronici ac rebelles morbi. Decocta hic itaque parentur à Chinæ radice, salsparilla, Guajaco et corticibus ejusdem, quibus incoquantur anagalis aquatica, seu beccabungæ, *m. ij.* Post peccans materia vehementioribus catharticis educenda est: nam levia hic non possunt. Talia sunt extract. Guttæ cambodja, elaterium; et si his non cedit, ad chynica, et mineralia deveniendum est: ut sunt mercurius vitæ, seu butyrum antimonii, turpeth minerale, tum mercurius præcipitatus albus. Unguenta quoque mercurialia secundum artem parata hic externe adhibenda sunt."

This disease very much resembles scherlievo, which, it would seem, ought to be assimilated with syphilis.

## SIBBENS.

1394. This disease has been observed in Scotland, particularly in the counties of Ayr, Galloway, and Dumfries.

According to Gilchrist, sibbens shows itself under several forms. Sometimes inflammation of the velum palati and surrounding parts takes place, and is accompanied with a kind of white eschar, or a superficial ulcer of a bright red colour. At the same time, aphthæ or small white spots or eschars often occur on the velum palati or insides of the cheeks. Small elevations, of a pearly or milky colour, also usually appear on the commissures of the lips. Often, too, a very small excrescence or *fleshy growth* is developed, resembling a raspberry, and which becomes covered with a scab. This growth is almost a certain indication of the disease, even when the sore throat does not exist. Dr. Trotter, who has also described this affection of the mouth, compares its appearance to that of toasted cheese.

Another form of this disease is that of destructive ulceration, which may cause the entire loss of the velum palati, and the death, from inanition, of infants at the breast, deglutition becoming impossible.

Sibbens appears in other cases on the skin, and under different aspects. Sometimes the whole surface of the body is spotted, and clouded with a coppery and dusky red blush. At other times, clusters of pustules appear, over which several successive desquamations of the epidermis take place. *Scabby eruptions* of the hairy scalp, forehead, inner sides of the thighs, &c., are accompanied with little hard lumps, in the thickness of the skin, and a feeling of unpleasant itchiness. At other times, a species of tumour, similar to furuncles, are seen on the arms, shoulders, face, legs and feet, which give rise to ulcers that perforate the whole thickness of the skin, and lay bare the muscles, which they sometimes also corrode. Adams is disposed to believe that these ulcers are the result of the immediate contact of the virulent matter proper to this disease.

Finally, the soft and spongy *raspberry tumours*, which have been mentioned (whence the name of *sibbens* or *sivvens*, which is derived from *sibbens frambæsia*), are the last symptoms of the disease; they do not seem to occur in all places alike, for several other forms of the disease are observed, several, indeed, which Gilchrist himself had never seen.

According to the same observer, the bones are not affected in this disease; Bell, on the contrary, speaks of *nodes* and *caries*.

1396. Sibbens is rarely communicated by sexual intercourse; the alterations which are sometimes seen in the genital organs take place consecutively. The disease is more frequently transmitted by nursing, and the common use of the same utensils, the use of the same pipe, for instance.

The silence of cotemporary writers on this disease leads me to imagine that it is now extinct.

The treatment adopted for sibbens, bears the greatest resemblance to that employed in syphilis.

*Historical Notices.*

1396. Since the publication of Doctor Gilchrist's paper (*An account of an infectious distemper prevailing in many places, &c.* Essays and Observ. Physic. and Literary, by a Society in Edinburgh, vol. iii. p. 154), Doctor Adam Freer has treated of sibbens, which he believed

to be produced by an insect similar to acarus, in an appendix to his inaugural treatise (*De syphilitide venerea*). Adams gives an account of several additional researches made by Doctors Hope and Barry, and particularly by Dr. Hill. Adams made a journey to Scotland himself, expressly to study this disease, and gives several cases of it (*Observat. on Morbid Poisons*, p. 176, 4to. Lond., 1807).

## PIAN DE NÉRAC,

(*Département de Lot et Garonne.*)

1397. Raulin has described an epidemic disease which seemed to be analogous to scherlievo and facaldine, under the objectionable name of *Pian de Nérac*.

"At the end of the month of June 1752, a singular epidemic disease appeared at Nérac; it was a species of lepra or frambæsia (*pian*), similar to that which affects the negroes in the Gulf of Mexico. It spreads among children at the breast; those affected by it begin to fall off; by degrees pustules appear on the face, mouth, neck, buttocks, and thighs. Nurses contract this eruption on the breasts, and it afterwards appears over the whole body. The pustules are generally round, hard, and rather callous; from some of them, a yellowish ichor is discharged; others are covered with a pulverulent crust; these pustules, covering the body, become confluent, and appear to form only a single incrustation; they degenerate into deep ulcers which lay bare the bones, and occasion death; towards the end of December it was calculated that more than forty infants had already been affected with this disease. The treatment that was most successful was the use of an ointment, made with one ounce of pure mercury, rubbed till the globules had disappeared in Venice turpentine, one ounce of lard, and one scruple of camphor, well mixed together. Mercurial frictions were tried upon several women, but mercury without camphor was often ineffectual. Children were cured in a fortnight, but it was necessary to continue the treatment for several days afterwards. The origin and cause of this disease were entirely unknown."

## FRAMBÆSIA OR YAWS (PIAN FRENCH).

1398. The identity of *yaws* and *pian* seems to be demonstrated, although some differences appear in the exposition of the symptoms of the two diseases, given by the English observers who have studied *yaws* in Guinea and in Jamaica, and by the French physicians who have observed *pian* in Saint Domingo, Guadaloupe, Brazil, Jamaica, &c.: these differences, however, seem at the most but to characterize two varieties of the same affection.

1399. Yaws begin by a state of languor and weakness; with pains in the joints, and in most cases with fever, which runs highest among children. Before the eruption, the skin is often covered with a white dust (Thomson), as though it had been powdered. Some days afterwards spots similar to flea bites or small papulæ appear on the skin, particularly on the forehead (Thomson). These elevations increase in size during from six to ten days; at the end of this time, a scab is formed on their top, from under the edge of which a crude purulent matter is discharged.

The size of the pustules still increases, and they become covered with irregular scabs not very adherent. Many of these pustules acquire the size of a shilling. On raising the scab an ulcer of a bad or gangrenous description is discovered. It does not assume the fungous appearance which it ultimately acquires, at any definite period of the disease; this sometimes occurs a month after the breaking out of the eruption, and sometimes three months afterwards; the development of these fungous growths seems to depend very much on the constitution of patients, taking place earlier in those who are lusty and well fed. A second eruption sometimes makes its appearance preceded by fever, the progress of which is the same as of that which has gone before it, so that the eruption may occasionally be seen in different states in the same individual. The elevations are broader and more numerous on the face, groins, axillæ, verge of the anus, and labia majora than on any other part of the body. New eruptions take place as soon as the first begin to dry off, so that after these

successive eruptions, the number of pustules existing together is sometimes very considerable. If the writers who have studied this disease are to be credited, there is always one pustule larger and more raised than the others, which it is more difficult to cure, and which is designated by the name of the *mother yaw*.

This affection is said to be sometimes accompanied with nocturnal pains and swelling of the bones, ulcers in the pharynx, &c. In this last case the disease becomes very distressing; the ulcers of the throat resemble toasted cheese; they never become fungous, and a great part of the palate is very apt to be destroyed by them.

The fungus of frambæsia, in patients of a good constitution, is red, like a piece of flesh; in delicate or diseased subjects, it is white like a piece of cauliflower; it bleeds on the slightest touch; in the latter case it is less raised than in the former. After having continued some time in this state, the fungus gradually diminishes in dimensions and in height, shrinking and generally disappearing without leaving any scar, except in places where the inflammation has been very great (Thomson). The cicatrices that then result resemble those of cow-pox, only they are larger and more superficial.

In the successive eruptions of yaws, there is often one pustule which does not heal like the rest; left to itself it is apt to produce caries of the neighbouring bones.

Yaws appear under a different aspect in cachectic persons: the pustules are smaller, the eruption which is less copious is successive; the fungous growths which usually characterize the disease either do not exist at all, or are very small and watery.

The length of time during which this disease continues is uncertain; in some patients it lasts six months, in others a year; in general, its term may be stated at about eight months. Fever and the symptoms generally, are mostly very well marked in weakly and ill fed children.

1400. *Causes*.—We are informed that frambæsia usually occurs among the ill fed negroes, whose skin is continually irritated by a burning sun, by the bites of insects, and by the rancid oils with which they are in the habit of anointing their bodies. This disease is contagious, is transmitted by the union of the sexes, by suckling or by the application of the matter of the pustules or cutaneous ulcers to any part of the excoriated skin; perhaps it is also transmitted in still other ways.

It is difficult to determine the time of incubation. Thomson relates that a certain number of negroes in good health were sent with their children to a sugar farm in a mountainous district, and the healthy children having eaten and drunk with those at the farm who were affected with yaws, three of the former were, seven weeks afterwards, attacked with fever and pains followed by a general eruption; the others were not affected until three weeks later; at the end of eight months all were cured. Thomson inoculated a child in five places with the matter of an ulcer from which the scab had been removed. Three of the punctures healed; the two others looked like simple scratches during three weeks, when they formed into small ulcers, which spread until they had assumed a gangrenous appearance with jagged edges, &c. Seven weeks afterwards papulæ appeared on the forehead, and by and by extended over the whole body; the fungus now formed; the patient had an abundant eruption which lasted nine months. The two ulcers which followed the punctures never became fungous, but they left deep scars. Thomson relates that variolous matter having been taken from a little negress affected with yaws, the child who was inoculated with this pus had the small-pox in a very mild form, and was afterwards attacked with yaws. The blood of a negro covered with yaws, was inoculated upon four children in five different places without producing the disease.

The usual progress of cow-pox, small-pox and varicella is not impeded by the existence of yaws.

The matter of yaws has not been found to occasion any eruption in rabbits or dogs, even after repeated inoculations.

The disease can only be communicated once to the human subject. A woman, however, who suckles a child affected with yaws may have the breast excoriated; death has even been known to follow this circumstance: phagedenic ulceration of the breasts which extended to the axillæ and was accompanied with great irritation, took place and proved fatal.

If a person affected with an ulcer of considerable size, contracts yaws, it may happen that this ulcer continues and presents the granulated aspect characteristic of yaws without the eruption appearing. If this ulcer be healed, an eruption similar to that which occurs in the usual course of the malady is developed; left to itself the ulcer gets into a progressively worse and worse condition.

1401. *Diagnosis*.—Thomson says, that an old Scotch physician, who had long been familiar with yaws in Jamaica, was struck, on his return to Scotland, with the identity of sibbens and this disease in most of their phenomena. (a)

Yaws is regarded by some writers as a modification of syphilis, by others as a peculiar disease of the skin. (b)

1402. *Treatment*.—According to Thomson the usual practice in the island of Jamaica is to leave the disease to the efforts of nature. Good food is recommended, and moderate work; sulphur, a decoction of the sudorific woods, and antimonial preparations, are exhibited in the cases of children with success. A great many diseases are generally attributed to the *dregs* of yaws. Thomson thinks that the number of these has been greatly exaggerated.

Finally, Thomson is convinced that though mercurial preparations may cause the symptoms to disappear in the course of a month, they generally reappear at a later period, and with greater violence than before. Hunter had already declared against the use of mercury in frambæsia.

1403. The description given of *pian* by the French physicians who have seen it in St. Domingo, Guadaloupe, Cayenne, &c., differs in

(a) Dr. Kerr (*Cyclopædia of Pract. Med.*, art. *Yaws*), establishes the diagnosis between the latter (frambæsia) and sibbens or sivvens, in the following terms. "The identity of many of the phenomena, as well as of the original signification of the names of the disease under our consideration, with sivvens or sibbens, (sibbens in the Erse dialect signifies a raspberry,) a malady well known in the western parts of Scotland, renders it a matter of interest, if not of importance, that we should notice their characteristic distinctions. The sivvens, it is remarked, at first seizes the throat and nose; the yaws never, until after a length of time or improper treatment. The eruptions in sivvens are watery, of a dirty hue, and of intolerable fætor; those of the yaws are at first as small as a pin's head, hard, and without any peculiar odour. In sivvens boils appear here and there, forming deep and ill-disposed ulcers, a character which does not belong to yaws. In sivvens itchy tetters break out in form of ringworms, and occasion either a deep ulcer or a scabby large spot with inflammation; the yaws have no such appearances. The sivvens rarely affect the bones, the yaws always unless well managed. In the yaws the excrescences succeed the pimples as well on the face and body as on the axillæ and pudenda; in sivvens the fungi appear on the groin and perineum in a very advanced stage of the disease. The sivvens is highly contagious without sensible inoculation, the only mode, as it appears, by which yaws is propagated. The sivvens may be cured early by mercurials, but mercurials in the yaws, at least in the early stage, are pernicious. In constitutions otherwise healthy the yaws will usually run a definite course, be spontaneously exhausted, and terminate in health even without medicine; but if speedy and effectual means be not used to counteract sivvens, it will almost certainly proceed to a fatal issue."

(b) The distinction between yaws and syphilis is drawn by Dr. Kerr in the work just referred to. "The yaws and syphilis have frequently been considered as modifications of the same disease, but a comparison between the descriptions of the two will at once establish some important distinctions. It is true that the yaws will affect the bones, the cartilages of the nose, and the palate, like syphilis, and will admit of cure by similar means; but in primary syphilis neither eruptions nor fungi appear as in the yaws, except on the pudenda, and then only in the form of warts. Syphilis will never cease spontaneously, (c) like yaws, and, unlike yaws, it may be and is contracted repeatedly. Persons who are suffering from the yaws may contract gonorrhœa, and even syphilis; and it is very remarkable that the former may be cured independently of the yaws, but that the latter cannot until the yaws have begun to decline."

(c) This averment is not sustained by the history of syphilis.

several respects from that which I have just sketched from the works of the English physicians who have studied this disease in the West Indies, and particularly in Jamaica. I shall, therefore, add a short abstract of the descriptions and opinions of the French physicians in the colonies.

*Pian* is announced by small red spots which appear on different parts of the body; the patient at the same time experiences a slight degree of fever, pains in the limbs, and even in the bones; the skin becomes scaly; the patient becomes sensibly thinner. By degrees the intensity of these symptoms decreases, the eruption is developed, and shows itself under three aspects: 1st, *large pians*, or *white pians*; 2d, *small pians*; 3d, *red pians*. The first, of great size, sometimes as large as the hand, are formed of fungous flesh, from which a thick sanious matter exudes. The small pians, less in size than the former, are much more numerous; their excrescences are redder and less fungous. The *red pians*, larger than the latter, less than the former, round, and of a more marked flesh colour, developed slowly and successively, are accompanied and followed by much more serious symptoms than those of the other two species, particularly than the first, which is the mildest of all.

One of the pustules of *pian* generally becomes larger than any of the others, and takes the form of a deep ulcer of bad character, but without fungi, from whence a sanious matter is discharged. If this ulcer is dressed with the usual remedies, it becomes irritable, and assumes a worse appearance than it had before. This ulcer is called the *mother pian*. It is dangerous to attempt to dry it up, or to effect its cicatrization before the symptoms of the general infection are manifested. If a patient have an ulcer on any part of the body, the first pustules are generally developed upon it, and the ulcer itself sometimes becomes the *mother pian*.

Several affections have been attached to the pianic eruption, as consecutive diseases: 1st, *guignes*, a species of excrescence which principally appears on the soles of the feet, palms of the hands, and tips of the fingers, which are so tender to the touch that the patients can neither walk nor lay hold of any thing without experiencing the greatest pain. 2d, certain whitish excrescences on the soles of the feet, named *crabs* from their shape, from which a purulent matter is discharged. 3d, *Saouaouas*, considerable thickenings of the skin of the soles of the feet, and of the insides of the hands; they are red, acutely sensible, and very painful in walking, without any exudation, but with simple increase and hardening of the parts. After *pian*, an affection of the bones, entitled *mal aux os* or bone evil, occurs, characterized by wandering pains in the bones, generally by the tumefaction of those that are spongy, and of the extremities of long bones, by exostoses, softening, caries, &c. These, as may be imagined, are serious symptoms, and being accompanied by the formation of numerous ulcers, often reduce patients to a horrible state. (a)

1404. Chopitré, Dazille, &c., think that mercurial preparations, frictions of mercurial ointment, the internal use of the bichloride of mercury, diluents of sarsaparilla, and guaiacum are the best remedies for *pian*. The diet should be mild and succulent; broths made from turtle, crabs, fresh vegetables, and white meats are recommended.

1405. To conclude, in studying the documents published by the English and French physicians comparatively, it will be seen that the former have carefully described the elevations, pustules, scabs, and ulcers which precede the *fungus of frambæsia*, and that the latter have exclusively confined themselves to this latter appearance, and to several consecutive lesions (*guignes*, *crabs*, *saouaouas*, *bone evil*), which the English writers hardly mention. Besides, most of the latter think that yaws only attack the same individual once during the course of his life, whilst the French physicians maintain the contrary, with regard to *pian*. Hunter and Thomson assure us that mercury is detrimental, whilst the French physicians recommend it as the most efficacious remedy. Notwithstanding this diversity of opinion, yaws and *pian* are generally regarded as the same disease. Sauvages, Lorry, and Sprengel, however, are agreed in considering them as distinct from each other.

1406. *Frambæsia* differs from syphilis in several of its characters,

(a) *Pian* or yaws is represented to be a common precursor of leprosy in Brazil.

its progress, the time it lasts, the inefficacy of mercury in its cure, and above all, the constantly fungiform aspect of the ulcers. This latter appearance has been observed in some scrofulous ulcers, but they presented other distinct characters. (Martin. *Obs. d'un ulcère scrofuleux simulant le frambæsia*.—Bulletin des sc. médicales, t. vii. p. 217.)

#### Historical Notices.

1407. Yaws have been observed in Brazil, by Piso (*De medicina Brasiliæ*, lib. ii. chap. 9, 1643, in fol.); in America, by Labat (*Nouveau voyage en Amérique*, 1722, 6 vols. in 12); in Africa, by Winterbottom (*Account of the native Africans of Sierra-Leone*, vol. ii. chap. 8); by Hume (John) (*A description of the African distemper called the Yaws*, &c., Medic. Essays and Obs. by a society in Edinburgh, vol. v. pt. ii. p. 87); and by Bancroft (*An Essay on the Natural History of Guiana*, in 8vo. London, 1769); in Jamaica, by J. Thomson (*Obs. and Experiments on the Nature of the Morbid Poison called Yaws*, &c., Edin. Med. and Surg. Journ., v. xv. p. 321; and *Remarks on Tropical Diseases*, ibid., v. xviii. p. 31); in Barbadoes, by Hillary (*Obs. on the changes of the air and the concomitant epidemical diseases in the Island of Barbadoes*. London, 1759, in 8vo.); in St. Domingo, and in Cayenne, by Bajou (*Mémoire pour servir à l'histoire de Cayenne et de la Guiane*. Paris, 1777, 1778); in St. Domingo, by Dazille (*Obs. sur les maladies des nègres*, in 8vo. 2 vols. Paris, 1742); and Chopitré (*Aperçu sur le pian et sur les maladies dont il est suivi*, in 4to. Paris, 1804). Bern. Peyrilhe may also be consulted (*Précis théorique et pratique sur le pian et la maladie d'Amboine*, in 8vo. Paris, 1783); as also Gomez (B. A.) (*Mem. de l'Académie Royale des Sciences de Lisbonne*, t. iv. p. i.); and Arthaud (*Traité des pians au Cap François*, in 4to. 1776). Sprengel is decided in separating yaws from *pian* (*Beitrag zur Geschichte der Medizin*, Stuck, 3); see also several papers inserted in the *Edin. Med. and Surg. Journal*. (a)

### FIFTH GROUP.

#### PELLAGROUS DISEASES.

This group comprises pellagra and some squamous diseases.

#### PELLAGRA.

1408. Pellagra, *dermotagra*, *colore del fegato*, *male della spienza*, *mal de misère*, *scorbuto*, *alpino*, &c., is a disease peculiar to certain parts of Italy, reappearing in an aggravated form every spring, characterized by chronic inflammation of the skin of an exanthematous and squamous description, confined to the parts exposed to the sun, preceded, and often accompanied with very serious functional derangements of the digestive organs, and of the cerebro-spinal axis.

1409. *Symptoms*. (*Slight Pellagra*). Pellagra is often preceded by lassitude, uneasiness, ennui, dislike to all kinds of occupation, and less frequently by nausea and vomiting. Some patients also experience vertigo, and pains in the head: but pellagra generally shows itself without precursory symptoms.

This disease most commonly appears first on the back of the hands and feet, on the chest, throat, nape of the neck, arms and legs of

(a) M. Sigaud (*Du Climat et des Maladies du Brésil*), in his account of *pian* (*frambæsia*), refers to B. M. Gomès (*Ensaí dermosographico*, Lisbon, 1820), J. V. Couto and J. Alvès Carneiro (*Revista medica fluminense*, 1833), and J. A. Carneiro (*Memoria sobre as bobas*), among Portuguese writers on *pian*, called, also, *boubas* of Brazil. It is described in that country as found in three species; the moist, the dry and the crystalline.

persons whose clothes do not cover these parts. The face is seldom attacked.

The eruption of pellagra presents three principal forms: in the first the back of the hands, the fingers, and feet become the seat of a sensation of heat, smarting or unpleasant pricking which exposure to the sun renders insupportable. These parts redden; this redness is sometimes pretty deep, at others paler, or livid, brownish or dusky; some time afterwards the epidermis splits, is detached and falls off in the form of squamæ, leaving the subjacent skin, which is reddish, shining, and rather swelled and rough, quite bare. In the second variety, this inflammation is sometimes still more intense; the epidermis is raised in vesicles, or more frequently in large irregular bullæ, formed of a yellowish or reddish serum, which produces slight scabs in drying; excoriations and slight cracks are also sometimes, though very rarely, seen in this case. Thirdly, the epidermis thickens, undergoes change, becomes yellowish, brownish or blackish, dry and often hard, and scaly like the bodies of certain fish, without the skin smarting or becoming red.

The morbid appearances of the skin are not at first very marked, and patients pay little attention to what is passing, considering all as the simple effect of exposure to the sun. In fact it almost always only requires the parts affected to be kept covered, for them to recover their natural appearance, and indeed the alterations all disappear spontaneously towards the end of summer, but reappear in the spring with fresh intensity, to vanish again, at least in great part, during the autumn.

The patient may thus continue for a great number of years, to present symptoms of a local affection, disappearing in the winter, and reappearing in the summer, without any functional disturbance worth noticing. General symptoms and disorder of the digestive organs sometimes also happen along with the cutaneous affection; a foul tongue, often red at the edges or point, heat in the mouth and throat, thirst, more or less pain in the epigastrium, loss of appetite, or an irregular and excessive appetite, nausea, sometimes vomiting, bad digestion, eructations, abdominal pains, either spontaneous or experienced on pressure, and diarrhœa or obstinate constipation of the bowels.

The *nervous system* frequently appears affected in a no less remarkable manner. Some patients are much dejected, take a disgust to their former occupation, and suffer from vertigo, giddiness, and pains in the head. These symptoms are in general aggravated in the same degree as the alterations of the skin make progress.

1410. But pellagra may appear in a totally irregular manner instead of following this even tenour, and progressive increase in its symptoms. Serious symptoms, mostly *secondary*, occasionally occur without the skin being visibly, or, indeed, in any way affected; sometimes, again, they take place only a very short time after the appearance of the cutaneous affection. These anomalies are more particularly observed in individuals born of parents who have died labouring under pellagra. Pellagra is occasionally seen to commence by *desquamation of the lips*, accompanied by great heat of the mouth, and ardor urinæ. Boërio has several times seen periodical *ophthalmia* appearing in the spring, followed by very severe and acute pellagra; he makes the same remark with respect to some periodical *rheumatisms*, which he has known to appear in the spring, in persons whose parents had suffered from pellagra; he has also seen several of the *neuroses*, such as hysteria and hypochondria, &c., occur at this season, in many individuals in countries where pellagra was endemic, the external characters of this disease appearing at a later period.

1411. *Severe Pellagra*.—Pellagra often shows itself under more serious forms; and then the digestive and cerebro-spinal organs are deranged to a much greater degree, and other systems, and the constitution itself, are more or less deeply implicated.

In these *severe varieties* of pellagra, the lips become pale and livid, dry and cracked; the nostrils inflamed; the gums red, swollen and bleeding (scorbuto alpino); the saliva flows abundantly from the mouth, and acquires a salt taste (salsadina); the tongue becomes red, sometimes brownish, and presents ulcers and cracks; the mouth is painful, and there is a feeling of heat complained of in it which extends to the throat. Other symptoms are also observed: aphthæ, excessive thirst, pains in the pit of the stomach, nausea, vomiting of

greenish or yellowish fluids, abdominal pains, liquid-greenish, yellowish, or grayish, and occasionally, though rarely, blackish evacuations, from the bowels, immediately after drinking or taking food, generally without pain, and still less frequently with *tormina*, tenesmus, &c.

The *nervous system* presents phenomena no less remarkable. Patients are habitually in a state of the greatest dejection; their look is sombre and melancholy; their sight is disordered; they see things double; they are subject to giddiness or vertigo, to numbness, singing, and noises in the ears, and experience the most singular hallucinations. They complain of feeling a heat in the head and spinal marrow, of tingling and darting along its course, and that of the nerves which proceed from it, of pains in the chest, in the belly and in the organs of the senses, which seem to them to be traversed from time to time by the electric spark. Besides this, they have a feeling of heat in the limbs, in the palms of the hands, and particularly in the soles of the feet, very painful at times, and less frequently replaced by a sensation of coldness.

These pains sometimes only affect one side of the body. Some patients suffer from distressing cramps; and Strambio has seen a case of tetanic spasm of the whole body. Irregular muscular contractions are more frequently observed (*Saint Vitus's dance*, *general trembling*); continual motion of the lips; involuntary movements of the head and body forwards; convulsions, and sometimes epileptic fits.

A general prostration of strength is also seen without any other serious symptom; a great degree of debility in the limbs, particularly of the legs, with a feeling of weakness at the bottom of the back, to such an extent that the patients tremble when they stand up, and are sometimes even incapable of supporting themselves seated in their beds. Finally, true *contractions* of the lower limbs, by which the feet are drawn up to the buttocks, have occasionally been observed; anæsthesia and paralysis of the bladder sometimes take place.

Pellagrous subjects often present all these symptoms, particularly the nervous pains and cramps, without being affected with delirium. This delirium is of two descriptions: *acute* and *chronic*. The first, which may prove fatal in a few days, is accompanied with a hard and full pulse. Some patients are melancholy, refuse to eat or drink, or answer any questions which are put to them; others are boisterous and cry out; some are even furious; the greatest number in moving their heads backwards and forwards, imitate the sound of bells (Strambio). This acute delirium does not occur in the first stages of the disease.

1412. The *chronic delirium*, or *pellagrous mania* appears under several forms; one of them is a sort of madness; another is a loss of memory (amnesia), and of the faculty of attention; a third and much more common one, is religious melancholy, with the desire to destroy themselves, particularly by drowning (*hydromania*), (Strambio): this chronic delirium is most frequently incurable; sometimes, however, it is cured after lasting many years. In the hospitals for the insane in certain countries in Italy, pellagrous mania forms a considerable proportion of the cases.

Strambio mentions cough as a frequent symptom among the pellagrous. He believes in the existence of a pulmonary phthisis of *pellagrous* origin.

The menstrual flux is generally suppressed in women on the appearance of the serious symptoms of pellagra. Besides this the organs of generation often become the seat of inflammation and excoriation, which extend to the surrounding parts, and are kept up by a considerable whitish or yellowish discharge from the vagina. In men pains in the bladder, and great heat of the urine occur.

Persons affected with pellagra are observed to have a very slow pulse (thirty pulsations in a minute) (Strambio), before the development of gastro-intestinal inflammation. Two descriptions of fever are also observed in pellagrous subjects; in the one there is a strong, hard and unequal pulse, with prostration of strength and great heat of skin; the tongue is dry, red, blackish, the lips dry, and the teeth black; gangrene of the sacrum, picking at the bed-clothes, and other symptoms analogous to those which are observed in the acute dothi-enteritis, also occur, &c. This species of fever is constantly fatal. In another species, which, according to Strambio, is more connected than the former with the cause of the disease, and probably with the

internal lesions which accompany it, the fever continues with irregular exacerbations. The pulse is frequent and hard, with heat of skin, followed by a sweating of a particular odour, and which does not afford any relief. This species of fever is tedious, and reduces patients to such a degree as is seldom seen in other chronic diseases: they become like real mummies, and die consumed with the most horrible of all consumptions.

In other cases *anasarca* and *ascites* have been observed; these symptoms occur rarely in the first stages of the disease, but pretty frequently towards its termination. Spontaneous ecchymosis of the skin is also sometimes seen, a phenomenon which, with the swelling of the gums, has induced many to give pellagra the name of *Alpine scurvy*.

1413. Strambio has seen acute febrile delirium disappear after profuse sweats over the whole body. The sweating which occurs in hectic fever does not, on the contrary, afford any alleviation, but rather reduces the strength of the patient. Apyretic local sweating, particularly of the palms of the hands and soles of the feet, is often followed by an abatement of these symptoms (Strambio). The matter perspired, particularly in the fever with acute delirium, is of a very fetid and peculiar smell: Strambio compares it to that of the larvæ of the silk worm, steeped in water, and half putrid; Jansen thought it similar to that of mouldy bread.

Pellagra is always aggravated by the return of spring, when the patients remain under the influence of the causes which produced the disease; profuse secretion of saliva with a salt taste, is added to the eruption on the skin, accompanied with heat of the mouth, diarrhoea, &c. Dejection is changed to *melancholy*, and acute delirium supervenes, or otherwise various nervous symptoms, pains, cramps, trembling, &c., make their appearance.

These last symptoms increase, becoming continually more and more violent; fever is lighted up, the diarrhoea becomes colliquative and involuntary, and death takes place, preceded by spasmodic stiffness or convulsions of the muscles, &c.

1414. Some anomalies have been observed in the nature, progress and succession of the symptoms of pellagra. During its first ravages in Italy, this disease was remarkable for the intensity of its nervous symptoms, cramps, spinal pains, &c., and the trifling development of the cutaneous phenomena. At a later period, alterations of the skin became very prominent features of the disease, whilst affections of the digestive organs, and mania occurred only as *secondary* symptoms. Different symptoms have also been known to predominate; in certain years ptialism was very common, while in others it was not observed, or was replaced by heat in the mouth, aphthæ, and an extremely disagreeable desquamation of the lips. Very recently, the various nervous symptoms, cramps, spinal pains, &c., on which former writers expatiate at such length, have been very little noticed, while pellagrous mania is spoken of as very common, and gastro-intestinal lesions as habitual.

These symptoms have been known to declare themselves during winter, and to be the forerunners of pellagra, which did not appear till the spring. Pellagra has also been known to occur in a mild winter (1796), and to prevail longer than usual.

1415. Pellagra may be complicated with other diseases of the skin, such as lepra, psoriasis, pityriasis, lichen, erysipelas, urticaria, prurigo, acne, eczema, purpura, syphilis, &c. The spots of *ephelis* which have been remarked on the forehead are, perhaps, an alteration of the epidermis similar to that which is seen in other parts of the body in pellagra. Other diseases, such as intermittent fever, scrofulous affections, white swellings, peritonitis, phthisis, &c., may be complicated with pellagra.

1416. *Anatomical researches.*—Gaetano Strambio sometimes found lesions in the head, at other times in the chest, and always in the abdomen of pellagrous subjects. Several of these lesions were probably accidental. I have remarked in these *post-mortem* examinations, the frequency of local or general peritonitis either recent or of older date, and of bronchitis and pulmonary tubercles. Fantonetti has given a detail of the morbid alterations found in the body of a woman who had been affected with pellagra for twelve years. This patient had often been insane, and in the last stage of her disease became paralytic; she died labouring under *dementia*, and in a state of *maras-*

*mus*. The skin of the back of the hands and feet was like *leather*; this alteration extended to the whole thickness of the skin; examined with the lens, it presented a great number of irregular cracks, very close together, crossing at acute angles, and sometimes implicating the whole thickness of the corion. At the edges of some of these cracks there were small, thin, yellow crusts. Between the cracks, furfuraceous lamellæ of a dirty white, adhering very firmly, and of an irregular form, were seen. The epidermis was six or eight times thicker than usual, brownish, cracking, friable, and dry, and could not be readily detached from the skin; the sub-epidermic layers were everywhere of a most singular appearance, and, once or twice, as thick again as in their natural state.

The cutaneous branch of the radial nerve when laid bare, seemed a little larger than usual; on being divided, serum flowed from it; its pulp was reddish and of soft consistence. The membranes of the brain were injected with black blood. The dura-mater adhered very closely to the right parietal bone; the pia-mater adhered to the cerebral convolutions, in which a slight degree of atrophy had taken place; the substance of the brain was in general rather softer than usual; there were about two ounces of serum in the ventricles; the cerebellum was slightly injected and rather softer than in its natural state; the spinal marrow was very soft and pulpy; its membranes looked thinner than common, and contained a great quantity of serum.

M. Brierre de Boismont has carefully examined the bodies of five individuals who had died of pellagrous affections. "The result," says he, "of our researches is that lesions always occur in the digestive organs; the mucous membrane of the stomach is often red, intersected with bluish or brownish vessels, soft, pultaceous, or easily removed with the nail. The redness may be confined to the great end of the stomach, or at least appear more marked in this region; it is sometimes of a uniform red colour, sometimes of a brownish red, and sometimes bordering upon gray. The mucous membrane may farther be thinner, though in other cases it also occurs thicker than natural. The stomach, again, is sometimes distended and presents no alteration, but the redness is then found in the intestines. The valves of the duodenum partake of this colour; the mucous membrane of the small intestines, and those of the great, are generally coloured red of a lighter or darker tint, and sometimes brown. Hypertrophy and softening ought to be classed among the number of the lesions of the mucous membrane. Ulcers are common; they may be irregular, round, numerous, surrounded by an inflamed tissue, or one quite white. The subjacent cellular tissue and the muscular coat have been found hypertrophied. In the five subjects that we opened, the intestines contained lumbrici. Dr. Carswell has met with a large perforation arising from the softening of the stomach, in two individuals in whom there had been evident symptoms of chronic irritation of the digestive organs; and in other parts the mucous membrane showed unequivocal traces of chronic inflammation."

The nervous system presents alterations no less evident. The membranes of the brain, particularly the tunica arachnoides and pia-mater, are injected, infiltrated, adherent, thickened, and opalescent; the consistence of the brain is sometimes increased, the gray substance is more deeply coloured, fuller of blood, the white substance is gritty [*sablée*], and dotted; there is generally no serum in the ventricles. It is not uncommon to find the bones thickened, and a considerable quantity of blood at the base of the cranium. The lesions of the spinal marrow are also very remarkable; the membranes, and particularly the arachnoid and the pia-mater, are red, the vessels gorged with blood; a frothy serum has sometimes been seen. The gray substance is almost always hard to the touch, and injected; the white, on the contrary, is soft, reduced to a pap or cream, along a greater or less extent, and infiltrated with pus; its colour is commonly a yellowish or dirty gray.

1417. *Causes.*—Pellagra is endemical in certain parts of Italy and Spain; particularly in the environs of Milan, Pavia, Padua and in Piedmont, &c. It is not contagious. It is confined almost exclusively to the country among labourers, herdsmen, &c., is more frequent among women than men, and more frequent in full-grown persons than in young people and the aged. It is supposed that nervous, hypochondriacal, hysterical or melancholy persons, particularly those who have been weakened by privations, the depressing passions,

excesses, or any previous disease, are more liable to be affected by pellagra than the generality of individuals. It has also been remarked that the children of pellagrous parents bring a peculiar disposition to this disease into the world with them, which generally passes as hereditary. Pellagra has been attributed to the use of maize (Margari), to the abuse of common salt (Guereschi), to the habitual use of sour rye bread, or the want of good water in several parts; to dirty and ill ventilated dwellings (Aglietti), to fatigue and bad food, to depressing passions and misery among the unhappy peasantry, &c. The influence of exposure to the sun upon the production of the cutaneous affection in pellagra is incontestable; ever since pellagra has been observed, it has been well known that the eruption could be excited or caused to disappear at will in pellagrous subjects, by merely exposing various parts of the body to, or covering them from, the light of the sun. M. Aug. Spessa attributes pellagra to the habit which the poorer inhabitants of some parts of Italy have of passing the evenings, and sometimes part of the day, in winter, in their dirty and unhealthy cow-houses, by way of escaping from the cold. He is persuaded that pellagra is not endemic in countries where this habit does not exist; that where it is endemic it is only seen among those who inhabit stables; finally, he adds, that pellagra has only attracted the attention of physicians since 1770, an epoch when fire-wood had already become exceedingly scarce in countries where this disease prevails. M. Spessa seems to think, besides, that exposure to the sun is the *occasional* cause of this disease.

1418. *Diagnosis*—Pellagra is distinguished from acute erythema inasmuch as the latter, which may appear on any part of the body whether covered with the clothes or not, shows itself not only in the spring but at all other seasons, and generally terminates after continuing for a week or two. As to *chronic* erythema, it is never accompanied by serious symptoms, and the lesions of the digestive organs and nervous system which are observed in pellagra. These general symptoms, when they exist, also distinguish pellagra sufficiently from lepra, to prevent any mistake; the prominent rings of lepra, besides, covered with squamæ, heal from the centre, and appear indiscriminately on parts either covered with clothing or not. This absence of general symptoms is also remarked in psoriasis, the white and pearly squamæ of which differ from the generally embrowned state of the epidermis in pellagra.

*Pityriasis rubra*, in a severe form, has more analogy with pellagra, on account of the gastro-intestinal symptoms which sometimes accompany it during its course; but it differs from pellagra in never being accompanied with secondary lesions of the nervous system, and in the eruption being general.

Of all the diseases seen in France, the epidemic which prevailed in Paris and its neighbourhood, in 1828 (acrodynia), is, without exception, the one which bears the greatest resemblance to pellagra. In fact, as in pellagra, from the commencement of the disease, redness varying in tint from bright to dark red, was commonly seen on the feet and hands, less frequently on the legs, and more rarely still on other parts of the body; vesicles and bullæ also accompanied this first form of the eruption, and at other times the skin assumed a brown or blackish hue, particularly on the belly, neck and about the joints, a hue produced by an alteration of the epidermis, which falls off at a later period. Profuse, irregular, periodical *local sweats* also occurred in acrodynia as in pellegra. Disorder of the digestive functions, characterized in some by simple loss of appetite, and a feeling of fullness and weight in the stomach, in others by nausea or vomitings, particularly after taking food or drink, by colic, and very frequently by a diarrhœa of longer or shorter duration, were almost always superadded to the other symptoms of acrodynia either in the commencement of this affection, or at some period during its course. As in pellagra, too, a sense of numbness, and of tingling, and occasionally smart shooting pains were felt in the hands and feet, extending sometimes along the legs, thighs or arms to the trunk, and even to the hairy scalp; the sense of touch was even affected in some cases (anæsthesia). Paralysis, and contractions, and shrinking of the limbs, tremblings and painful cramps were observed in the one as in the other disease. Œdema, mostly partial, but sometimes general was more frequently seen in acrodynia than in pellagra. As has been remarked in pellagrous epidemics, these various symptoms presented

a very considerable number of *anomalies* in their progress and succession in acrodynia. In some cases the redness and black discoloration of the skin were the principal phenomena of the disease; in others, lesions of the digestive passages seemed to predominate; in others, again, such disorders of the nervous system were observed that it alone seemed to be affected. As in pellagra, also, the small number of bodies which have been examined, have exhibited alterations which were owing, perhaps, as much to accidental and intervening affections as to the disease itself.

*Acrodynia*, like pellagra, broke out in the spring, prevailed particularly during the summer, and seemed to become extinct in the middle of the severe winter of 1829–1830. As for the differences between these two diseases, they are much less striking than the analogies which exist; still it must be remarked that the pain in the feet and impossibility of walking were much more marked in the epidemic of Paris; that exposure to the sun is an evident occasional cause of pellagra, and that this latter affection, which almost always reappears each year in an aggravated form, is more frequently fatal, and gives rise to a species of insanity which was not seen in the epidemic of Paris.

The *mal de la rosa*, a disease epidemic in the Asturias, ought not, it would seem, to be separated from pellagra, of which it presents the principal symptoms. Some difference in the alterations of the skin only are remarked; in the *mal de la rosa* it becomes covered with scabs sometimes followed by cicatrices, whilst in pellagra, the form of the cutaneous disease is exanthematous or squamous.

Upon the whole, pellagra, the *mal de la rosa*, and the epidemic of Paris, seem to me to form one very natural group.

There is, without doubt, much similarity between pellagra and the epidemic disease which prevailed at Brünn (Moravia), in 1578, and which has been assimilated with syphilis: after the cutaneous symptoms, however, signs of melancholy, and other nervous phenomena, which are so commonly seen in pellagra, are known to have occurred (See Jordan (T.), *Brunno-Gallicus, seu luis novæ in Moraviâ exortæ descriptio*. Frankfort, 1577, 8vo.).

Certain epidemics which have been observed in Europe, and particularly in the north, from the middle of the sixteenth century till towards the end of the eighteenth, and which have generally been attributed to the use of damaged grain, as of spurred wheat or rye, may be assimilated to a certain point with pellagra. Ptyalism, functional disorders of the digestive organs, acute pains, a feeling of heat in the palms of the hands and soles of the feet, swellings and vesicles on the skin, cramps, tremblings of the body, and mania as a secondary phenomenon, have been remarked in these epidemics as in pellagra. Independently of the special cause assigned to these diseases, they are distinguished from pellagra by a variety of characters, and particularly the development and reappearance of their symptoms under the form of *fits* or *paroxysms*. (See, for a history of these epidemics, Ozanam, *Histoire des maladies épidémiques*, in 8vo. t. v. p. 120.)

1419. *Prognosis*.—Medical practitioners have distinguished three degrees of intensity in pellagra. In the *first*, *local* lesions are seen, produced by exposure to the sun, sometimes only with slight accompanying indisposition; in this case it is sufficient to remove the patient beyond the influence of the causes which have produced pellagra to accomplish a cure. The *second degree* is much more serious, still it is sometimes cured; it embraces those cases in which the alterations of the skin, after several relapses, become of a more decided nature, and disorders of the digestive organs more apparent. Nervous symptoms, vertigo, pains, cramps, slow pulse, &c., are added to ptyalism, heat in the throat, vomiting, and diarrhœa. The *third degree*, or confirmed pellagra, is constantly fatal; it is known by a constant febrile state, involuntary stools, and other phenomena, such as melancholy, pellagrous mania, stiffness of the body, convulsions, loss of flesh, &c. Acute delirium, although of a serious nature, is a less formidable symptom than chronic delirium.

Upon the whole, the prognosis should be based, not upon the state of the skin, or the alterations it has undergone, but upon due appreciation of the disorders of the various systems of the body generally.

The condition in life of individuals affected with pellagra must also be considered in prognosticating in regard to the issue of the disease. The mischief is aggravated, and the affection generally proves fatal to

those who are a prey to poverty and wretchedness, and obliged to remain within the influences of the causes which produce it. The state of the constitution, previous diseases, and complication, must also be taken into the account. *Pregnancy* and lactation exercise a pernicious influence. Writers have particularly insisted upon the serious character which pellagra assumes in those whose parents have died of the disease.

1420. *Treatment*.—Upon the first symptoms of the pellagrous affection, the patient ought to change his habits and occupation, or at least, abstract himself from the influence of the causes which appear to have occasioned it. Change of climate, of regimen and habits, will be the most certain remedy; unfortunately, those affected with pellagra, the poor inhabitants of the country, are scarcely ever in circumstances to follow this advice.

In the *slight* forms of pellagra, physicians are agreed upon the necessity of avoiding exposure to the sun, and of placing patients in a healthy and well-aired dwelling. The food should be good and substantial, consisting of animal and vegetable substances, in quantities proportionate to the wants of the system, and to the powers of the digestive organs. Milk sweetened, or old wine much diluted with water, are appropriate drinks.

Fontanetti has advised, at the commencement of the disease, the moderate use of bleeding and purgatives, according to the state of the skin and the mucous membranes. Tepid baths, both general and local, fomentations, anointing the skin, dry friction, sudorific or slightly laxative tisans, &c., may be made use of with advantage.

1421. In the more serious forms of this disease the treatment should be modified according to the various symptoms which present themselves. In pellagrous affections of the *digestive passages*, fomentations, emollient cataplasms, sometimes even the application of leeches to the pit of the stomach, to the abdomen or anus, should be had recourse to. Preparations of opium, rice water, barley water, emollient and narcotic injections will be useful in cases of obstinate diarrhœa.

Serious affections of the *brain* and spinal marrow must be attacked by blisters, and issues in the nucha, or along the course of the spine; a seton should be inserted in the nape of the neck, or several moxas applied along the back.

Cold applications to the head, leeches behind the ears, or bleeding, should be had recourse to in cases of *acute delirium*.

In *general trembling*, cold sulphureous baths, combined with antispasmodic remedies, are worthy of a trial.

Opium seems to be of use in *cramps*, in pains and tetanic stiffenings of the limbs.

Pellagrous *mania* requires treatment similar to that which is pursued in mental affections produced by other causes; only in almost all cases, the strength should be supported by mild and nutritious diet, and the other symptoms of the disease treated with circumspection.

#### Historical Notices.

1422. Frappoli, of Milan, (*animadversiones in morbum vulgò pellagram dict.* Mediolani, 1771,) was the first who published upon pellagra. Odoardi (*Dissertazione di una specie particolare di scorbutto*, Venezia, 1776), has assimilated the disease to scurvy, and has considered its causes, symptoms, and treatment, in this point of view. Gherardini (Mich.), in his *Descrizione della pellagra*, Milano, 1780, has given a good description of pellagra: he has well appreciated the influence of exposure to the sun on the cutaneous eruption. Albera (G. M.) (*Trattato teorico-prattico delle malattie dell' insolato di primavera volgarmente detto della Pellagra*, Venezia, 1784), is remarkable for his therapeutic views. Strambio (Gaetano) (*de pellagra*, Mediolani, 1786, 1787, 1789; *Dissertazione sulla pellagra*, 1794), has given a very good description of pellagra, and particularly of the nervous forms which it presents. Fanzago has published a series of memoirs on pellagra; he has studied its causes, its diagnosis, and treatment with care, and has related several particular cases: *Memorie sopra la pellagra*, Padova, 8vo. 1798; *Paralleli tra la pellagra ed alcune malattie*, Padova, 8vo. 1792; *sulla Pellagra memorie*, Padova, 8vo. Videmar (*De quadam impetiginis specie vulgò pellagra nuncupata disquisitio*, Mediol. 1790), Jansen (*de Pellagra morbo in Mediolanensi ducatu endemico*, in Dilect. opusc., vol. i. 325), and Boerio,

Ant. (*Storia della pellagra nel Carnovese*, Torino, 1811, 8vo.), have left a good summary of the information extant respecting pellagra, and some remarks on various symptoms of this disease. Jourdan has published a remarkable article on pellagra (*Dictionnaire des Sciences Médicales*). Strambio has insisted on the inflammatory character of the functional disorder of the digestive organs in pellagra (*Natura, sede e cagioni della pellagra disunte dai libri di Gaetano Strambio, e della dottrina Broussesiiana*, Milano, 1820). Fantonetti has dissected the skin, with great care, of a man affected with pellagra (*Trattato dei mali della pelle di P. Rayer*, art. *Pellagra*). Brierre de Boismont (*de la Pellagra et de la folie pellagreuse*, 8vo. Paris, 1834), has published an interesting paper on pellagra, particularly in a therapeutical and anatomico-pathological point of view. And. Aug. Spessa (*sulla Pellagra*, *Annali universali di medicina di Omodei*, Milano, 1832, vol. lxiv. p. 207), has attributed pellagra to inhabiting stables, &c. (a)

#### ROSA; OR DISEASE OF THE ASTURIAS.

1423. Thierry has given the following description of *la rosa*:

This disease generally appears at the spring equinox. It shows itself on different parts of the body by simple redness, and harshness of the skin. It then degenerates into rough, dry, blackish crusts, intersected with deep cracks, which often penetrate to the quick. These dry and fall off in summer, leaving reddish, very smooth and shining stains or marks behind them, devoid of hair, depressed below the level of the surrounding skin, and very similar to the cicatrices of burns. It is probably from the appearance of these marks that the disease has been denominated *rosa*. They remain through life. In the spring of every year they are covered anew with fresh crusts, which become ever more and more disgusting to look upon. Occasionally a large yellowish or ash-coloured crust occupies the forehead of the neck, and extends from thence over the clavicles and upper portion of the sternum, forming a band of two fingers breadth, and descending half way down the breast, like the collar of one of the orders of knighthood; this appearance is quite characteristic.

To these symptoms there is added a constant *shaking* or *trembling* of the head and upper parts of the body, which sometimes becomes so violent that patients experience great difficulty in keeping themselves erect; there are also heat in the mouth, vesicles on the lips, foulness of tongue, extreme weakness of stomach and of the body generally, and a feeling of general heaviness. Through the night burning heat is complained of, insomnia, dejection, melancholy, groaning without any assignable reason, &c. Patients for the most part are in the entire possession of their intellectual faculties: several, however, suffer from slight delirium, hebetude, and a loss of the sense of taste, and particularly of touch. This state may be succeeded by erysipelas, ulcers and erratic fever.

This disease may end in dropsy, in scrofulous affections, and in marasmus; at other times it terminates in *mania*, which is seldom of a violent kind; the patients sink into an undefinable state of dejection, which leads them to forsake their homes and to seek solitude, and their excess of depression and of suffering often reduces them to utter despair. This insanity, which does not generally show itself save about the summer solstice, commonly proves fatal.

*Rosa* is particularly frequent in the province of Oviedo, where the sky is generally overcast, and the soil is barren (Thierry, *Obs. de Physique et de Médecine, faites en Espagne*, 8vo. Paris, 1791).

Casal, who practised for thirty years in the Asturias, informs us that the *rosa* is extremely rebellious. Thierry cured one woman after two months of treatment with the æthiops mineral, crude antimony, saffron, and some of the balsams.

All we have upon this disease is still too little to enable us to come

(a) M. Rayer has omitted, in the preceding list, the work of Sig. Vincenzo Chiarugi, M. D., entitled *Saggio di Ricerche sulla Pellagra*, Firenze, 1814: with two coloured drawings. The editor's first knowledge of pellagra was derived from this volume, which he procured many years since, when in Italy.

to any definitive opinion in regard to its character and proper treatment. The analogy it bears to pellagra is nevertheless striking.

#### Historical Notices.

1424. The chief documents we possess upon *la rosa*, are contained in the work of Thierry, the title of which is given above, and in that by Casal, entitled *Historia natural y medica de principado de Asturias*, 4to. Madrid, 1762.

#### ACRODYNIA.

1425. In the month of June, 1828, an epidemic disease, principally characterized by pain and numbness of the lower extremities, erythematous patches, and more rarely by a blackish discoloration of the cuticle, attracted the attention of the practitioners of Paris. This malady first appeared at the Hôspice de Marie Thérèse, and was soon afterwards observed in various quarters of the city. It made its way at the same time into several barracks; in one, 560 out of 700 individuals were attacked with it. A great number of patients labouring under it were received into the different hospitals, and I had many under my charge in that of St. Antoine. During the following winter the disease abated; but in the month of March, it again made its appearance in the Barrack de la Courtille. The epidemic seemed to have become completely extinct towards the midwinter of 1829-30.

1426. *Symptoms*.—Some patients complained at first of simple loss of appetite; others suffered with sickness and vomiting, colicky pains in the bowels, frequently with diarrhœa, and the eyes at the same time became inflamed and watery. From the very commencement a kind of puffing of the face was observed among many patients, which occasionally extended to other regions of the body.

The skin of the palms of the hands and soles of the feet presented, often from the invasion of the disease, a red colour which frequently extended along their edges to other parts of the body, to the legs more especially, in the shape of patches of various shades of red, sometimes very similar to ecchymoses. Pretty frequently, too, the skin assumed a blackish or brown appearance, as if it had been rubbed over with soot; this happened more particularly on the abdomen, neck, and about the bends of the joints; it very rarely happened that this discoloration extended to the face.

Numbers of small spots, pustules, phlyctenæ, coppery spots or patches, and even boils were evolved upon the hands and feet. A process of desquamation, assisted by profuse local sweats, ended by laying the corpus mucosum completely bare. This process was often renewed again and again upon the same place, and took place over all the regions affected.

Occasionally an evident thickening of the cuticle was observed, especially over the articulations of the feet; this sometimes formed an elongated and painful roll between the nail and the pulp composing the point of the finger.

Sensations of numbness, and of tingling, and occasionally painful shootings were felt in the hands and feet, more especially in the latter, and generally of greater severity through the night than during the day, and more intense at all times in the palms and soles than anywhere else. They sometimes extended up the legs, thighs and arms, to the trunk. A feeling of cold, succeeded by one of burning heat, sometimes obliged patients to put their feet and hands out of their bed; some complained of the slightest pressure made upon those parts as intolerably painful; in others the feet and hands were so much benumbed that sensation and touch were almost entirely abolished; others, again, were affected with true paralysis of these parts, accompanied with contraction and wasting of the limbs, in which, nevertheless, occasional painful twitchings and shootings were experienced.

The symptoms presented very considerable variety at different periods of the epidemic; in one the alteration of the sensibility was one of the most marked; in another the digestive organs were the parts principally implicated, and in a third, œdema and the brownish hue of the surface were the most striking peculiarities. In the Prison Montaigu, almost all who were affected presented the brown discolora-

tion of the skin, whilst this symptom was not seen in the Barracks de l'Oursine and de la Courtille; in the latter, violent convulsive twitchings in the limbs were the principal phenomenon, in that de l'Oursine, after the numbness, œdema of the face, ophthalmia and vomiting were the most remarkable symptoms.

The disease generally lasted for several months, sometimes it ceased after a few weeks. Many patients, after recovering completely to all appearance, had relapses which did not end but with the epidemic. It rarely proved fatal except among the aged. The lesions of the viscera discovered after death were evidently owing to complications.

1427. *Causes*.—A variety of causes have been presumed for this disease, such as the adulteration of the articles used for food, bread, wine, &c., some change in the water, salt, potatoes, &c.; a vitiated state of the atmosphere, &c. But the epidemic prevailed in the most healthy barracks, in the best ventilated apartments, and did not show itself in other places much less advantageously situated. It was observed, during its prevalence, that it attacked adults and the aged more particularly, that men were more liable to it than women, and the poor than the rich; it did not appear to be contagious. The disease was viewed variously as rheumatic in its nature, as an inflammation of the skin and mucous membranes, as the effect of a peculiar lesion of the nervous system, especially of the spinal marrow; lastly, as a new disease.

1428. *Diagnosis*.—Pellagra, of all known diseases, is that with which acrodynia has the greatest analogy; both are characterized by a triple manifestation of cutaneous symptoms, of gastro-intestinal symptoms, and of nervous symptoms, the similarity of which is certainly striking. (Vide *Pellagra*.) In several epidemics attributed to indifferent qualities of the cerealia, the spurred rye, &c., the greater number of the symptoms of acrodynia will also be found noted, such as tinglings and numbness of the feet and hands, amounting sometimes to paralysis, contraction of the fingers, cramps of the legs, swelling of the feet, phlyctenæ on these parts, &c. These epidemics, like that of Paris of 1828, also occurred in cold and moist summers.

1429. *Treatment*.—Uncertain of the actual nature of acrodynia, I, like the rest of the profession, tried a variety of means which I conceived calculated to abate the predominating symptoms, but without very marked success, the disease almost constantly proving very tedious and various in its phenomena. I generally prescribed Seltzer water and anodynes when the gastric symptoms were pressing. When the nervous symptoms appeared with great intensity from the first, I ordered a small bleeding, and the patient was put into the warm bath, and took a grain of opium at night. If these symptoms only occurred in the second or third stages of the disease, and when the general system had already suffered, I ordered the sulphureous water bath, and sometimes with good effect. As to the cutaneous symptoms, I never treated them save with tepid baths and fomentations and emollient applications.

#### Historical Notices.

1430. First pointed out by M. Cayol, and subsequently by M. Chomel, acrodynia has since been the subject of numerous researches: Genest, *Recherches sur l'affection épidémique qui régné maintenant à Paris*. (Arch. Génér. de Médéc., 1828, t. xviii. p. 232, t. xix. p. 63, p. 357.) *Constitution médicale ou tableau des obs. météorol. et méd. recueillies en 1829, à la clinique de M. Cayol* (Revue Méd., 1830, t. ii. p. 48). Dalmás, *Compte rendu de la clinique de M. Chomel* (Journ. Hebdomad., t. i. p. 333). Chardon fils, *De l'acrodynie ou de l'épidémie qui a régné à Paris et dans ses environs, l'année 1828*, in 8vo., Paris. Dezeimeris, *Sur l'épidémie de Paris* (Journal général des hôpitaux, nos. 2, 4, 8, 17.—Dance, art. *Acrodynie* (Diction. de médéc., 1832).

#### DISEASE OF MELADA,

(An Island in the Gulf of Venice).

1431. In a village of the Isle of Melada, known for the slight detentions which are there heard, several of the inhabitants are subject

to a disease affecting the skin of the extremities which bears a certain resemblance to that of Anna Jackson (§ 1173), and of the brothers Lambert (§ 1102).

Eleven individuals belonging to three families present a similar alteration of the skin of the palms of the hands and of the soles of the feet and toes.

It is not above half a century ago since this alteration of the integuments was first described; how long it may have existed previously is uncertain; the accounts we have of it extend over no more than fifty years, and exhibit it as possessing the same features during the whole of this time.

1432. Children at their birth present in the palms of their hands, unequivocal signs of this disease, which is developed as they advance in years. The skin of this region becomes gradually thicker and thicker and firmer, and extends so as to cover the whole superficies of the parts above mentioned. The alteration then spreads round upon both sides of the fingers and toes, and in the angles between them, and to the articulations of the metacarpus and metatarsus, so that the skin at length acquires the appearance of a long layer of yellowish tallow, but of the consistence of leather; it is rough and uneven in consequence of the fissures, with which it is traversed, which give it the look of the bark of the cork tree. The outermost layer of the skin is then transformed into a substance that is almost completely inorganic, through which neither cutaneous exhalation nor sweat ever finds its way. There is no longer the albuminous transudation by which the cuticle is renewed as it is worn away.

The cuticle of the elbows is also thickened; the corion and rete mucosum form but a single layer; the integuments of the carpus and tarsus are sallow and wrinkled; the knees, too, are often covered with squamæ and warty excrescences; the hands, in addition to this, and feet, are impotent. The parts affected are entirely without sensation; they never swell; the epidermis over them seems never to be raised by the effusion of a fluid under it; neither do they ever ulcerate.

The feet of the persons affected diffuse a very fetid odour. The perspiration seems to be retained within the deep cracks of the skin, and there to acquire great fetor. The cause of the cracks appears to be entirely mechanical.

This disease is an organic and hereditary defect or vice of conformation. It does not extend to the other parts of the body, and does not seem to influence the general health.

The children who present this defect of conformation of the skin are occasionally born of parents who are free from it, but who were themselves the offspring of individuals who had laboured under it. It is common to both sexes. Some of the children of a family are born with the disease, others altogether free from it. Propagation by way of contagion is inadmissible. The disease bears some analogy to ichthyosis; but it is followed by worse effects than this complaint, preventing the unfortunate persons who labour under it from earning their livelihood by their industry, the fingers, especially the ring and little finger being in a permanent state of forced flexion. (Letter of Dr. Stulli: *Sur une espèce de maladie cutanée. Bullet des sc. Méd. de Feruss.*, t. xxi. p. 96.)

## SIXTH GROUP.

### ENDEMIC BLANCHING AND DISCOLORATION OF THE SKIN.

1433. This group comprises the particular blanchings and discolorations of the skin endemical in certain countries.

#### CARATE.

1434. Under the name of *Carate*, a disease of the skin peculiar to the countries bordering the Cordilleras, and especially prevalent in the kingdom of New Granada, has been described. Bonpland observed it on the banks of the river Magdalena at Monpox, and onwards to

the confines of Peru. It was so common in some villages, that but few individuals were encountered altogether free from it. It is said, however, to attack negroes and mulattoes more particularly.

Carate appears under the form of spots or patches spread over the whole body, but more abundantly over the arms and forearms, cheeks and breasts among women. These patches are, in some cases, of the colour of coffee, in others of a dull white, in others of a crimson red, and in others of a livid white; the skin, by the mingling and contrast of these different tints, often presents a marbled appearance. Amongst the natives, *Carate* is said to whiten the blacks, and to blacken the whites. The disease is not contagious.

M. Daste assures us, that this affection is successfully treated by means of the corrosive sublimate. M. Zea says it is incurable when it has made a certain progress. It does not influence the general health; it is only unpleasant to look upon.

These accounts are extracted from a note, by M. Alibert, *sur la carate ou taches endémiques des Cordillères*, in the *Revue Méd.*, t. xxiii. p. 228, 1829.

#### PINTA.

1435. M'Lellan states that a disease of the skin, known under the name of *pinta*, or *blue spots*, made its appearance in the neighbourhood of the volcano of Jorulla, in the northern part of the province of Valladolid, Mexico, and soon spread southwards as far as the town of Mascala, on the road from Mexico to Aispuello. The populace, whose skins are of a dark colour, were the principal sufferers. The disease began with slight shivering and nausea, followed by trifling fever. These symptoms lasted for a few days only; when they subsided, pale and yellowish-coloured spots were observed over the face, chest, and extremities; these spots grew paler and paler, till they became nearly white; but they then began to deepen in their tint, and went on till they acquired the same depth of shade as the skin of the negro. The integuments, too, grew rough and squamous, appeared slightly inflamed, and fell readily into open ulcers. The cutaneous perspiration was fetid, but the general health was not much affected. M'Lellan informs us that in Mexico there was a regiment composed of individuals whose skin had undergone this singular change, and which was denominated the *pinta* regiment. The disease appears to be contagious. Individuals born and brought up in districts where the *pinta* is only known by name, become affected with it after a residence of a few years, in parts where it prevails, and nurses have been known to communicate it to their nurslings. Persons in easy circumstances, nevertheless, live all their lives in the district of *Pinta*, and take into their service individuals affected with the spots in question, without contracting it themselves. They appear to enjoy immunity from its attacks, by the most sedulous attention to personal cleanliness, by using the bath continually, performing ablutions, &c. Although the individuals affected with *pinta* are to be met with all around Mexico, selling a variety of wares, &c., the disease is only known by name on the coast of the Pacific Ocean and adjacent countries, divided by the mountains from the *Tierra Caliente*. The physicians of the country regard *pinta* as a specific and incurable disease (*An acct. of the pinta or blue stain, a singular cutaneous disease prevailing in Mexico*, by S. M'Lellan, *Ed. Med. and Surg. Journ.*, 1826).

*Pinta* must be looked upon as associated with the other morbid or accidental discolorations of the skin observed in Europe—cloasma, nigrities, &c.

## SEVENTH GROUP.

### ACUTE ENDEMIC ERUPTIONS.

1436. This group comprises the acute diseases which are peculiar to certain countries.

## LICHEN TROPICUS; PRICKLY HEAT.

1437. I have already noticed the chief observations made on this disease (§ 628) by Boutius in India (*De Medicina Indorum*, cap. 18), by Hillary in Barbadoes (*Obs. on the Changes of the Air and concomitant Epidemical Diseases in the island of Barbadoes*, 8vo., Lond. 1759), in Africa by Winterbottom, whose remarks are published by Willan (on *Cutaneous Diseases*, p. 57), and by Dr. James Johnson (*the Influence of Tropical Climates, &c.*), who also mentions the researches of Dr. Moseley.

## ILLINOIS ITCH.

1438. Horiatio Newhall states that four-fifths of the individuals who have lived for a year in the state of Illinois (United States), become affected with a disease known under the name of the *Illinois itch*.

The disease begins with severe itching of the arms and thighs, without any eruption, which induces the individual affected to rub and scratch himself vigorously to appease the sensation. The effect of this indulgence, however, is to bring out in a few seconds an eruption of small papulæ, of the same colour as the skin. These papulæ are not pointed, and are not inflamed around their bases. One crop often disappears whilst another is evolved; the latter become vesicular after the lapse of a day or two. The vesicles are more pointed than the papulæ, and are filled with a clear transparent fluid, which, in the course of a few days, changes into an opaque matter of a pale yellow colour. There is no inflammation around the vesicles until after a great deal of scratching, which seems to occasion the inflammation that subsequently occurs.

If the vesicles are punctured at the first with the point of a needle, they disappear without leaving any traces of their presence; but if their apices be torn off at a later period, a watery fluid, mixed with blood, exudes, and black or brownish crusts are formed, which vanish in the course of time, but leave small permanent cicatrices behind them.

Where the affection has lasted long, the vesicles are occasionally intermingled with psyracious pustules containing a straw-coloured matter. These often become confluent, and by drying give rise to broad and irregular crusts. The crusts are commonly situated on the legs in men, on the legs and breasts of women, and on the head and a variety of other parts in children, among whom the disease might very well be confounded with crusta lactea. Occurring around the fingers, the eruption has sometimes caused the loss of the nails.

In this affection, then, we have papulæ without inflammation about their bases, papulæ with inflammation round them, vesicles, pustules, minute squamæ and broad crusts, external characters which prevent its being assigned to any particular place in the chart of cutaneous diseases.

The eruption is most copious on the inner parts of the thighs, arms, wrists, between the fingers, and around the axillæ and scrotum. In young children the sole of the foot is particularly affected; the face is never implicated. The pruritus is intolerable, and is increased by heat; the hands are occasionally swelled to such a degree as to force the individual to abstain from all kind of manual labour. There is not in general any fever; the disease is not contagious, and cannot be communicated by inoculation. Mr. Newhall has seen persons affected with this disease during four and five years at a time (Newhall, *Rem. on the disease of the skin called Illinois Itch*, *New. Engl. Journal*, vol. xviii. p. 134. Ext. in *Bullet. des Sciences Méd. de Ferussac*, t. xviii. p. 65).

## EIGHTH GROUP.

## GANGRENOUS EPIDEMICS.

1439. This eighth group comprises two gangrenous affections; the *Nome* of Sweden and the *Mal des Ardens* or *ignis sacer* of the middle ages.

## NOME OF SWEDEN.

1440. In the ninth volume of the Memoirs of the Academy of Stockholm, we read the following accounts: "Among the children of the poor in Sweden, from one to ten years of age, who live on salted meats and breathe a corrupt atmosphere, there prevails a species of ulcer denominated *nome*. This disease begins with uneasiness, lassitude, pallor, fetor of the breath, heat, thirst, diarrhœa, inappetence, restlessness, sleeplessness, and rambling, and transient swellings of the body. A *black pustule* or spot then makes its appearance on the face or neck; the gums assume a dark green colour; the teeth fall out; fetid saliva distils from the mouth; the tongue, face and lips swell; the whole body becomes painful; the urine is brown; the pulse small and quick; the respiration frequent; trembling from weakness. From the second day the extremities become cold; the black spot extends; the crust falls off and exposes an ulcer covered with a grayish-black, thick and fetid pus; the pulse becomes frequent, unequal and weak, and the patient soon dies.

The disease consists in a scorbutic gangrene, which requires the most prompt measures for its relief. The best internal medicine is the decoction of bark with sulphuric acid; externally, the gangrenous spot is bathed with diluted muriatic acid. When the eschar is detached, the sore is dressed with decoction of bark, some digestive ointment, with a solution of sublimate in alcohol, volatile alkali, myrrh, diluted sulphuric acid, &c.

Change of air, exercise, and wholesome food, are necessary to complete the cure. The ulcer never bleeds; the patients sometimes suffer from epistaxis, the blood being then watery and pale.

It is worth while to compare this description with that of the *rouge* of Hippocrates (*Prædict.*, lib. ii.), and of the gangrenous affection of the cheeks of children in France.

## IGNIS SACER OF THE MIDDLE AGES.

1441. In the eleventh, twelfth, and thirteenth centuries a disease variously entitled *ignis sacer*, *mal des ardens*, and *St. Anthony's fire*, committed great ravages in France. Rudolphe (*Hist.*, lib. 2, cap. 7, *de incendiis*), tells us, that when this fire attacked a limb, it was straightway detached from the body, after being burned. Sigebert, speaking of the *St. Anthony's fire* which prevailed in *Basse Lorraine*, assures us that the extremities, as black as charcoal, were detached from the body, and that the sufferers, having lost their feet and hands, died miserably, or dragged out a still more miserable existence.

The Martyrologia has further, under the date of 1140, in the reign of Louis VII: "A disease showed itself in Paris which the physicians called *ignis sacer*, and which attacked persons on their genitals." (Consult Mezerai, *Abregé Chronol. de l'Hist. de la France*, and particularly the learned memoir of Jussieu, Paulet, Saillant, and Tessier: *Rech. sur le feu Saint Antoine*, lues le 31 Dec. 1776. *Mém. de l'Acad. Royale de Médecine*, t. i. p. 260.)

This epidemic *ignis sacer* must not be confounded with the *ignis sacer* described by Celsus, which cannot certainly be assimilated to any disease known at the present day: "Sacer quoque *ignis malis* ulceribus annumerari debet. Ejus duæ species sunt: *alterum genus* est subrubicundum aut mixtum rubore atque pallore, exasperatumque per pustulas continuas, quarum nulla altera major est, sed plurimæ perëxiguæ. In his semper ferè pus, et sæpè rubor cum calore est, serpentine id nonnunquàm, sanescente eo quod primum vitium est, nonnunquàm etiam exulcerato, ubi ruptis pustulis ulcus continuatur, humorque exit qui esse inter saniem et pus videri potest. Fit maximè in pectore, aut lateribus, aut eminentibus partibus, præcipueque in plantis. *Alterum* autem est in summæ cutis exulceratione, sed sine altitudine, latum, sublividum inæqualiter tamen, mediumque sanescit, extremis procedentibus, ac sæpè id quod jam sanum videbatur, interùm exulceratur. At circà proxima cutis quæ vitium receptura est, tumidior et durior est, coloremque habet ex rubro subnigrum. Atque hoc quoque malo ferè corpora seniora tentantur, aut quæ mali habitûs sunt, sed in cruribus maximè. Omnis autem sacer *ignis*, aut minimum periculum habet ex his quæ serpunt, sic propè difficillimè tollitur. Medicamentum ejus fortuitum est febris quæ uno die humorem noxium

absumat. Pus quò crassius et albidius est, eò periculi minùs est. Prodest etiam infrà os ulcerum cædi, quò plus puris exeat, et id, quo ibi corruptum corpus est, extrahat. Sed tamen si febricula accessit, abstinentiâ, lectulo, alvi ductione opus est. In omni verò sacro igni, neque lenibus et glutinosis cibis, neque salsis et acribus utendum est, sed his quæ inter utrumque sunt, qualis est panis sine fermento, piscis, hædus, aves, exceptoque apro, omnis ferè venatio. Si non est febricula, et gestatio utilis est, et ambulatio, et vinum, et balneum. Atque in hoc quoque genere potio magis liberalis esse quàm cibus debet. Ipsa autem ulcera si mediocriter serpunt, aquâ calidâ; si vehementius, vino calido fovenda sunt; deindè acu pustulæ, quæcumque sunt, aperientiæ: tùm imponenda ea quæ putrem carnem excedant. Ubi inflammatio sublata, ulcusque purgatum est, imponi lene medicamentum debet. In altero autem genere possunt proficere mala cotonea in vino cocta atque contrita; potest emplastrum vel Hieræ, vel tetrapharmacum, cui quinta pars thuris adjecta sit: potest nigra edera ex vino austero cocta: ac, si celeriter malum serpit, non aliud magis proficit. Purgato ulcere quod in summâ cute esse proposui, satis ad sanitatem eadem lenia medicamenta proficiunt.” (Celsus. *De Medicina*, lib. v. sect. xxviii. 4.)

## NINTH GROUP.

### CONTAGIOUS PSEUDO-MEMBRANOUS DISEASES.

1442. The skin excoriated by the action of blisters or accidental ulcers is liable to be attacked with two contagious diseases of a pseudo-membranous appearance, *diphtheritis* and *hospital gangrene*. For a particular account of the latter, I beg to refer to the works of Delpech. (*Mem. sur la pourriture d'hôpital*, 8vo. Paris, 1815.)

#### CUTANEOUS DIPHtherITIS.

1443. From the researches of Messrs. Bretonneau and Trousseau, *diphtheritis*, *angina maligna* or *angina membranacea*, is occasionally accompanied with a pseudo-membranous inflammation of the skin of the same nature, and which, during the prevalence of epidemic *diphtheritis* may even display itself upon the skin, without there being any accompanying affection of the mouth or throat, in those who are exposed to the contagion. Not having myself had an opportunity of observing any epidemic *angina membranacea*, I shall here give an abstract of the remarks of M. Trousseau, and for further details, beg to refer to his memoir (*Archives Gén. de Méd.*, t. xxiii. *De la diphtherite cutanée*).

*Angina maligna* prevailed epidemically in September, 1828, at Nouan-le-Fusilier, Cher et Loir. A blister having been applied to the nape of the neck of a young girl labouring under the above-mentioned pharyngeal *diphtheritis*, suppurated abundantly, and the excoriated surface became covered with false membranes, as did an ulcer also which this girl had long laboured under on her foot. The blister, which was but four inches in diameter at first, four days afterwards was more than six; it was excessively painful, and discharged profusely. It spread down the back, throwing out irregular pointed rays like the scores of a backgammon-board, and was surrounded with a broad erysipelatous areola, much deeper in colour below than above. The part denuded of epidermis appeared depressed, and really was so, when the level of the tumefied surrounding parts was made the standard of reckoning. This part was covered with fibrinous superposed layers, of a more yellowish white towards the centre than about the circumference of the part. In the middle they were two, three, and even four lines in thickness, and bore a perfect resemblance to the dry pleuritic concretions found in the cavity of the chest when inflammation is on the decline, and the serous fluid, which had also been effused, had almost entirely disappeared. On raising several of these layers with the blade of a knife, they were found to adhere so firmly to the tissue of the skin, that they could only be detached with a cer-

tain difficulty. The blister had always been dressed with butter. The surrounding erysipelas had a peculiar appearance; the redness was so much the deeper the nearer it was considered to the excoriated surfaces. The cuticle was raised in multitudes of points by the effusion under it of small quantities of milky serum, so that the skin was covered with confluent vesicles in the vicinity of the sore, and with others, but fewer and fewer in number, as the healthy integument was neared. Some of the vesicles appeared to be formed by the fusion of several others; several, simple or agglomerated, had opened, and there the skin was seen covered with a whitish pseudo-membranous deposit; these ulcers ran into others of smaller size, and this was the way in which the disease appeared to spread.

M. Trousseau gives several other cases which go to prove that blistered surfaces and excoriations, in individuals labouring under *diphtheritis* of the throat and mouth, had a great tendency during the epidemic prevalence of this disease, to assume a peculiar appearance, and to undergo alterations analogous to those exhibited by the mucous membranes. Other facts have shown, that persons unaffected themselves with *diphtheritis*, but in contact with those who were, and having an excoriated part about them, were very apt to have this covered with a false membrane. M. Trousseau mentions five cases of *diphtheritic* affection behind the ears, or of the scalp. In one, the affection extended to the nape of the neck; in another, to this part and down the back; and in a third, to the back and loins. He also mentions instances of pseudo-membranous deposits upon an excoriation of the nape of the neck, of the side of the neck and face, of the lips, of the chin, two of the breasts, one of the abdomen, one of the prepuce, one of the scrotum, two of the anus, three of the vulva, one of the thigh, one of the foot, and two or three others on different parts of the body.

The treatment of *diphtheritis* of the skin ought to be directed upon the same principles as that of the affection of the mucous membranes.

## TENTH GROUP.

### TRICHOMATOUS AFFECTIONS.

1444. In Poland, the inhabitants, and several species of animals, are subject to an epidemic disease which attacks the hair especially, and the nails; this disease is denominated *Plica*; its influence, however, does not always end there, but sometimes extends to other organs, and then gives rise to a variety of affections which are entitled *trichomatous*.

#### PLICA.

1445. *Plica* is a chronic disease, peculiar to Poland, and characterized by the agglutination and anomalous development of the hair, and sometimes by an alteration of the nails, which become spongy and blackish.

1446. *Symptoms*.—*Plica* often begins after an attack of acute fever, preceded by languor, pains like those of rheumatism in the head and extremities, occasionally vertigo, and a singular and invincible disposition to sleep, tingling and rushing noises in the ears, pains in the orbits, ophthalmia, and coryza; *plica* also occurs occasionally after an attack of acute fever, with *clammy* sweats (*sueurs gluantes*); sometimes, too, a kind of redness is observed over the thighs, and an alteration of the nails, which become black and rough. In other cases, however, *plica* makes its attack suddenly without precursory symptoms.

When the head is the part affected, the scalp is sore to the touch and excessively itchy; a clammy or agglutinating sweat of a disagreeable odour then occurs over part of the cranium; the hair becomes unctuous, is stuck together, and appears altered; the hairs affected appear distended with an adhesive or unctuous matter of a reddish or brownish colour, which has been believed to be sanguinolent in its nature by a great many observers. This matter is produced at the

extremity of the bulb, and ascends to the very end of the hair. The hair is so acutely sensible that the slightest touch occasions severe pain in the roots. A viscid matter of a very offensive smell, like spoiled vinegar, mice, or garlic, exudes from the whole surface of each affected hair. This matter glues the hairs together at first at their exit from their skin, and then along their entire length; this matter, which also appears to be secreted from the whole surface of the scalp, congeals, and then dries into a kind of incrustation. If there be no exudation, as happens sometimes, though rarely, the disease is entitled *plica sicca*, or dry plica.

The hair is matted and stuck together in a variety of ways, sometimes in single locks of various thickness and length, so as to resemble ropes (*plica multiformis*, *common male plica*); sometimes these masses unite together and compose one very long and thick club, like the tail of a horse (*plica caudiformis*); and, again, the hair gets matted and glued together, without separating into locks, into one uniform intricate mass of various magnitudes (*common female plica*). The hair of the beard, axillæ and pubes, is also liable to be attacked with this disease.

Professor Kaltschmidt, of Jena, possesses the pubes of a woman, the hair of which is of such length that it must readily have gone round the body. The nails of the hands and feet generally become long, yellowish, livid, black, and sometimes hooked.

Immense numbers of pediculi are occasionally developed, even among those who are most careful of their persons, in the course of this affection.

1447. *Anatomical observations.*—We are informed by Joseph Frank, that the hair bulbs are enlarged, and that the surface of the scalp here and there presents running ulcers in this disease. In the museum of Meckel, at Halle, there are the scalps of two individuals who died whilst labouring under plica, which have been injected with the greatest minuteness, without the smallest particle of the injection having found its way into the stems of the hair. Lafontaine, having examined the pilliferous bulbs of a patient affected with plica, after his death, found them excessively tumefied, and full of a glutinous matter of a yellowish-white colour, which they poured out when compressed. Gilbert has also seen the bulbs of the affected hairs distended with a black and fetid matter. Rolink and Vicat assure us that the hairs are often distended with a fluid which ultimately bursts them, and is discharged externally. Schlegel says, that in one case he found the whole hairs of the body enlarged, and some of them distended with a fluid of a yellowish-brown colour, to six times their natural size. Gasc saw a woman, whose body, about the seventh month of her pregnancy, assumed a blackish hue, and whose hair appeared enlarged and distended with a fluid of a darker colour than that which penetrates it generally. M. Blandin is of opinion that in plica, the papillæ or bulbs of the hair rise above the level of the skin, within the infundibuliform cavity of the root of the hair, in the same manner as the papilla or bulb of the feather elongates and produces the quill in the young bird. M. Sedillot, who removed five or six locks of hair affected with plica from the head of a child between seven and eight years of age, in Galicia, examined these particularly with the microscope. The internal canal of each individual hair was found much larger than it is in healthy hair, and the cellular cavities, especially those near the canal, were much more distinct than usual.

1448. *Causes.*—Hercules de Saxonia and Thomas Minadous speak, in 1610, of plica as a disease already long known. The greater number of writers fix the date of its first appearance in Poland about the year 1285, under the reign of Nezek-le-Noir. This disease would seem to be getting rarer and rarer every year. Lafontaine states, that in the provinces of Cracow and Sandomir, plica attacks the peasantry, beggars, and Jews, in the proportion of one and a half in twenty, the nobility and the wealthy burghers in that of two in thirty or forty. At Warsaw and in the surrounding districts, the disease attacks the first classes in the proportion of four in from forty to forty-five, and the second classes in that of three in from ninety to a hundred. In Lithuania the same proportions are observed as at Warsaw; in Volhynia and the Ukraine, the same as at Cracow. Schlegel, Gasc, and Hartmann, say that these ratios are too large, that the disease is not so frequent.

Plica has always been more frequent on the banks of the Vistula and Borysthenes, in damp and marshy situations, than in any other parts of Poland.

Plica attacks the human subject primarily. Some writers have imagined that it could be communicated from animals to man.

The custom which prevails in Poland, of shaving the heads of the children, (a) neglect of cleanliness, the heat of the head-dress, and the exposure of the skin to cold subsequently, appear to favour the production of this disease.

1449. *Diagnosis.*—The precursory symptoms of plica, the alterations of the nails which very commonly accompany it, the swelling of the hair, the glutinous fluid discharged from its roots, &c., are so many unequivocal characters which distinguish plica from simple felting of the hair, or any other affection of the hairy scalp.

1450. *Prognosis and treatment.*—The occurrence of plica in individuals labouring under paralysis, and a variety of serious diseases, has occasionally seemed to be beneficial. When plica is left to itself, the febrile or precursory symptoms disappear after a certain time; as an effect of the growth of the hair, the diseased portion extends to a distance from the skin; in the course of several months or a year, the discharge diminishes, and ends in disappearing entirely; it is now only that the generality of the Poles themselves, or of their physicians, recommend the hair to be cut; Lafontaine, Schlegel, and Hartmann, all assure us, that the section of the affected masses before this time, has been known to be followed by amaurosis, convulsions, apoplexy, epilepsy, and even death. Alarmed or taught by such occurrences, the common people often go about with the plica till it drops off, and sometimes all their lives.

Various measures have been tried to lessen the severity of this disease, or to obtain its cure; the results of such experiments as have been made with bitters and tonics, with antimonials, lotions of different kinds, baths and fumigations, appear to be little conclusive as to their worth or inefficacy.

#### Historical Notices.

1451. Among the works published on plica, those of Lafontaine (*Traité de la plique Polonoise*, &c., trad. par A. J. L. Jourdan, 8vo. Paris, 1808), and of Schlegel, (*Ueber die Ursachen des Weichselzopfes*, 8vo. Jena, 1806,) are particularly worthy of notice. Dr. Burckhard Elbe (*Die Lehre von den Huaren*, 2 vols. 8vo. Wien, 1831), has given a bibliographical note, which completes that of Lafontaine. Messrs. Sedillot (*Nouv. considerations sur la Pligue*, 8vo. Paris, 1832), and Brière de Boismont (*Archiv. Gén. de Médecine*, t. xxxiii. p. 66), (b) have more recently published on the actual state of the disease.

### ELEVENTH GROUP.

#### DISEASES WHICH HAVE DISAPPEARED.

1452. In this group I have united several diseases which do not now occur, at least which never show themselves with the characters they presented in former times, when they prevailed often extensively.

#### SUDOR ANGLICUS. [SWEATY SICKNESS.]

1453. The description of this disease, by Dr. John Kaye, or Caius, is looked upon as the best we possess:

(a) Is not the author mistaken here? It was a religious custom in Poland, prevalent before the introduction of Christianity, to refrain from cutting the hair of children till they had reached their second year, when it was cut off with ceremony, and they received their names.

(b) The paper of Brière de Boismont is extracted from an unpublished memoir of Dr. Marcinkowske. A number of its chief details is given in the *Edinb. Med. and Surg. Journ.*, 1834.

"Ad decimum septimum calendas maias anni quinquagesimi primi suprâ millesimum et quingentesimum à Christo nato, cum jam in alt pace omnia et tranquilla essent, nec ullis perturbata molestiis, subita et insueta nostris hominibus aegritudo, *Salopiæ* (clari munitique ad Sabrinam flumen oppidi), irrepsit, cujus et nomen et natura primo suo ortu multos fefellerunt. Sed hi postea malo docti, et veteris injuriæ memores, sudorem, quem britannicum dicunt, esse tandem intellexerunt. Is tamen inclementer populum habebat, ut propè dicam omnes per ea loca et vicina illis prosterneret. Quosdam enim in viâ, cum iter facerent, sustulit; quosdam domi ostia et fenestras reserando interemit; quosdam per lusum atque jocos parùm joculariter jugulavit; per jejunia quosdam, quosdam per saturitatem abripuit; in somno aliquos, nonnullos vigiles interfecit: usque adeò, ut ex multis ejusdem familiæ, pauci à febre incolumes perstiterint: ex paucis, nulli plerumque intacti evaserint. Ex his alios brevi momento, alios unius, daurum aut trium, alios quatuor, aut eo amplius horarum spatio, postquam sudare cœperant, de vitâ sustulit. Sæpiissime qui in prandio hilares erant, sub cenam mortui fuerunt. Sed nemo qui devicto malo superfuera, ante horas viginti quatuor quam citissimè mali molestiâ et periculo liberatum se gloriari potuit. Itaque ex talibus initiis in dies ingravescentibus, ubi acerbiora incrementa, longius latiusque se fundente malo, subsecuta sunt vix credas quis pavor, quantus metus omnes Britannos invasit; præsertim cùm ejus conditionis miserandæ, quæ tum urgebat, contemplatio funestaque mortis imago nullis spem vitæ (cujus usura omnibus solet esse carissima) non ademerit. Neque enim morbo ulla clementia fuit, nec ullum miseris mortalibus securum refugium. Etenim nusquam non populabatur, nusquam non sæviebat malum. Alios qui se vivos ab hominibus relegarunt, eosdem mortuos in publicum revocavit. Alios conclusos ac penè abditos, contagione enectos in apertum reduxit. Neque sensere id malum fœminæ aut servitiæ, plebesque humilis aut mediæ solum, sed proceres etiam cùm notum sit æquo pede nobiliumque turres humiliumque casas id pulsasse iniquis tamen modis, ut dicemus postea. In eo hic conquerebatur se siti premi, ille ardoribus consumi, omnes sudore confici. Hunc rursùm amentia cœpit, hunc gravis sopor oppressit, hunc inquietudo exagitavit. Hic moribundus ingemuit, ille animam expiravit. Et qui valebat dudum jam febrescebat, versâque vice, qui ante morbo laborabat, nunc aiterius sanitatum procurabat. In summa, ita nulli ferè hominum perpeccit, ita in orbem crudele malum rediit, ut qui alios operâ officioque juvissent priùs, eos vicissim ab illis subsidium officiumque mutuum petere; et contrâ, qui ab aliis essent adjuti, eos sine quiete, magnâ fætigatione operam mutuum præbere, inque vices gravi periculo colla sub jugum mittere cogeret. Jam verò de fugâ (quæ aliàs in pestiferis morbis solet esse præsidio), cogitare au in alium locum commigrare, inane et supervacuum planè fuit. Nusquam enim tutus portus nostris, nulla ex mutato loco securitas erat, quod nulla malo oberranti omnia requies esset."

The author then describes the frightful disorder occasioned by this dreadful epidemic. He says, "he knows not how many deaths it caused," but he adds (p. 15): "In unâ civitate pauculis diebus plus minus sexaginta suprâ noningentos crudeli morbo intercidiisse."

Farther on he expresses himself in the following terms in regard to the origin of the sudor anglicus: "Hic enim morbus, sic ut adventitius non est, ita novus non est. Si quidem ex historiis britannicis intelligo, malum hoc ex Britannia ortum esse (quantum scire licet), in exercitû Henrici regis Angliæ ejus nominis septimi, quem partim ex Galliâ tunc nuper secum adduxerat, partim a Walliâ propter *Milfordiam*, quo classe appulit conscripserat: exercuisseque nostros per anteacta tempora, afflxisseque eo quo dixi modo per intervalla quinquies: anno scilicet 1485, primo ab Augusto mense inito, ad octobrem ultimum; iterùm 1506, æstivo tempore; tertio 1517, a julio mense, ad decembrem medium; quarto 1528, per omnem æstatem; quinto denique, anno hoc quinquagesimo et altero suprâ sesquimillesimum, ad menses quinque et eo amplius."

1454. The picture he presents of the symptoms of the disease contains several remarkable passages (p. 23): "Primo insultu, aliis cervicibus aut scapulis, aliis crus aut brachium occupavit. Aliis sensus erat veluti spiritus, aut flatus calidi per membra ea discurrentis. Una cum his subitus et sine manifestâ causâ huic morbo insuetis, largus sudor manavit. Interiora calebant primo, postea ardebant, calore jam indè ad extimas corporis partes diffusio. Sitis ingens, jactatio inqui-

cta. Cor, jecur, atque stomachum malè morbus habuit. Omnia subsecutus est gravis dolor capitis, vanum loquaxque delirium, post marcor, et inexpugnabilis penè dormiendi necessitas.

"Rursùm, aliis principio cohibitus sudor est, frigeabant membra leviter. At postea erupit idem promotus, sed odore gravis, calore in alio alius pro humoris ratione, quantitate subindè diminutus, subindè copiosus, substantia crassus. Aliis nausea, aliis vomitus erat, sed perpauca, et penè solis ex cibo saturis. Omnes spiritum gravem ac frequentem, vocem gemebundam expeditere. Urina colore tincta leviter, substantia crassior, levamento ambigua (nulla enim erat naturæ regula propter veneni impetum), cætera pro naturali. Pulsus, si quis prætentet, concitior, frequentior; hæc certa morbi indicia erant." (*Joannis Cuii Britanni De Ephemerâ Britannicâ. Liber unus summâ curâ recognitus.* Londini, 1721, 8vo., p. 9.) Vide an analysis of the investigations of Hecker on the *sudor anglicus*, by Ch. Martins. (*Revue Médicale*, août, 1834.) (a)

## EPINYCTIS.

1455. Hippocrates mentions numerous eruptions of *epinyctis* (*ἐπινυκτίδος πολλῆς*; De aere, locis et aquis), and many ulcers consequent upon these *epinyctides* (*Prorrhæti*, lib. ii. sect. 2. p. 95).

Celsus expresses himself as follows: "Pessima pustula est quæ *ἐπινυκτίς* vocatur: ea colore vel sublivida, vel subnigra, vel alba esse consuevit. Circa hanc autem vehemens inflammatio est; et cùm adaperita est, reperitur intus exulceratio mucosa, colore humori suo similis. Dolor ex eâ supra magnitudinem ejus est; neque enim ea fabâ major est. Atque hæc quoque oritur in eminentibus partibus, et ferè noctû undè nomen quoque à Græcis ei impositum est. In omni verò pustularum curatione primum est multum ambulare, atque exerceri; si quid ista prohibet, gestari. Secundum est cibum minuere, abstinere ab omnibus acribus, et extenuantibus; eadem quoque nutrices facere oportet si lectens puer ita affectus est. Præter hæc is qui jam robustus est, si pustulæ minutæ sunt, desudare in balneo debet, simulque super eas nitrum inspergere, oleoque vinum miscere, et sic ungi; tùm descendere in solium. Si nihil sic proficitur, aut si majus pustularum genus occupavit, imponenda lenticula est, detractâque summâ pelliculâ, ad medicamenta lenia transeundum. Epinyctis post lenticulum rectè herbâ quoque sanguinali vel viridi coriandro curatur. Ulcera ex pustulis facta tollit spuma argenti cum semine fœni Græci mixta, sic ut his in vicem rosa atque intubi succus adjiciatur, donec mellis crassitudo ei fiat. Propriè ad eas pustulas quæ infantes malè habent, lapidis quem pyriten Græci vocant, cum quinquaginta amaris nucibus miscetur; adjiciunturque olei cyathi tres: sed priùs ungi ex cerussâ pustulæ debent, tum hoc illini." (*Celsus, De re medicâ*, lib. v. sect. xxviii. 15.)

Lorry says he has never seen the epinyctis, such as it is described by the ancients: "Mihi vero epinyctidem qualem veteres medici describunt, sero periodicè dolores concitantem atroces, de die quiescentem, videre nunquam contigit." (Lorry, *De morbis cutaneis*, p. 263.) Neither have I myself met with a similar combination or succession of symptoms. Alibert, in his description of epinyctis, has included the itchy bites of various insects, and the nocturnal eruptions which appear to be analogous to urticaria or to lichen urticatus.

(a) The work of Hecker, referred to by M. Rayer, has been translated by Dr. Babington, together with the essays by the same author on the Black Death and the Dancing Mania, under the title of the Epidemics of the Middle Ages. The three have recently been printed in one volume by the *Sydenham Society*. London, 1844.

The strictly cutaneous symptoms, of an eruptive character, were few, and were not mentioned generally by the writers on the disease. Hecker quotes *Tyengius in Forest.*, p. 158, "a respectable Dutch physician," for the observation, that "after the perspiration was over there appeared on the limbs small vesicles, which were not confluent, but rendered the skin uneven." "Every thing," Hecker believes, "militates against the supposition that this phenomenon was consistent, or that the Sweating Sickness was an eruptive disorder."

## MENTAGRA OF THE LATINS.

1456. Pliny has described a kind of contagious mentagra which is not seen in Italy at the present day: "Sensit et facies hominum novos, omniq[ue] ævo priore incognitos, non Italiæ modò verum etiam universæ propè Europæ, inorbo: tunc quoque nec tota Italia, nec per Illyricum Galliasve aut Hispanias magnopere vagatos, aut alibi quàm Romæ circàque, sine dolore quidem illos, ac sine pernicie vitæ: sed tantà fœditate ut quæcumque mors præferenda esset. Gravissimum ex his lichenas appellavere. Græco nomine, latinè, quoniam à mento ferè oriebatur joculari primùm lascivia (ut est procax natura multorum in alienis miseris), mox et usurpato vocabulo *mentagram*, occupantem in multis totos utique vultus, oculis tantùm immunibus, descendentem verò et in colla pectusque ac manus, fœdo cutis fuffure. Non fuerat hæc lues apud majores patresque nostros. Et primùm Tiberii Claudii Cæsaris principatu medio irrepsit in Italiam, quodam Perusino equite romano quæstorio scriba, cùm in Asia apparuisset, inde contagionem ejus importante. Nec sensere id malum fœminæ, aut servitiæ, plebisque humilis, aut media, sed proceres veloci transitu osculi maximè, fœdiore multorum, qui perpeti medicinam toleraverant, cicatrice, quàm morbo. Causticis namque curabatur, ni usque in ossa corpus exustum esset, rebellante tædio. Adveneruntque ex Ægypto genitrice talium vitiorum medici, hanc solam operam afferentes, magna sua præda. Siquidem certum est, Manilium Cornutum ex prætoris legatum Aquitanicæ provinciæ H-S CC. elocasse in eo morbo curandum sese." (C. Plini secundi *Historiæ mundi*, lib. xxxvii. Lond., 1587, p. 641, fol.)

## WAREN OF WESTPHALIA.

1457. A disease formerly prevailed hereditarily in Westphalia, among several families, which was denominated *Waren*. The disease, says Henricus a Bra, began with wandering and very acute pains over the whole body, and particularly in the back and loins, attacking one part first, and being then transferred with rapidity to others; leaving the feet, for instance, to fasten themselves in the shoulders, in the arms or in the hands. The pain is compared to what might be supposed to be produced by worms piercing and gnawing the flesh, and it is from this circumstance, indeed, that the disease received its title *waren*, (worms.) Two varieties of it were remarked: in the first, swellings succeeded the pains in the articulations, where they continued for a long time, and became covered with *livid spots*, like those of scorbutus; these spots were apt to degenerate into malignant *ulcers*, especially on the feet, and little worms were engendered in them similar to ascarides. These ulcers very frequently became fistulous. In the second variety, no swelling occurred, but general emaciation or marasmus followed the attack, and atrophy of some part which became paralyzed.

The pains were generally more severe during the night than during the day; they were without fever, or accompanied with very slight slow fever. The bowels were constipated; small worms were frequently seen in the evacuations.

Patients were treated with purgatives, alexipharmics, and anodynes in wine. The tumours were covered with cataplasms of plantago and salt; the ulcers were dressed with cicuta aquatica, bruised, mixed with honey or with a poultice of polypodium, &c., boiled in beer. (Vide Hen. a Bra *de morbo quodam novo et incognito*, Westphalis, Geldris et Frisis quasi endemico, Epist. ad Pet. Forestum, exhibita circa finem, lib. 20, Observationum ejusdem Foresti.) Schenckius quotes another important work upon this disease in his *Obs. Méd.*, lib. vi.: *De novis aliquot morbis*.

## TWELFTH GROUP.

## CUTANEOUS DISEASES OF ANIMALS SUSCEPTIBLE OF TRANSMISSION TO MAN.

1458. Cow-pox, grease, glanders, scabies, and carbuncle, are the

only external diseases of animals which appear capable of being transmitted to the human subject.

## COW-POX.

1459. Cow-pox is an eruptive disease, which appears on the teats of cows, and is capable of being communicated to man, in whom it engenders vaccinia. Cow-pox in the animal presents four periods.

1st period. (*Infection.*) Loss of appetite, repugnance to food; the animals purse up their lips as a man does who blows tobacco smoke slowly out of his mouth; the secretion of milk is diminished; it is more watery than usual; the eye is dull; the creature becomes feverish.

2d period. Three or four days after (*period of the eruption*), hard red elevations as large as a pea appear upon the udder, particularly around the teats; sometimes, but very rarely, others are observed upon the nostrils and eyelids. By and by a yellowish point is perceived on the summit of these elevations, about the size of a pin's head. In three or four days the elevations or spots have assumed the form of flat circular pustules, depressed in their centre and surrounded at their base by a red circle, the extent of which increases gradually. On the fourth and fifth days of the eruption, the animal becomes restless; the pustules grow turbid, and approach maturity, which occurs on the seventh and eighth days of the disease, the third or fourth of the eruption. If the pustules be pressed, the animal shows symptoms of great suffering. The pustules become still larger, always preserving a depression in their centre; they are diaphanous, and acquire a leaden or silver gray colour.

In the fourth period (*desiccation*), the inflamed areola takes a livid colour; the udder becomes deeply indurated under the pustules; at the same time the restlessness of the creature increases; the fluid contained in the pustules grows turbid, gets thicker insensibly, and begins to dry off towards the eleventh or twelfth day. The pustules become brown from the centre gradually towards the circumference; they ultimately appear as dry crusts of a dusky red colour, thick and uniform, which are detached towards the twentieth day, leaving circular cicatrices behind them. (a)

1460. First particularly observed by Jenner, at Berkeley, in the great dairy county of Gloucester, cow-pox has since been seen in several other counties of England, as also in Holstein, Mecklenberg, Saxony, Norway, Prussia, Holland, Spain, Italy and France. (b)

(a) Mr. Ceely (*Observations on the variolæ vaccinæ*), has examined the anatomical structure of the vesicle, and found that "its colour, indurated margin, and central depression, depend on the existence of an adventitious membrane, formed in the corium and secreted by the papillæ. It is raised in the form of a zone, and is intimately connected with the epidermis. It has a cellular structure, in which is secreted and contained a clear viscid lymph. The cells appear to be arranged in two concentric rows, and are separated from each other by whitish radiating partitions, which, at their converging extremities, are united by a central membranous band. The dusky central spot which marked the first change of the pimple into the vesicle, and which has now become darker and more distinct, seems to be caused by a greater or less degree of separation and desiccation of the epidermis, stretched over a crypt-like recess, which contains a small quantity of semi-concrete lymph-like matter, occasionally a turbid opaque fluid. This cellular, adventitious, membranous conformation, though differing in texture and amount in different vesicles, is invariably present, and is not less essential than diagnostic. About the fourth or fifth day of the eruption, or two days before the decline of the vesicle, there often appears at its base a red circle, which gradually increases in extent till that event occurs. During this period, the lymph within the cells having become more abundant and less viscid, and somewhat opaque, bursts and breaks up the cells and their connecting band, separates the epidermis from its attachment to the subjacent adventitious membrane, and the vesicle, losing its central depression, becomes more or less acuminate, presenting a conoidal or semiglobular form."—p. 317.

(b) Since M. Rayer wrote, the natural disease has been observed by M. Bousquet at Passy in 1836, M. Girard at Rambouillet in 1836,

Cows only contract the disease once. Neergaard, Luders, &c., have noticed vaccine epizooties. The disease is transmissible to man, when he has not had small-pox, from which it generally preserves him.

Brown at Sylhet, in Bengal, in 1837, Mr. Eslin in Gloucestershire in 1836, and by Mr. Ceely in Oxfordshire and Bedfordshire.

The natural or casual cow-pox is represented by Mr. Ceely to appear most commonly during the spring, rarely in the heat of summer, though he has observed the disease at all seasons. It is occasionally epizootic, more commonly sporadic, and extremely irregular in the periods of its occurrence, even in dairies situated in the same immediate vicinity, and apparently placed in circumstances in all respects similar. The disease is considered to be peculiar to the milch cow, occurring primarily while the animal is in that condition, and being casually propagated to others by the hands of the milkers. Many intelligent dairymen are inclined to trace its origin to the equine vesicle, but Mr. Ceely has himself never been able to trace it to this source. Different from what is described by M. Rayer in the text, fever or other constitutional symptoms, either in the animals primarily affected or in those to which the disease has been conveyed, are very rarely observed; heat, induration and tenderness of the udder being generally the first symptoms noticed.

The regular duration of the disease would seem to be from twenty to twenty-three days; the eruption appearing about the third or fourth day after exposure, reaching its full development in from six to seven days, and declining in five or six more; the crust separates in about five or six days from its formation, leaving a cicatrix behind.

Mr. Ceely treats of *variola vaccinae*, 1st, as they appear naturally or are produced casually in the cow by the manipulations of the milkers; 2d, as they are produced by vaccination; 3d, by retro-vaccination; 4th, by variolation.

Of the casual cow-pox notice has been already taken. Vaccination of the cow with primary lymph, requires a few words of explanation. "The process followed by Mr. Ceely for the effecting of this object differs from the casual vaccination of the cow by the milkers, in the designated application of the lymph through punctures artificially made on parts selected as being appropriate for its reception. The animals chosen were *sturks* (young heifers), with a view of ascertaining how far other than milch cows were susceptible. Some of these, about ten months old, were vaccinated with lymph taken from a milch cow in the inside of the ear, on the teats, and near the vulva. The punctures in general were early inflamed, but the papular stage was not well marked, and appeared postponed; the vesicles were normal, but declining on the eleventh day. The only constitutional affection observed was a slight acceleration of the pulse. The lymph taken from these vesicles on the tenth day, when transferred to man, produced an affection which differed in no respect from that produced by primary lymph from the milch cow, with the exception that the inflammation and induration at the base of the vesicles were less considerable, and the subsequent scars, though well defined, rather less deep."

Retro-vaccination is the vaccination of the cow with humanized lymph. The animals selected for these experiments were sturks under twelve months old, as cows were difficult to be had for that purpose. The parts selected for the operation were those in close proximity to the vulva, as most easy of access and most suitable in every respect. The lymph used was either dry, or liquid in capillary tubes; and no precautions were taken further than excluding the animals from cold and moisture immediately after the operation for a few hours, or occasionally for a night. Scarcely one-half of the operations succeeded. In the majority of instances, where the vaccination succeeded, the vesicles ran their normal course, and declined on the eleventh day. Four different kinds of lymph were used, each having been current in man for a longer or shorter period. Four of these experiments are given in detail, in order the better to illustrate the particular attendant phenomena; and as one will serve as an example, we give it in the author's words.

"Retro-vaccination with lymph which had been several years in use. — It appeared sufficiently active, and from arm to arm was attended with satisfactory results. *Subject*: a small ill-conditioned sturk,

1461. Observation has shown that there exists a *false* cow-pox, as well as a *false* or *spurious* variola, and vaccinia.

C. G. Kühn (*De morbo varioloso*, 4to. Lips., 1801, p. 82), has collected the chief documents published on these eruptions. He admits

strawberry coloured, thin skin. Seven punctures were made near the vulva, and eight points inserted recently charged with fifth-day lymph from a fine child on the 1st of February, 1839.

"Second day: Nothing remarkable.

"Fourth day: Some of the lower punctures rather red.

"Fifth day: Scarcely any traces of punctures left.

"Sixth day: Punctures appear perfectly passive.

"Seventh day: Two punctures rather elevated and inflamed.

"Ninth day: All the punctures raised in the normal form, but in different degrees, the vaccine tumours being of different sizes; tried to procure lymph, but failed, both on the surface of the tumid margins, which yielded only blood, and in the centres, where there is a slight crust.

"Tenth day: There are four fine large and three small vesicles, from two of which were charged one hundred points, abundantly, with clear adhesive lymph, some of which was used on the same and subsequent days. The punctures made yesterday had given rise to the exudation of lymph which is now visible in the form of light amber-coloured concretions on the parts.

"Eleventh day: The vesicles appear diminishing, and amber-coloured lymphatic concretions are formed in their centres. *Vespere*: Crusts enlarging; vesicles subsiding.

"Twelfth day: Upper vesicles have a pustular appearance in places; others have a yellowish-brown crust; others flattening.

"Thirteenth day: All subsiding; crusts larger.

"Fourteenth day: Subsiding.

"Fifteenth day: Crusts more elevated; margins flatter.

"Sixteenth day: Declining.

"Seventeenth day: Intumescent ring nearly disappeared; black crusts alone remaining.

"Eighteenth day: Every thing diminishing.

"Nineteenth day: Small elevations in the site of the vesicles, still lighter than the ground.

"Twentieth and twenty-second days: Some crusts prematurely removed by accident; others spontaneously fell on the twenty-second and twenty-third days, leaving small pale rose-coloured smooth scars slightly depressed in the centre.

"February 26th: Inoculated with liquid small-pox lymph (*variola discreta*, seventh day), in five punctures, from capillary tubes, on right side of labium pudendi, the wounds being at the same time deluged with fluid.

"Third day: Slight tumidity around the punctures.

"Fourth day: A shining glassy tumidity around the punctures, which are larger.

"Fifth day: *In statu quo*.

"Seventh day: All subsiding; no result.

"March 12th: Re-inoculated with dry sixth-day confluent small-pox lymph, inside and outside the left labium pudendi, with several points; four punctures. Re-vaccinated with seventh-day "*variola vaccine*" lymph, two removes, inside and outside of the right labium pudendi; several points; four punctures. No result from either." — pp. 355–357.

In one of his experiments, no apparent effect was produced on the fourth day, but on opening the punctures, and re-vaccinating with the same matter, vesicles suddenly became developed, without having passed through a palpable and progressive state of papulation, and attained their full development by the tenth day. Analogous occurrences, he remarks, from various causes, take place in man, especially in using primary retro-vaccine and unassimilated lymph; and similar phenomena are noticed in the natural and casual disease in the cow.

The retro-vaccine lymph from these experiments, when taken on points thoroughly and trebly charged, and immediately used, produced perfect vesicles in man. The papular stage, however, was late, being not till the sixth or seventh day. This matter was vaccinated on subjects of different ages, and excepting in respect of the lateness

three species. The first of a deep colour, broader than a Holstein shilling, and depressed in its centre, is filled with thick pus. Transmitted to milkers by inoculation it occasions slight fever, with headache, and pains in the axillary glands. The pustules are painful,

of the papular stage, and in the vesicles themselves being somewhat smaller, did not appear to differ from the matter which had not undergone the transit through the system of the cow; no difference being noticed in local or constitutional symptoms. Even the slight change which it had undergone in its transit through the system of the cow was not apparent after the third remove.

Mr. Ceely concludes, from these experiments, that it is more difficult to vaccinate the cow with humanized than with primary lymph, and that, when vaccination is successful, the disease is milder; that vaccine lymph, therefore, in passing from the cow to man, undergoes a change which renders it less acceptable and less energetic on being returned to the animals of the class which produced it; some, indeed, being incapable altogether of being affected by it. He also remarks that this difficulty of infecting the cow with humanized lymph is not, however, so great as that experienced in passing primary lymph from the cow to man. His experiments also demonstrate that the age of the humanized lymph did not appear to influence its reception in the system of the cow; for provided the lymph was of ordinary activity, and possessed its normal qualities, it succeeded equally well in its operation, whether it had been current in man for only a few weeks, or for many years; exciting in both cases equally perfect and productive vesicles.

As to the question whether the practice of retro-vaccination is of any real value, as a means of renovating humanized vaccine lymph, Mr. Ceely says, "I confess, that from my limited experience, (these few observations and experiments,) I am unable to discover its advantages, or to admit more than its questionable utility, from one transit through the cow. What humanized vaccine might acquire by repeated and indefinite transmissions, I am not prepared to say."

Mr. Ceely, whose opinion is highly valuable, in this alleged degeneration of the vaccine lymph in its passing through many individuals, as he has had frequent opportunities of comparing the primary with the old lymph, coincides in opinion with the correspondents of the French Academy of Medicine, and also with Dr. Griva, of Turin, and his correspondents, and the report of the National Vaccine Establishment, that the vaccine virus has not degenerated. He states that his "own repeated applications to the cow have been chiefly for the purpose of experiment, for the satisfaction of his patients or the accommodation of friends, not from any belief in its superior protective efficacy over active humanized lymph."

On the other hand we are very properly told: "But when lymph is found uniformly deficient in infecting property, vesicles abnormally rapid in their course, at their greatest development on the seventh day, yellowish in appearance on the eighth, with turbid lymph, central desiccation on the ninth, and a miserably small crust falling on the fifteenth or eighteenth day, common prudence dictates its discontinuance, and urges the adoption of a new supply, although constitutional symptoms may not be absent, for *weak* lymph may not be better than *late* lymph." (p. 376.)

To the last source of variolæ vaccinæ, viz., variolation, or the introduction of the virus of small-pox of the human subject in the cow, great interest naturally attaches, as showing the identity of variolous and vaccine matter,—the latter being the former, only modified in its passage through the system of the cow. Of the different experiments performed by Mr. Ceely, the second is the more conclusive. It is detailed as follows:

"*Experiment second.* White sturk, thin skin, [which had been inoculated with small-pox matter fourteen days previously without effect,] February 15th, reinoculated with small-pox virus of the seventh and eighth day (variola discreta), on the left side of the vulva and under fold thereof, as before, and near the verge of the anus. Virus liquid, some pellucid, some opaque and puriform, in capillary tubes, was forced into eight punctures, which were deluged with it; the punctures being afterwards irritated with points deeply charged with the same, which were suffered to remain in the punctures. Third day, nothing remarkable. Fifth day, four upper punctures

ulcerate, and get well with difficulty. The pustules of the second species are not so large, of an amber colour, and filled with a yellowish fetid ichor. The animals suffer more from these than from the former pustules, and the secretion of milk is lessened. Transmitted

near the verge of the anus enlarged and elevated; four on the under fold of the labium, elevated and red, but less enlarged. Sixth day, all present the appearance of the vaccine vesicle. The four upper are larger, but seem only tubercular; four lower on the under fold of the labium have a deep damask hue, and appear like oval or circular solid elevated rings, with central depressions; from one of these took clear lymph with much difficulty, and scantily charged thirty-nine points. Seventh day, upper tubercles seem diminishing, lower vesicles seem flatter but broader. Eighth day, four upper still appear tubercular, of a lighter colour than their ground; four lower vesicles rather augmented, have a light damask hue. Took lymph again from one of them; the other three, not readily yielding lymph on a careful puncturing, were not further disturbed, from a desire to witness their progress; slight central crusts. Ninth day, the four vesicles enlarging; again opened the inner margin under the daily increasing central crust of the vesicle first opened, and charged twenty points; tubercles diminishing. Tenth day, one of the tubercles rather larger; four lower vesicles increasing. Charged twenty-seven points. Vesicles have a bluish, reddish, glistening appearance; two of them rather red at the base; one or two rather raw on each side. Eleventh day, brown crusts over the centre of the vesicles, which appear declining. Twelfth day, declining, with increasing crusts of a blackish-brown colour, within a slightly elevated margin. Vaccinated in several punctures on the margin of the right labium with many points, well charged with sixth-day retro-vaccine lymph; two removes. Punctures slightly tumid for a day or two, but quickly subsided. No result. March 12th, four scars as large as peas, in the situation of the four vesicles, depressed, pale rose colour. Re-inoculated with small-pox virus (confluent), fifth day, in four punctures, on inside of left labium. Re-vaccinated in three punctures, many points, of fifth and seventh day lymph from a child. No result." (pp. 385-7.)

"The third experiment was a failure. Every precaution to avoid error seems to have been adopted in these experiments; the small-pox virus was taken by Mr. Ceely himself on newly-prepared points which had never been used before; and for the second experiment new capillary tubes were charged: the subjects from which the virus was taken were healthy young men, the pocks being remarkably fine, large, plump, and numerous. The first experiment, which, in consequence of vaccination having been performed on the ninth day of variolation, presents, as Mr. Ceely observes, the application of Bryce's test in the cow, is illustrated by six beautiful coloured plates, in which the simultaneous progress of the variolous vesicle, and of the subsequent vaccine vesicles rapidly overtaking it, is faithfully delineated. The drawings are taken on the tenth, eleventh, twelfth, thirteenth, fifteenth, and sixteenth days of variolation, corresponding with the second, third, fourth, fifth, seventh, and eighth of vaccination, the whole of the vaccine vesicles, as well as the variolous one, being at their height on the fifteenth day of variolation, and manifestly on the decline on the sixteenth. The second experiment is illustrated by seven plates, representing the appearances respectively observed on the fifth, sixth, eighth, ninth, tenth, twelfth, and twenty-sixth days, the last plate showing the smooth pale marks left after the fall of the crusts. Both animals were re-inoculated and re-vaccinated without effect. No indisposition was observed during the progress of the disease; and increased heat and redness of the mucous membrane of the vulva, with slight acceleration of the pulse, were the only symptoms noticed."

Mr. Ceely then proceeds to relate the effects of the lymph, illustrating his remarks by examples and plates. But we shall best convey an idea of his first experiments on this point in his own words. "I had inserted twenty points, charged from the variolous vesicle, on the tenth day, into five children, making four punctures in the left arm of each child, viz., James Bryant, aged two years, in delicate health, dark complexion; Ann Nicholson, aged one year, healthy, fat, florid, but phlegmatic; Henry Gibbs, aged one year and three-quarters, very fair, healthy; Joseph Woodbridge, aged three years, robust and

to the human subject, this *false* cow-pox, produces more serious symptoms than the preceding. These two species were observed by Nissen, a practitioner at Segebert. A third species has been described by Helweg, under the name of *yellow false cow-pox*. It differs from

remarkably florid; George Woodbridge, aged five months, plump and healthy. In all, the punctures were early inflamed; but the inflammation subsided, and the papular stage was late in all—the sixth, seventh, or eighth day before it was possible to determine the probability of any result, when a dark dull red pimple occupied the place of some of the punctures, for many of them failed. Vesicles with areolæ were formed at different periods in each.

“Bryant, becoming ill with diarrhœa soon after vaccination, produced only one vesicle, with an areola at the height on the fifteenth day; the vesicle bluish and remarkably large. Nicholson yielded two fine vesicles with full areolæ, and two papulæ on the thirteenth day. Gibbs had but one vesicle, fine and pearl-like, with fully developed areola on the eleventh day. Joseph Woodbridge had two vesicles, attended with areolæ on the tenth day, which were very extensive on the twelfth, and did not decline till the fourteenth day. George Woodbridge entirely failed. Thus twenty punctures yielded but six vesicles. In all these cases the primary constitutional symptoms were very slight; the secondary proportioned to the extent and character of the areola; hence Joseph Woodbridge suffered severely, had vomiting and delirium. No eruption was observed in any of the cases except his; he had extensive roseola.

“On three subjects, aged respectively eleven years, ten months, and two years and a-half, some of the remaining points were employed; into these, also were inserted, at the same time, points charged with ordinary vaccine lymph. In all three subjects the latter took effect in every puncture; while only five out of eight punctures with the new lymph answered, papulation being tardy as before; while the old lymph advanced as usual. As the areolæ of the vesicles from this lymph began to form, the sluggish vesicles from the new began rapidly to advance, and ultimately ran the same course, but did not eventually attain the same size, though perfectly well developed.

“Six points, charged with lymph taken from the vaccine vesicle of the fifth day, on the variolated sturk, were inserted into two subjects at the same time as points charged with lymph from the variolous vesicle of the tenth day. One Emma Churchill, aged five years, produced, from three punctures with the latter, two *papulæ* only; but from three punctures on the right arm, with the former lymph, two very fine active *vesicles*, in which the areolæ began on the ninth day, and was fully developed on the eleventh. In the other case, Richard Tompkins, aged four years, both sets of punctures took effect, but those with the retro-vaccine lymph were more early developed; the areolæ of both commenced on the ninth day, and declined after the eleventh. The symptoms in both subjects appeared on the approach of the areolæ, and were rather severe during its activity. In the subsequent removes of the lymph from the variolous vesicle and the retro-vaccine vesicles, and when propagated from arm to arm, it appeared rather more energetic than the ordinary lymph. Trials were made of both on the same and on separate subjects. In the subsequent removes of the new lymph, in the liquid state, by trials on the same and on different subjects at the same time, it was impossible to discover the slightest difference in its course and effects, whether derived from the variolous vesicle of the tenth day, or the retro-vaccine vesicles of the fifth or seventh day.”—pp. 404–406.

The phenomena presented by the lymph taken from the vesicles produced on the second variolated heifer, were very analogous to those above quoted. It is only necessary to mention that it was found that after the fourth remove “the vesicles were every thing that could be desired, even on a puny, sickly, rickety child, aged two years and a-half.”

In the case of his assistant, Mr. Taylor, who had accidentally inoculated himself from the matter of the single variolous vesicle developed in the first experiment on the cow, he had in consequence modified vaccine with a general eruption of roseola and vesicular or vaccine lichen. This gentleman had been vaccinated in infancy, and had subsequently modified small-pox. With the exception of this case, no attendant eruption was observed by Mr. Ceely in adults;

the two preceding species in its colour, in the nature of the fluid included in the pustules, and in not being contagious. A fourth species signalized by Jenner, differs from the preceding in the absence of erysipelatous inflammation, in the slight degree in which the secretion of milk is affected, and the rapid formation of the crusts. Viborg admits all these species, and describes several others. One of them of a fiery red colour is transmissible to man, and extremely benign; another (warty vaccinia) shows itself first upon the teats under the form of small hard white bodies, like mustard seeds, which increase in size, become reddish on the flesh-coloured teats, and livid on the black, and secrete from their bottom matter of a yellowish colour. The fever accompanying this species is not very intense; and the milk does not decrease in quantity unless the eruption be extremely abundant. At the height of the disease the teats become inflamed and painful, and the animal will hardly suffer itself to be milked. The disease is transmitted from one cow to another, but not to man.

A. F. Luders (*Rem. sur la Vaccine des Vaches de Holstein, Journ. Complémentaire des Sciences Méd.*, t. xxi. p. 53), has also published interesting observations upon *epizootic cow-pox*, and upon *spurious cow-pox*.

1462. I have myself met with an eruption which I conceive ought rather to be ranked among the spurious than the *true* cow-pox. Still it may have been the true disease, the accidental inoculation of which upon the person of a woman who had had the small-pox, produced a modified vaccinia, followed by secondary eruption. I showed the case to M. Bonnet, now Professor of Anatomy at Poitiers, and to M. Leblanc, the distinguished veterinary surgeon, who agreed in opinion as to the vaccinal character of the eruption. Here is the case:

I was consulted at Bellevue, in the month of June, 1829, by a woman, aged thirty-eight, of good constitution, and who had had small-pox, the marks of which she bore about her, who had been attacked during the last few days with an eruption of large pustules upon the corresponding sides of the index and medius fingers of both hands, which she employed to milk the cows she tended, seizing the teats between these two fingers. Three pustules were observed on the ulnar edge of the forefinger of the left hand. Another pustule existed on the same side of the right forefinger, and one upon the radial side of the right middle finger. These pustules, rather distant from one another, prominent, and of the size of a pea, were inflamed at their base, which was of a violet red colour. The broadest of the pustules was somewhat flattened in its centre. The epidermis being detached from the surface of one of these spots, a little blood was discharged, but neither pus nor serum. The spot thus denuded, examined with the lens presented four or five transparent, rounded points like globules of blood, divided from each other by a kind of septa, somewhat opaque. These spots had not been painful on their first appearance; but by and by the patient felt shootings in them as if (as she said), they were going to fester.

I saw the patient three days afterwards. The pustules had increased in size, and now contained a transparent serous fluid, deposited within cells or compartments. I collected some of this fluid, with which I next day inoculated three children, none of whom had any eruption. Three days later, the hands of the patient were tumefied; the fingers especially were excessively swollen; the bases of the pustules were of deeper red and had extended, and the serum they now contained looked sanguinolent. The patient had still gone on milking

nor in any child was there the slightest approach to any thing of a varioloid character. In one case true varicella appeared six days after vaccination at the sixth remove. Roseola, strophulus and lichen were the principal eruptions observed. Supernumerary vaccine vesicles were frequently observed in the proximity of the punctures. This lymph has been extensively used both at the Small-pox and Vaccination Hospital at London, at the Cow-pox Institution at Dublin, at Cheltenham and at Bristol, and found equal to any at present in use.

Not having had access to Mr. Ceely's paper, which is published in the *Transactions of the Provincial Medical and Surgical Association*, 1840, we have made use of the full analyses in the *British and Foreign Medical Review*, October, 1840, and the *Edinburgh Medical and Surgical Journal*, October, 1840.

her cows. The deep red colour of the pustules gave them a pretty strong resemblance to strawberries, though they were smooth and even on the surface. One of the pustules, situated on the middle finger, had discharged its contents almost completely, and the cuticle, loosened and whitish, was still kept moist by the excretion of a small quantity of thick and purulent serum. The patient complained greatly of pain, and was very unwell. During the last two days a *secondary eruption* had made its appearance over the forearms, hands, legs, and several other regions of the body. This eruption was vesicular, generally of the size of millet-seeds, and scattered, nowhere appearing clustered. The vesicles were transparent; their base was not inflamed, and the skin in the spaces between them was not red. They occasioned considerable pruritus, especially during the night. These vesicles, in their interior, presented numbers of small reddish inequalities, similar to what were observed in the pustules of the fingers. On the twenty-fourth day the pustules of the fingers were nearly well; the small vesicles, of the secondary eruption, were opaque and yellowish; a very considerable number were wrinkled on their surface; a few days afterwards the recovery was perfect.

The appearance of these pustules, and their seat upon the edges of the fingers, which were the parts more particularly brought into contact with the teats of the cows, excited my attention, and on the very day when I first observed this eruption, I examined the cows belonging to the family, and on one I discovered an eruption having the appearance of *cow-pox*. On the four teats there existed pustules of a circular form, and of the size of a large lentil. The base of one of these pustules, evolved on the point of the teat where there was no pigmentum, was of a citron-yellow colour, and its centre contained a purulent fluid. This pustule was not umbilicated, but a small black point was perceived on its summit; its base was but very slightly inflamed. The citrine-coloured fluid it contained was rather thick. A second pustule, of larger size than the preceding, contained less serum and more pus. Others were already partially dry. (a)

## GREASE.

1463. Under the name of grease is designated a pustular or vesicular eruption of the lower parts of the legs, and particularly of the

(a) Mr. Ceely points out various eruptive diseases, and spurious pocks, as they are termed, to which milch cows are subject, in addition to the variolæ vaccinae. Among these are the yellow pock, the bluish or black pock, and the white pock. Cases of spurious eruptive disease, communicated from the cow, and mistaken for genuine cow-pock, are frequent in dairy districts, a circumstance meriting the attention of the practitioner residing in them, since by leading to the neglect of correct and efficient vaccination, fatal consequences have ultimately resulted from subsequent exposure to the infection of small-pox.

Of the spurious eruptions liable to be confounded with the genuine vaccine, the white pock would seem to lead to the most frequent mistakes. "On very thick skins, about the sixth or seventh day of its existence, it sometimes appears as a raised, circular, well-defined, firm vesicle, with a small violet or pink areola, and a slight central depression, with a light brown discoloration." On close examination, however, it will be found to be neither cellular in its structure, nor possessed of fluid contents.

The cow, like children, is described as being subject to a purely vesicular eruption, consequent upon vaccine fever, which often bears a striking resemblance to vesicular varicella. This usually occurs about the ninth or tenth day of the vaccine, in the form of erythematous-papular elevations of different sizes, solitary, or in groups, evidently of sub-epidermic origin, which, within twenty-four hours, contains a pellucid serous fluid, which raises the epidermis. On the second day the fluid is straw-coloured and turbid; and before the fifth the vesicles are desiccated with brown and black thin, brittle crusts, which speedily fall. They often continued to form and desiccate for three or four weeks. Several eruptions were noticed as occurring at this period; but none of them so liable to be mistaken for the vaccine as the white pock.

pastern, of several species of animals, but more particularly of the horse.

This affection is ushered in by symptoms of uneasiness and of fever. The eruption then makes its appearance. The hair of the parts affected looks bristly; the size of the limb is increased, and has a great tendency to enlarge; the animal rubs the diseased leg against the others, and tries to bite it; he often lifts the affected member, especially if it be a hind leg. Examined closely, vesicular or pustular elevations may commonly be perceived, but still more frequently a discharge of a serous fluid having a peculiar smell, from a number of small orifices situated at the roots of the hairs. The redness and the discharge increase; the hair is thrown out, excoriations and chaps are formed, to which sores succeed, that pour out a faint smelling or fœtid discharge, and upon the edges of which soft and fungous-looking excrescences sprout up.

Jenner was of opinion that the accidental inoculation of the matter discharged in this disease, was the determining cause of cow-pox among cows. This idea was combated by Woodville, Simmons, Coleman, Buniva, Luciano, Bertholini, and others, who all tried, but in vain, to inoculate the virus of grease upon the teats of the cow. Other observers, Godine, Tanner, Lupton, Loy, Laffont, and Sacco, from repeated experiments, have held themselves bound to adopt the views of Jenner. But several of them, and particularly Saco, maintain that the virus of grease is not the only cause of cow-pox, and that it may be evolved spontaneously among cattle. The following fact, observed by M. Husson, appears conclusive. A coachman, who had never had small-pox, and who had, within a few days, dressed the leg of a horse affected with grease, came to consult the surgeons of one of the dispensaries of Paris, on account of a number of spots or pustules which had been evolved on his wrists, and were exactly like those of vaccinia. This resemblance struck the surgeons, who immediately inoculated two children with the fluid from the pustules of this coachman's wrists. Vaccinia, of the most regular kind, ensued in both of these children, and the virus was used again and again to transmit this disease. A third child was afterwards inoculated with the matter of one of the crusts from the coachman's wrist, and had regular vaccinia, which, eight days afterwards, served to commence an indefinite series of vaccinations.

1464. I think it right to observe that in all probability the whole of the affections designated as *grease* are not of the same nature. Several cases of grease which I have examined bore a stronger resemblance to impetiginous eczema than to any other disease.

1465. On this subject,—the relation of *grease* to cow-pox, consult Jenner's *Inquiry into the Causes and Effects of Variolæ Vaccinae*, 8vo. Lond., 1798; Loy's *account of some experiments on the origin of cow-pox*, 8vo. Lond., 1802; Sacco's *Trattato di vaccinazione, con osservazioni su'l giavardo e vajuolo pecorino, con quattro tavole miniate*, 4to. Milan, 1829; and Husson's article: *Eaux aux Jambes*, in Dict. des Sc. Médicales. (a)

## CARBUNCLE (CHARBON).

1466. M. Hurler d'Arboval relates (*Dict. de Méd. et Chirurg. Veter.*, in art. *Typhus charbonneux*), that a veterinary surgeon, opening the body of an ox which had died of *typhus charbonneux*, imprudently carried his hand soiled with blood to his face naturally covered with spots; on this there followed an *erysipele charbonneux* accompanied with shivering fits, nausea, syncope, &c., so that the man died. A woman who had introduced her arm into the rectum of a horse, labouring under carbuncle (*charbon*), to remove the accumulated excrement, died very shortly afterwards of the same disease. A veterinary surgeon having removed a *tumeur charbonneuse* whilst suffering with a wound on his hand, contracted the disease and died.

(a) Numerous cases are recorded of a similar kind to the one mentioned in the text, of the propagation of vaccinia from the pustules of the lower part of the legs of a horse. But it must be borne in mind that this result can only follow the inoculation with the matter from one specific kind, of the many varieties of eruption, designated vaguely by the term grease.

Two men having bled a bull from the neck affected with a charbon, of the nature of those which are held very malignant, were afterwards affected with a considerable swelling of the right arm, and a number of livid spots, in consequence of the contact of the blood with this part. Shortly afterwards they complained of weight about the heart, (*maux de cœur*), and violent fever, and became exceedingly ill. A woman, after having bled a sheep which died of charbon, having let two drops of blood fall on her hand, two malignant pustules were evolved on the places. Petit instances the production of an *affection charbonneuse* in two children, by the intermedium of a cloth which had been used to cover the skins of some animals dead of charbon.

## SCABIES OF ANIMALS.

1467. According to the testimony of several writers worthy of credit, the *itch* of animals, a contagious disease in which a species of *acarus* is observed, may occasionally be propagated to man. We are even informed that these cases of itch are much more severe than ordinary scabies, and the same remark has been made in regard to scabies transmitted from one species of animal to another.

1468. The itch of the horse (*roux vieux*) is principally situated upon the neck, especially on its upper part near the insertion of the mane. It is characterized by the evolution of small spots hard at their base, vesicular on their apices, extremely numerous and very closely crowded together. Incessant itching leads the animals to rub themselves one against another, or against their stalls, trees, &c.; by this means they sometimes excite excoriations, which in healing become covered with dry crusts, or with squamæ which are detached in the shape of dust. In examining this dust in the sun or in a warm place, a number of shining transparent insects, which move with rapidity, may be perceived in it even with the naked eye. This is a species of the genus *acarus* of which Raspail has given an accurate figure and an excellent description (vide his *Nouv. syst. de chimie organique*, p. 509, 8vo. Paris, 1833, and the *Lancette Française*, 13me Août, 1831).

R. Fauvet gives the following case: In the month of January, 1820, a farmer bought a horse affected with the itch (*cheval galeux*) at the market of Bergamo, which he mounted to return to his home. The day after his arrival he experienced great itchiness over almost the whole of his body; the same symptom was farther complained of by his son and a friend who had accompanied him to market. The stable boy, too, to whom the horse was given in charge, began to scratch himself incessantly within two days; so did a labourer who had used the brute in some field work during a few hours, and this went on till more than thirty persons and several other horses attached to the farm were infected with itch. The mangy animal was, therefore, got rid of, and being sold to a miller, he and his men were forthwith attacked with itch merely from having put their hands on the back of the purchase; a cow, also, which had rubbed her neck against the manger of the horse, contracted the itch like the rest.

The scabious character (*caractère psorique*) of the eruption communicated, was ascertained by several distinguished physicians and surgeons (*Revue Médicale*, t. x.).

Messrs. Dumeril, Geoffroy St. Hilaire, Bosc and other naturalists have borne testimony to the fact of a quadruped (*un phascolome*) which was affected with itch when placed in the Jardin du Roi, having infected the man who was ordered to preserve the skin (the animal having been accidentally killed by the elephant), with a very decided scabies.

The vesicles which characterized the disease of the phascolome contained insects of much larger dimensions than the *acarus scabei* of the human subject; neither did they degenerate transferred to the man who has been mentioned; they occasioned vesicles of greater magnitude than common, which were attended with pruritus of the most intolerable kind, and considerable redness of the skin. Sulphur, the true specific in ordinary scabies, was found equally efficacious in the present instance, and soon restored the individual to health.

Several instances of the itch of dogs having been communicated to man have been mentioned, but unaccompanied with perfectly irrefragable proofs.

## ERUPTION FROM TOUCHING THE SKIN OF A LIONESS AFFECTED WITH A DISEASE OF THE SKIN.

1469. Captain Nonencourt, of the *Echo*, arrived at Brest, from Senegal, having on board a young lioness, labouring under a scabious affection of the skin, and a chronic diarrhœa which before long proved fatal. A man of the name of Dupont, who skinned the animal, was attacked, the night after the operation, with an insupportable itchiness which was followed, by and by, by the appearance over the back, shoulders and legs, of a considerable eruption of little red, pyramidal elevations containing a serous sanguinolent fluid. The eruption on the back disappeared under the use of certain remedies, and that on the other parts was in a state of desquamation, when the treatment was discontinued. On the 23d of September, Dupont felt a considerable degree of itchiness in the head during the night, and next morning he found his forehead, eyebrows and ears covered with pustules, similar to millet seeds. The face, too, was so thickly beset, and so much swelled that the nostrils were obstructed. The eruption continued for three or four days in this state. The pustules then burst, and poured out a sharp fluid, which dried up into a thick crust, that covered the face like a mask. The desquamation commenced on the sixth day; the crust fell off in large flakes; the denuded skin looked red, and only recovered its natural colour slowly.

A person of the name of Bertin stuffed the skin of this lioness. Two days afterwards his eyelids swelled during the night, and a pustular eruption broke out which spread over the whole of the face, the skin of which generally presented an erysipelatous redness. The eruption disappeared from the face by and by, but attacked the hands and shortly afterwards the soles of the feet; on the fourth day it fastened on the thighs. It was accompanied with violent and incessant itchiness. The thighs were covered with broad pustules. They burst, and were succeeded by thick crusts which fell off after a time. Shortly after this, Capt. Nonencourt himself began to complain of being affected with a scabious eruption. The formation and detachment of the incrustations put an end to this disease in the three persons affected. The skin, after this process, continued red and shining, but without ulceration.

Drs. Duval and Coxil Saint Vincent made use of the same remedies in these cases, namely, sudorifics, bitters, sulphur, sulphureous baths and purgative medicines, with success. Dr. Saint Vincent at the same time made use of mucilaginous anodyne and saturnine lotions to appease the pruritus and lessen the irritation of the skin.

## GLANDERS.

1470. Acute glanders occurs in the horse and the ass with the following characters:—the pituitary membrane is very red, and highly inflamed; small eroded points soon appear and spread into foul and cankerous sores with thick and raised edges; the lips and point of the nose are sometimes swelled; the ulcers extend, and discharge a fetid purulent matter, with which a quantity of sanguinolent sanies is from time to time mingled. The mucous membrane becomes gangrenous. The discharge continues in greater quantity than ever; the sublingual glands are painful; the conjunctivæ and eyelids, at first inflamed and injected, assume a violet colour, swell, and a discharge takes place from between the eyelids; the inflammation then extends to the surrounding parts, the breathing becomes laborious, and the animal dies within a few days. If the disease has not now its termination, the inflammation declines and passes into the chronic state. Pustules and gangrenous spots then occur over the face, the extremities swell, and ulcers and abscesses are formed in their substance. In a stable of eighteen horses and three asses attacked with glanders, Dr. Elliotson informs us that ten horses died within the few first days of the disease; four after the first violence of the symptoms had subsided, and the disease had continued apparently stationary for two months; the seven others which survived, presented all the symptoms of chronic glanders. They were sent into the country where they worked for nearly a year, at the end of which time they were killed.

It is long since glanders was familiarly known to be a highly contagious disease among animals of the same species; but it has only

recently been discovered that acute glanders accidentally inoculated upon the human body, give rise to very serious symptoms, to a disease, in fact, analogous to the glanders of the horse.

Dr. Elliotson has studied this point of pathology particularly, and has thrown much light upon it by his researches. He reminds us of the case related by Mr. Travers, of a student who lost his life from accidentally puncturing his finger whilst engaged in dissecting the head of an ass affected with glanders. He died with abscesses in the arm, lungs, kidneys and knee-joints. An ass inoculated with the matter from the abscess in the arm, by Professor Coleman, contracted glanders, and died twelve days afterwards.

Two other cases, the particulars of which Dr. Elliotson has detailed, are still more remarkable:

Thomas Maskall, aged seventeen, presented the following symptoms:—The upper half of the face, including the eyelids and the nose, with the portion of the cheek on each side, especially on the right, was greatly tumefied, so that the eyes were closed. The eyelids and swollen portions of the cheeks were red and hot, dry and shining, but the nose was dark-coloured, and on its right half, black, cold, and senseless. From around the gangrened portion of the nose and some other points a little pus was oozing, as well as a thin dark-coloured fluid, and from the nostrils a thick discharge of a deep yellow colour, here and there a little bloody, was taking place, exceedingly copious from the right nostril. Several hard phlyzacious pustules existed on and immediately around the nose, still principally on the right side, and in various parts of the trunk and extremities. Tumefactions were observed in both forearms and in the back of the right hand. Some of these were hard, others softening into suppuration. The temperature was high; the pulse 136, and sharp: the tongue white, and rather dry. The respiratory murmur was indistinct on the right lower part of the chest, and the respiration quick and difficult. The gums were slightly turgid. He died next day; on opening the body there were proofs of a violent pleuropneumonia in the lower part of the right side, and two ounces of healthy pus were found between the adherent lung and diaphragm. A dark red patch existed in the stomach, and several at irregular distances throughout the intestines. The mucous membrane of the stomach was very lacerable at that spot. The other viscera, and all the contents of the head as well as the veins of the extremities, were reported healthy: but the mucous membrane of the nostrils was not examined. The abscess which had been opened in the back of the right hand communicated with the joint of the metacarpal bone of the middle finger, but those on the arm did not communicate with the elbow.

On Friday, the 26th of the following June, it being my week to admit patients, I was surprised to find another young man, named Thomas Dixon, and twenty-one years of age, lying in bed in William's ward, with the same symptoms as the former.

The nose and surrounding parts were exceedingly swollen, so that the left eye was closed completely, and the right nearly. The tumefied parts were hot, and of a bright red, with the exception of an inch of the left half of the nose, which was of a mulberry colour: a profusion of deep-yellow tenacious mucus, with a few streaks of blood, exuded from each nostril, but particularly from the left. Several hard phlyzacious pustules existed on the nose and adjacent parts, on the arms, thighs, and legs, and each was surrounded in the latter situations by a blush of red. A patch of the same colour was observed on the left elbow. The temperature of the surface of the abdomen was 107°. The pulse 144, broad, soft, and weak, so as to be rather an undulation than a pulsation. The respiration 30, and so shallow that the chest scarcely appeared to move. The tongue was dry and rough, and of a brownish red. The skin sweated copiously. He gave rational answers in a fluttering voice, but immediately afterwards always fell into a little incoherence. His movements were tremulous, and though otherwise exceedingly tranquil, he tossed his arms about, and requested that his wrists might be tied together to prevent this involuntary action. He complained of coldness in the lower extremities, which, however, were sufficiently warm, though cooler than the rest of the body. This patient also died. On opening the body, many parts of the lungs were gorged with blood and frothy fluid, and the corresponding bronchial branches were very dark; numerous papillæ, with pointed black summits, were seen at the end of the ilium,

and clusters of minute grayish-black points throughout the small intestines, and most abundantly at the commencement of the duodenum; the walls of the left ventricle of the heart were very thick: but nothing was detected, either peculiar or important, or calculated to throw the faintest light upon the disease.

1471. Dr. Elliotson having contrasted the symptoms of these two cases with those presented in a young soldier, the detail of which is given by Mr. Brown, surgeon of the second regiment of Dragoons, under the title of, *A fatal case of acute glanders in the human subject* (London Medical Gazette, vol. iv. p. 134), was immediately struck with the resemblance which the whole of the three cases bore to one another, and forthwith instituted inquiries to ascertain whether or not his own patients could have had any intercourse with glandered horses. The result of these inquiries were next to certain evidence that they had. Some time afterwards Dr. Elliotson had a case communicated to him by Mr. John Parrot, in which there was no doubt of the patient having been in contact with a glandered horse. Mr. Brown's case, moreover, was quite decisive upon this point. The circumstances are as follows:—A fine healthy corporal in the 2d regiment of Dragoons, aged thirty-eight, suddenly awoke, while stationed at Caher, in Ireland, in the night of the 16th of April, with rigors, headache, and slight irritability of stomach, which in the morning were joined by depression of spirits, general disturbance, and stiffness and severe and constant pains of all the large joints, aggravated on the slightest motion. The pains increased to an alarming degree, but especially in the left shoulder, which was somewhat tumefied at the scapula, but not inflamed. On the 24th, the tumefaction was considerable, and of a livid hue. Similar swellings, but smaller, took place on the arms, legs, thighs and sacrum; all, like it, hard, insensible, and of a chocolate colour, and at first a slightly discoloured puffiness only, but becoming, after twelve or fifteen hours, of a deep vermilion, and soon of a dark brown; the integuments growing thick and callous, slightly cracking, and exuding a thin and acrid sanies. One precisely similar, and of large size, appeared upon the left temple, and the eyelids became tumefied. "The right nostril was gummed with an inspissated discharge." The "posterior fauces" were much inflamed, and nearly of a purple hue. On the 28th, several "wartlike pustules," acquiring about the size of a pea, rose high above the skin, in various situations around each of the tumefactions, particularly numerous and large over the right side of the neck and shoulders, and on the inside of the arms and thighs, and were found after death to be filled "with a violet-coloured inspissated lymph." The thirst was always great, the tongue foul and parched: the pulse from eighty-eight to ninety-six, full, but easily compressed; the blood, abstracted at the commencement, buffed, but much attenuated; the urinary and alvine excretions "always natural in every respect." "The copious exhibition of tonics and antiseptics" had not the slightest effect: and at the date last mentioned,—the 28th, many of the tumours, particularly that upon the shoulders, were rapidly running into gangrene; the pulse was scarcely perceptible, the surface bathed with a cold, clammy sweat; imperfect stupor, and mild muttering delirium occurred, and he died upon the morning of the 30th.

Neither the thoracic nor abdominal viscera presented any vestige of disease, but, as there was in this case no impediment to a full examination, the head, extremities, and walls of the trunk were carefully inspected. A cluster of tubercles was found in the cellular membrane, exterior to the pericranium of the left superciliary ridge, and in the right frontal sinus, according to the veterinary surgeon of the regiment, exactly similar to those observed in the frontal and other sinuses of the horse after acute glanders. On dividing the various livid tumours of the surface down to the bone, "the muscles appeared perfectly decomposed, and of a dark liver colour, exhaling a peculiarly fetid odour, with points of purulent matter, as it were infiltrated everywhere through their entire substance, resembling much a hepatised or tuberculated lung;" and under each "was a cluster of gray circular tubercles, the whole composed of fine cellular tissues, enclosed in small cysts, proportionate in size and consistence to the extent and duration of the tumour, and firmly attached to the periosteum." The muscles generally, even perhaps the heart, appeared

pale and flabby, "and the cellular membrane infiltrated with a yellow serosity."

"It appeared that the patient had had the sole charge of a glandered horse for some time, which had been destroyed on the very evening of his attack; and that he had skinned him, and exerted himself a good deal in cutting up and burying the carcass. But these circumstances did not at first create the least suspicion, and his complaint was considered a very severe case of acute rheumatism, and treated as such."

1472. These data on glanders in man are derived from Dr. Elliotson's first paper on this subject inserted in the sixteenth volume of the *Medico-Chirurgical Transactions*, published in 1830. In 1833 the same gentleman gave to the public an additional number of observations on the subject. (*Additional facts respecting glanders in the human subject*, 7th March 1823, which were republished in two of the French periodicals, *Journ. de Méd. Vétérinaire*, 1832, p. 124; 1833, p. 427; and in the *Lancette Française*, 1833, p. 384.)

Dr. Elliotson was afterwards informed that two cases, similar to those he had seen, were recorded in the eleventh and seventeenth volumes of *Rust's Magazin für die gesammte Heilkunde*, 8vo. 1821, 1824, to which he refers particularly. The cases in the first of these volumes are noticed in the *Journal der Praktischen Heilkunde*, for March, 1822.

M. Vogeli, of Lyons, has also given several cases, one of which particularly, that, namely, of Pierre Couderac, appears to me analogous to those seen and related by Dr. Elliotson (*Quelques faits tendant à établir la contagion du farcin du cheval à l'homme*. *Journ. de Méd. Vétérin.*, January, 1825).

It would, therefore, appear satisfactorily demonstrated, that glanders is communicable to man; first, by the perfect similitude and uniformity of the symptoms in all the cases in which inoculation was ascertained; by the peculiarity of the symptoms, and their distinctness from those of every other disease; by the exact correspondence of the morbid alterations discovered after death, with those encountered in the bodies of horses labouring under acute glanders; and, finally, by the actual excitement of glanders in asses, inoculated with matter taken from the sores of two different individuals, who died with the peculiar symptoms mentioned.

This rare disease is represented in the Atlas, after drawings, for the correctness of which Dr. Elliotson vouches. The cases, the experiments, and the learned researches of this gentleman, on glanders, are replete with interest. (a)

(a) Within the short period that has elapsed since M. Rayer wrote the above brief notice of Glanders, large contributions have been made to a better knowledge of the disease, and by few with more effect than the author himself; first, in a paper entitled *De la Morve et du Farcin chez l'Homme*, 1837, in the *Mémoires de l'Académie de Médecine*, and afterwards in an essay, jointly by him and M. Breschet, *De la Morve chez l'Homme, chez les Solipèdes, &c.* (*Compte rendu de l'Académie des Sciences*, 1840).

Among the German writers on this disease may be mentioned Dr. Eck (*Beitrag zu den Erfahrungen über die Schädliche Einwirkung des Rotzgifts auf Menschen*, 1837). Dr. Graves, also, makes glanders and button farcy the subject of one of his clinical lectures (*Graves and Gerhard*, p. 313, Philad. edit). Several cases of the disease in the human species have been recorded of late years in the Medical Journals, some of which I shall soon notice more particularly. I must mention, however, at this time, two valuable papers, containing much valuable information on the subject, in the *British and Foreign Medical Review*, vol. vi. 1838, and the *Edinburgh Medical and Surgical Journal*, 1840. But the fullest monograph of glanders and farcy which has yet come under my notice, is the essay of M. Tardieu (*De la Morve et du Farcin Chroniques chez l'Homme et chez les Solipèdes*. Paris, 1843), dedicated to his former preceptor, M. Rayer.

It was while preparing to make an analysis of this last work that I was induced to write a short monograph of the disease for my *Bulletin of Medical Science*, July, 1843. This article will constitute the staple of my remarks on the present occasion. Now, as then, I shall refer to the admirable work on the Horse, by M. Youatt, whose clinical

experience in glanders and farcy, as they attack this animal, have a direct application to those diseases, when transmitted to man.

*Close connection between glanders and farcy.*—First, we would devote a few words to the connection between glanders and farcy, and the reason for their being regarded varieties of the same disease; attacking, indeed, different tissues, but acknowledging a community of origin:

"'Farcy,' says Mr. Youatt, 'is intimately connected with glanders; they will run into each other, or their symptoms will mingle together, and before either arrives at its fatal termination, its associate will almost invariably appear. An animal, inoculated with the matter of farcy, will often be affected with glanders, while the matter of glanders will frequently produce farcy. They are different types or stages of the same disease. There is, however, a very material difference in their symptoms and progress, and this most important one of all, that while glanders are generally incurable, farcy, in its early stage and mild form, may be successfully treated.'

"M. Tardieu (p. 13) adduces many experiments performed by Albigaard and Viborg, of the veterinary school at Copenhagen, Coleman and White among the English, and Jolivet and Gerard among the French veterinarians, all proving the identity of origin, in their intercommunicableness by inoculation, of glanders and farcy. Wherein, then, consists the differences of these morbid states? M. Tardieu replies, by saying, that the *lesion of the nasal fossæ* is the characteristic feature of glanders, *Morve* of the French, *Rotz* *Rotzkrankheit* of the Germans. All the cases in which this is wanting are those of farcy. Mr. Youatt holds an identical opinion, in his declaring that 'glanders is an inflammation of the membrane of the nose, producing an altered and poisonous secretion; and when sufficient of this vitiated secretion has been taken up to produce inflammation and ulceration of the absorbents, farcy is established.'—p. 137.

"*Post-mortem* appearances clearly point out the anatomical seat of lesions in glanders. 'The nostril is generally more or less blanched with spots or lines of inflammation of considerable intensity. Ulceration is almost invariably found, and of a chancreous character, in the septum, and also on the ethmoid and turbinated bones. The ulcers evidently follow the course of the absorbents, sometimes almost confined to the trunk of the main vessel, or, if scattered over the membranes generally, thickest over the path of the lymphatic. The ethmoid and turbinated bones are often filled with pus, and sometimes eaten through and carious; but, in the majority of cases, the ulceration is confined to the external membrane, although there may be pus within. In aggravated cases the disease extends through all the cells of the face and head.' (Youatt, p. 132.) The extension of the disease to the larynx and trachea, and even, in aggravated cases, down to the lungs, is easily traced; but, as in other cases, there is no morbid affection whatever of these organs, we cannot regard pulmonic alterations as distinctive of glanders. In the chronic variety of this disease, miliary granulations are met with, which have been viewed, erroneously, as analogous and even identical with tubercles in the lungs of the human subject. M. Rayer, in his examination of this point of comparative pathology, affirms that the granulations in glanders are different in their origin, progress and termination, from the true tuberculous granules in man (Tardieu, p. 42).

"Among the *symptoms* of glanders, the earliest is 'an increased discharge from the nostril, generally the left, small in quantity, constantly flowing, of an aqueous character, and a little mucous constantly mingling with it.' Mr. Youatt, who gives this definition, adds, with earnestness, a caution not to wait until the discharge assumes a viscid or gluey character, before the disease is pronounced glanders, or before suspicion even is excited of its indicating the first stage. He admits, however, 'that, in a majority of cases, some degree of stickiness does characterize the discharge of glanders from a very early period.' Swelling of the submaxillary glands follows the discharge, but at an uncertain interval: these are distinct from adjacent tissue, and adhere closely to the affected side. The membrane of the nose is of a dark purplish hue, or almost of a leaden colour, or of some shade between the two, or, if there is some redness of inflammation, it will have a purplish tinge. Spots of ulceration appear in the membrane covering the cartilage of the nose, which

usually approach to a circular form, are deep, and with the edges abrupt and prominent.

"The farther progress of the disease is thus described by Mr. Youatt:

"When ulcers begin to appear on the membrane of the nose, the constitution of the horse is soon evidently affected. The patient loses flesh—his belly is tucked up—his coat unthrifty, and readily coming off—the appetite is impaired—the strength fails—cough, more or less urgent, may be heard—the discharge from the nose will increase in quantity; it will be discoloured, bloody, offensive to the smell—the ulcers in the nose will become larger and more numerous, and the air-passages being obstructed, a grating, choking noise will be heard at every act of breathing. There is now a peculiar tenderness about the forehead. The membrane lining the frontal sinuses is inflamed and ulcerated, and the integument of the forehead becomes thickened and somewhat swelled. Farcy is now superadded to glanders, or glanders has degenerated into farcy, and more or less of the absorbents are involved.

"At or before this time, little tumours appear about the muscles, and face, and neck, following the course of the veins and the absorbents, for they run side by side; and these, the tumours, soon ulcerate. Tumours or buds, still pursuing the path of the absorbents, soon appear on the inside of the thighs. They are connected together by a corded substance. This is the inflamed and enlarged lymphatic; and ulceration quickly follows the appearance of these buds. The deeper-seated absorbents are next affected; and one or both of the hind-legs swell to a great size, and become stiff, and hot, and tender. The loss of rest and strength is more marked every day. The membrane of a dirty livid colour. The membrane of the mouth is strangely pallid. The eye is infiltrated with a yellow fluid; and the discharge from the nose becomes more profuse, and insufferably offensive. The animal presents one mass of putrefaction, and at last dies exhausted."—pp. 130-1.

"Farcy (*Farcin* of the French, *Wurm* of the Germans, *Rogna dei Cavalli* of the Italians, and *Lamparones del Cavallo* of the Spaniards), as may have been already inferred from a quotation from Mr. Youatt, is, he thinks, always necessarily preceded by glanders, however slight the latter may be. Few things, says Mr. Youatt, are more unlike, or more perplexing than the different forms which farcy assumes at different times. 'One of the legs, and particularly one of the hinder legs, will suddenly swell to an enormous size. At night the horse will appear to be perfectly well, and in the morning one leg will be three times the size of the other, with considerable fever, and scarcely the power of moving the limb.'

"At other times the head will be subject to this enlargement, the muzzle particularly will swell, and an offensive discharge will proceed from the nose. Sometimes the horse will gradually lose flesh and strength; he will be hide-bound; many eruptions will appear in different parts; the legs will swell; cracks will be seen at the heels, and an inexperienced person may conceive it to be a mere want of condition, combined with grease."

"Multiplied hard knots and cords, owing to inflammation of the absorbents, are formed in different parts of the skin; some quite superficial, others deeper seated. Abscesses running into each other appear also on the skin, and open into ulcers; but some of them consist of blood.

"As to the *etiology* of glanders and farcy, it has been already distinctly stated, that contagion is an undoubted cause; but it is not the only one. There are two modes of direct transmission; the one by inoculation, or the application of the glanderous matter to an abraded or absorbing surface of a healthy animal, by which it finds entrance into the system, and produces the specific taint and its characteristic effects: the other is by a contaminated air or fumes, caused by the emanations from the glandered animal, acting on the Schneiderian and pulmonary mucous membrane of a healthy one shut up in the same stable. Some may qualify the latter mode of transmission by the term infection. The French minister of war appointed a commission in 1836 to investigate the subject, both of the cause and treatment of glanders. A report of the conclusions arrived at has not yet been made. M. Barthelemy, a member of the commission, relates, however, the following experiment on the question of conta-

gion. Ten horses, chosen by the commission from among the horses of two effective cavalry regiments in garrison at Paris, were put into a clean and healthy stable, with horses affected with chronic glanders: nine out of ten of the first set of horses exhibited symptoms of the disease; and two of four, in which the disease had reached its third stage, have been killed." Coleman, Vibourg and Renaut have shown that the blood of a glandered horse will communicate the disease to a healthy one.

"Still more frequently than from contagion, does glanders originate from general causes acting on the health of the horse; and this, in the history and inquiries into contagious diseases in the human subject, is a fact of deep importance. We have, in glanders, irrefragable proof that the disease originates spontaneously in the animal; but yet, that in its progress virus of a specific nature is formed, capable of propagating the disease, by contagion, to another animal, previously quite healthy, and in which no causes of constitutional disturbance or deterioration had been in action. 'Improper stable management, we believe,' says Mr. Youatt, 'to be a far more frequent cause of glanders than contagion.' The air, changed and deteriorated by respiration of many horses kept together in small and illy ventilated stables, becomes an irritant, or rather a poison, to the nasal membrane. Professor Coleman, of veterinary fame, relates a circumstance in point, which shows also the rapid and fatal agency of the cause in question. In the expedition to Quiberon, the horses had not been long on board the transports before it became necessary to shut down the hatchways for a few hours; the consequence of this was, that some of them were suffocated, and that all the rest were disembarked either glandered or farcied. Glanders may be produced by any thing that injures, or for a length of time acts upon or weakens the vital energy of the nasal membrane; hence the disease has followed fractures of the bones of the nose, violent catarrh, the injection of acrid and stimulating substances into the nostril. Whatever weakens the constitution generally, such as bad stable management, either excessive labour or defective exercise, want of wholesome food, will give rise to glanders. Mr. Youatt very properly remarks:

"Every exciting cause of disease exerts its chief and its worst influence on this membrane. At the close of a severe campaign, the horses are more than decimated by this pest. At the termination of the Peninsular war, the ravages of this disease were dreadful. Every disease will predispose the membrane of the nose to take on the inflammation of glanders, and with many, as shingles, catarrh, bronchitis, and pneumonia, there is a continuity of membrane, an association of function, and a thousand sympathies."

"Among the hygienic agents, the excess or prolonged application of which has been found to be frequently productive of glanders, moisture, or moist exhalations, deserve particular notice. New stables are, on this account, unhealthy, and sometimes give rise to the disease in horses placed in them too early. M. Tardieu, in this part of his subject, refers with great confidence to the opinions of M. Youatt, as recorded in the lectures by the latter, published in the *London Lancet*.

"Hereditary predisposition is referred to by Mr. Youatt among the causes of glanders:

"There is scarcely a disease which does not run in the stock. There is that in the structure of various parts, or their disposition to be affected by certain influences, which perpetuates in the offspring the diseases of the sire; and thus contraction, ophthalmia, roaring, are decidedly hereditary, and so is glanders. M. Dupuy relates some decisive cases. A mare, on dissection, exhibited every appearance of glanders; her filly, who resembled her in form and in her vicious propensities, died glandered at six years old. A second and a third mare, and their foals, presented the same fatal proof that glanders are hereditary."

"M. Latour cites a case, showing direct transmission of the disease from parent to offspring. A foal from a glandered mare exhibited, at birth, two hard glands adhering to the jaw, and it had a whitish flux from the right nostril. Its health was not particularly affected for four months, after which period it was killed; but on dissection deep ulcerations were found in the right frontal and maxillary sinuses, and the cornets were almost completely destroyed.

"The two species of disease now described, have each been divided into two varieties,—acute and chronic; so that we have acute and

chronic glanders, and acute and chronic farcy. This division is applicable to the disease as it occurs in man as well as in the horse."

In proceeding next to describe glanders and farcy in the human subject, we repeat the division already made of both these species, into acute and chronic, but without insisting much on its practical value. The proportion of the first variety is much greater than that of the second. Of 132 cases, of all kinds in man, collected by M. Tardieu, he found that 89 were of the acute, and 43 of the chronic form, or, rather, more than two of the former to one of the latter. M. Rayer (*op. cit.*) indicates three varieties of the acute form of the disease, regarding it (farcy and glanders) as one in its essential characters. These are, the pustular, the gangrenous, and the pustulo-gangrenous.

"In some cases, the most striking phenomena consist of a pustular cutaneous eruption, a thick and glutinous nasal discharge, and a typhoid aspect. In others, the symptoms of nasal lesion are obscure, while the external characteristics (the pustular eruption and gangrenous affection of the skin), predominate. Again, pains in the limbs, purulent deposition in various parts of the body, and inflammation of the lymphatic vessels and glands, form, in the outset, the most striking features of another set of cases, still more strictly analogous in character to the acute farcy glanders of the horse. Lastly, there are others more violent and promptly fatal, in which all these morbid changes and symptoms appear rapidly, and at once, a few days after vague initiatory phenomena."—p. 642.

"His classification, founded on another view of the subject, viz.: the cases caused by inoculation and those by infection, without contact, cannot, as yet, rest on a firm basis, since we are unable to say whether the disease in man has arisen without the positive contact of glanders matter of the horse with some portion of the skin. But, even though this theory of the causation of the disease should not be tenable, a division depending on the physiognomy which would be supposed to indicate the two forms, may still be found convenient; and hence we shall have a disease distinguished from the very beginning by local symptoms, and another variety in which the whole system is affected.

"In acute glanders, caused by inoculation, a short period of incubation occurs, similar to that which follows the application of the variolous or other animal poison, to an abraded surface or wound. This period varies from two to eight days; after which, pain, heat, and swelling occur; the pain soon becomes lancinating; and red lines, or inflamed, painful hard cords extend up the limb, constituting angioleucitis, or inflammation of the lymphatic vessels and glands, with which are associated diffuse inflammation of the subcutaneous cellular tissue, and active feverish symptoms. Often, at this time, there is a lull in the disease, which, so far, may be called farcy, but it is only to be followed by the symptoms peculiar to, and characteristic of, glanders.

"When infection was supposed to originate the disease; that is, when no local sore could be discovered, we find feverish symptoms, rigors, quick pulse and gastric affection or diarrhoea, and pain in the limbs. After the period of invasion, whatever had been the cause of the disease, whether inoculation or infection, its progress was the same, and marked by the following symptoms:

"Articular or muscular pains, in some cases simulating rheumatism, followed by subcutaneous, circumscribed painful swellings (the probable result of angioleucitis), which either undergo superficial mortification, or are converted into abscesses, containing laudable or sanious pus; a yellowish, viscous, nasal discharge, of limited quantity, issuing, in the great majority of cases, from both nares, and first observed from the fourth to the sixteenth day, accompanied, in some instances, by a similar excretion from the mouth or eyelids; occasional tumefaction of the nose and adjoining parts, followed by gangrene in one-eighth of the cases; in very rare examples, swelling of the submaxillary lymphatic glands, or depositions of pus therein; and pretty frequently inflammation of the throat and tonsils; a peculiar pustular eruption, differing from all varieties hitherto observed, viz.: gangrenous bullæ appearing towards the twelfth day of infection, on the face, arms, thighs, and anterior surface of the trunk, and sometimes preceded or accompanied by profuse fetid sweats; rapid and full pulse at the outset, subsequently weak, depressible, and some-

times intermittent, and, as death approaches, extremely small and frequent; diarrhoea, with watery stools of cadaverous smell, and occasionally containing dark-coloured blood; dental sordes; dry, brown tongue; tympanitic abdomen, with hardly any abdominal tenderness; thirst in a few cases; difficult deglutition; occasional vomiting, especially towards the close; no typhoid maculae on the surface; violent cerebral symptoms, terminating in delirium, coma, and death."—*Brit. and For. Med. Rev.*, vol. vi.

"The post-mortem appearances in subjects dead of glanders, though not very minutely described in many cases, demonstrate their perfect similarity in man and the horse. Whenever the nasal cavities have been examined, they have presented the characteristic peculiarities found in the glandered horse. These consisted of ecchymosed and gangrenous spots, a peculiar miliary eruption, compared to minute abscesses of the size of a grain of millet-seed, ulceration, and a deposit of granular tubercles in the sinuses. The nasal membrane itself was usually thickened, infiltrated, and studded with numerous granular tubercles, and covered with a thick, tenacious, puriform discharge. The bones of the nose were sometimes found corroded.

"The larynx and trachea have occasionally exhibited marks of disease, in the mucous membrane being softened, injected and livid, and occasionally covered with a peculiar confluent pustular eruption and a glutinous mucous secretion. In the lungs the appearances are analogous to those met with in lobular pneumonia: they are, also, filled with innumerable brownish or whitish tubercles, varying in size from a hemp-seed to a hazelnut. Small abscesses are occasionally met with in the substance of the lungs. Ecchymosed spots have been noticed on the surface of the heart, liver, stomach, and intestinal canal. The liver has been the seat of abscesses.

"The lymphatic ganglia were usually enlarged, often presenting a red and injected appearance; or they were of a brown colour, soft and friable. Those chiefly affected were under the jaw, along the neck, in the axilla, elbow-joint, and groin. The bronchial lymphatic glands were also very commonly affected. The cellular tissue was always much diseased, being gangrenous in some places, and very generally infiltrated with turbid serous fluid. Here and there small collections of purulent matter had taken place.

"In summing up the diagnosis of the disease, as laid down by M. Rayer, but divested of needless detail and collateral matter, we find that acute glanders may be distinguished from the results of dissection wounds, absorption of pus after capital operations, from ordinary phlebitis, angioleucitis, malignant pustule, carbuncular affections, putrid variola, &c., by the peculiar nasal discharge, pustular eruption, and the property the secreted pus possesses of producing the specific disease in sound animals.

"The treatment of this terrible disease is most unsatisfactory. M. Rayer's statement cannot be formally contradicted, when he says that acute glanders in the human subject has hitherto invariably terminated in death (one doubtful case excepted). Two-thirds of the patients perished before the seventeenth day; two died from the twenty-first to the twenty-eighth day; one only survived to the fifty-ninth. In the latter case the symptoms were those of farcy, on which those of acute glanders supervened, in the same manner as has sometimes been observed in horses. This writer suggests, if the lymphatic vessels and glands are swollen, the immediate incision of the latter; and if the local inflammation following this operation be intense, free incisions and mercurial frictions might, he believes, be serviceable. Excision, however, is seldom practicable to any extent, and the safer practice is that adopted in veterinary surgery, viz.: to cauterize the diseased glands, or other parts, by the red-hot iron. Whatever be the number of abscesses formed, they should be incised, and the cutaneous pustules and bullæ opened and cauterized; while the patient's strength is supported by tonic drinks and generous wine, diluted with gaseous water. M. Rayer is averse to blood-letting, either topical or general; and, on the other hand, he has no opinion of the efficacy of bark, serpentaria, and other alleged tonic antiseptics. He gives a preference to repeated purging, and the exhibition of large doses of acetate of ammonia.

"Not more successful is the treatment of the acute glanders in horses. Marked, as the disease is, in both man and horse, by the same symptoms, and anatomical seat and changes, whatever remedy

is discovered to be serviceable in the one, may, with some degree of confidence, be relied on in the other; and, hence, we watch with interest, all the improvements, in this particular at least, of veterinary medicine.

"Acute or *button* farcy differs from acute glanders, only, in the absence of the nasal affection. The chief symptoms of acute farcy in man are the local inflammation, swelling of the lymphatic glands and vessels, and finally of the whole limb. Numerous small tumours extend, in lines, along the limbs, and terminate in suppuration or gangrene, whilst the inflamed cord-like lymphatics are seen extending from one to the other. Abscesses form over the surface of the body and limbs; gangrenous patches occur here and there; and there is frequently attendant inflammation of the superficial veins. In every case, the peculiar pustular eruption, so characteristic in glanders, is observed. The *post-mortem* appearances correspond precisely with those seen in glanders.

"*Chronic glanders*, in man, is described by M. Tardieu to be a disease resulting from the transmission of the glanders or farcy of the solipedes, characterized by peculiar ulcerations of the nasal fossæ and air-passages, pains of the joints and museles, general symptoms of cachexia, accompanied most commonly by farcy, and terminating in acute glanders or death. The patient complains, for some time, of weakness, prostration, acute pains in the limbs and joints, sometimes excessively painful pleurodynia, and cough, sore throat, and a troublesome stuffing of the nose. When the glanders is consecutive to the farcy, as is generally the case, after a period of two, four, six, or even ten months, during which the latter affection has undergone but slight changes, symptoms of disorder in the nasal fossæ and air-passages appear. In either case, the sore throat and cough generally precede the disturbance in the nasal fossæ. Pain is felt in the trachea, with a feeling of imminent suffocation, and alteration, and almost extinction of the voice. These last symptoms sometimes disappear after a time; there is then cough with dyspnœa, and a somewhat copious expectoration, which often is suppressed. Occasionally, the disorder of the respiratory apparatus is carried to the extent of true bronchitis or pneumonia, giving rise to considerable febrile reaction. The sensation of fulness in the nose increases, and breathing through it causes a perceptible snuffle. There is little or no pain of the nose, although sometimes patients complain in this way, and refer their distress especially to the root of the nose, and between the eyes, and to the sinuses. At times, blood is blown from the nose in clots; sometimes crusts are detached, or a simple grayish puriform mucus is discharged, which, in some rare cases, constitutes a regular flow. There may now be detected, on careful examination, ulcerations causing inequalities of surface, felt by a probe, or even perforations of the septum. In the mouth, similar inspection will reveal the existence, either in the palatine arch or in the pharynx, of ulcers, which we are allowed to infer extend to the larynx and trachea. Engorgement of the submaxillary glands is rarely met with. The skin is not affected with any eruption; but it sometimes becomes œdematous at the hands and feet. To this list of special symptoms are sometimes joined the general ones, which are also met with in farcy, viz.: pains of the muscles and joints, diarrhœa, nausea, fever, with paroxysms at irregular intervals, sweats alternating with dryness of the skin; the skin of an earthy and a sallow hue, emaciation, exhaustion, wakefulness, and all the symptoms of great cachexia.

"But, in contrast with this picture, cases are seen in which there is no external character, except farcy, from the very beginning of the disease; no pain, no discharge from the nose, and only a slight cough to indicate disturbance in the respiratory functions; but yet autopsy will reveal lesions of the most serious and distinctive nature, either in the pituitary membrane or trachea, leaving no doubt of the real character of the disease.

"The period of duration of chronic glanders is long, almost as much so as that of chronic farcy. Coming on after several months' duration of this latter, it may, in its turn, last as long. Commonly, however, chronic farcy-glanders runs its course in less time than that which occurs without farcy. In this latter state it may last for a period of six years. During this time the patient enjoys intervals of ease, but rarely is the health re-established even in appearance. The constitution, once compromised, rarely rallies entirely. As respects the

mode of termination of chronic glanders, one case only of cure forbids our seeing any other than that of death for the great majority of those unfortunate persons who are victims of the disease.

"*Chronic farcy*, in man, is a morbid condition, produced by the transmission of glanders or farcy from the solipedes. It is distinguished chiefly by numerous abscesses running into fistulous ulcers, specific angioloecitis, and an entire change in the constitution; and it terminates commonly in acute glanders. Chronic farcy may exist alone or in conjunction with chronic glanders; but is of much more frequent occurrence than the latter. Of the 43 cases of contagion in man, in which the disease appeared in a chronic form, and which have been made public, 33 belong to farcy and its varieties.

"In looking over an account of the symptoms of chronic farcy, we do not find that its invasion indicates the manner in which the contagion has been applied. More generally, however, local lesions follow immediate contagion, or the inoculation of the glanders or farcinous matter, and then the disease is ushered in by symptoms of acute angioloecitis or phlegmon; but even in this respect there is no uniformity—the local lesions being sometimes wanting, although there had been inoculation. At one time the disease makes its attack with violence—at another, its approach is quite insidious. After the common precursors of disease, such as languor, want of appetite, &c., symptoms resembling those of chronic rheumatism appear, and general weakness, without adequate cause, is complained of. In six weeks or so afterwards, numerous abscesses form rapidly, and, as it were, at one growth. Tumours make their appearance in a part already predisposed on account of a contusion or other local cause, and more frequently in the limbs than elsewhere. In a case of acute glanders, detailed by Mr. Denham, at Guy's Hospital, Mr. Morgan being the surgeon at the time, the patient, a carman, was attacked with glanders consequent to an injury of the left knee, by its being jammed between two barrels. This part continued to be the seat of such organic changes, as the formation of an abscess, during the whole course of the disease, which terminated about eighteen days after the injury to the knee.

"Engorgements of the lymphatic glands in the groin and axilla are only observed as consecutive to local angioloecitis, or to an abscess in an adjoining region. As new tumours form, they continue, after being opened, to distil a serous or ichorous matter, and are converted into indolent and ill-conditioned ulcers which cannot be healed. The more superficial bones in which these ulcers appear are denuded and become necrosed; the articulations are deformed, and lose all power of motion; the skin is dry, and of an earthy hue; the hair is matted on the temples; the eyes are sunken; the face of a yellow or a livid colour; the pulse small and irregular; repeated chills prelude a fever which returns every evening. The nights, during which the body is bathed in sweat, are passed without sleep, and sometimes in much dreaming, which preceeds delirium. The appetite may last for some time, but an intractable diarrhœa supervenes, and completes the breaking down of the system. Sometimes a dry hacking cough harasses the patient, whose intellect finally becomes weakened; and his body covered with ulcers, and all the springs of life nearly dried up, he falls into a state of frightful marasmus.

"The duration of chronic farcy varies from four months to three years; the mean period being from ten to fifteen months. Sometimes there is a deceitful remission and a seeming convalescence; but a renewal of the symptoms is the signal for the persistence in disease, which commonly has a fatal termination. Of 22 cases, collected by M. Tardieu, he knows but of 6 which have been cured; and he asks whether, to a certainty, the restoration to health was permanent in all of the latter.

"The seat of the abscesses in chronic farcy is for the most part in the extremities, and generally in the lower rather than the upper ones; and in the vicinity of the joints. The matter of the abscesses varies in appearance; sometimes it is sanguinolent or sanious, and sometimes purulent, or of a grayish colour, and viscous,—occasionally without odour, and again extremely fetid. Microscopical examination does not reveal any distinctive appearances. But, after all, the most important consideration is the fact, that the matter of farcy abscesses has the property, when applied, by inoculation, to a healthy subject, of generating the disease, whether it be in a man or horse.

"In the *treatment* of chronic glanders and farcy, we cannot place

much reliance. More is to be expected from preventive measures against the disease being contracted; and, perhaps, a due appreciation of the early symptoms, or of the stage of incubation, even, may point out a course of remedies which, after the disease is fully formed, by the whole system being poisoned, will be of little avail. When there has been obvious inoculation, by the application of the glandered matter of a diseased horse, measures ought to be promptly adopted, similar to those after the bite of a rabid animal, viz.: ablation of the poisoned part, either by the knife, or by cauterization, and the use, afterwards, of stimulating washes, such as of chlorine water, strong solution of iodine, &c. In the early stage of the disease, abscesses, as they appear, ought to be opened, and either cauterized with heated iron or dressed with stimulating washes and ointments, and the healing process, which, in these cases, is very slow and difficult, aided by compresses and moderate pressure.

"The actual cautery is, and long has been, a favourite remedy in veterinary surgery, and its tried advantages, in the cure of glandered horses ought, even if direct clinical experience were wanting, to encourage its use in the glandered human subject.

"As an application to the diseased mucous membrane of the nose, creasote, recommended strongly by Dr. Elliotson, still enjoys the greatest reputation. He cured two cases of chronic glanders by injecting a watery solution of creasote up the nostrils. Mr. Ions, also, veterinary surgeon, in Waterford (Ireland), relates the cure of his own son, who had been, while yet suffering from a bad cold, and with a small sore on one of the *alæ nasi*, poisoned with the glandered matter, snorted in his face by a horse labouring under acute glanders. In two days afterwards there was a profuse discharge from the nostril, of a ropy, glairy appearance. Solution of nitrate of silver to the ulcer in the nose, and internal remedies were used without effect; and at length creasote was employed by the medical attendants, at the urgent solicitation of Mr. Ions, sen., himself. The ointment was the preparation first used, but the slightest application produced the most dreadful pain, and in its stead Mr. Ions, who now took charge of the case himself, employed a solution of two minims of creasote in an ounce of water.

"The disease had now assumed the most fearful character; there was profuse nasal discharge, accompanied by the most offensive smell, and ulcerations extending into, and seemingly occupying, the whole of the nasal cavities. There was great prostration of strength, cold perspiration, pulse 112, laborious breathing, and every appearance of approaching death."

"The solution, as above, was injected 'as high up and as universally' as possible, and its use repeated three times a day. 'I pledge my honour,' says Mr. Ions, 'that after the third injection a change almost magical took place. The discharge, in a great measure, ceased, and, two days afterwards, the ulcers began to assume a healthy appearance, and have rapidly improved ever since.' The communication was made Feb. 28th, 1839. The poisoning took place on the 20th Jan. The ulcers had all lost their chancreous character, and were assuming a healthy granulating appearance. (*Lancet*, vol. ii., 1838-, pp. 111-15.)

"Of the internal remedies, most stress has been laid on iodine and sulphur. M. Delaharpe recommends the ioduret of starch, with a slight excess of iodine; and M. Andral used, in a case of farcy, reported as cured, the ioduretted iodide of potassium. M. Tardieu would prefer the tincture of the iodine, in doses increasing gradually from two to twenty drops. Thomson reports the successful use of this preparation in a case of chronic disease in the horse. Sulphur has long and generally been used in veterinary medicine in this disease; externally by vapour to the nostrils and by ointment to the ulcers, and internally mixed with the food. In man, an advantageous method of employing it is in mineral waters, which should be drank freely, and applied externally as a wash to the ulcerous sores. As suggestive knowledge, it may be well to say that M. Youatt, although laying little stress on any curative plan for the disease in horses, tells us that blue vitriol and Spanish flies have held out the longest, among those which, at different times, enjoyed reputation in the disease in question. The deutiodide of copper has, also, he adds, been of great service in farcy, but it is not to be depended on in glanders. The tonic treatment, in all its details, should be carried out, and more

especially in the use of good substantial and nourishing food. Abstinence, or any rigidity in diet must, in the present state of our knowledge of this subject, be regarded as very prejudicial in any case of chronic glanders or farcy. Fresh and pure air are always to be included among the hygienic agents of a tonic nature, which can never be dispensed with; and if the change of climate, from a variable to a mild and equable temperature, can be procured for the patient, the probability of restoration will be increased. Pure air is relied on among the foremost remedial measures by scientific and experienced veterinary surgeons, in their treatment of glandered horses.

"Where treatment is so uncertain in its results and so often of no avail, it becomes more imperative on us to adopt all possible measures of prophylaxis. Fortunately, the poison of glanders is not generated spontaneously in the human subject as it is in the solipedes, in which alone it originates, and from which originally the poison always proceeds with which man and some other animals, as the cat and the dog, have become affected. The poison once developed in man is transmissible to other men, as well as to horses, by inoculation. The average susceptibility, as Dr. Graves has remarked, (*Clinical Lectures, ut supra*), to the poison of glanders must be small, 'for grooms and veterinary surgeons take few or no precautions for examining the diseased animals, and yet the proportion infected, compared with the number exposed, is by no means considerable.' This writer tells us, however, that from the notices which he has been able to collect, it appears that glanders in man is of very frequent occurrence in Ireland; so frequent, indeed, that he thinks the legislature called on to imitate the wise example of the Prussian government, in placing glandered horses under the surveillance of the police. M. Tardieu (p. 178) inserts the regulations of the French police on this point, which have been approved of by the Board of Health (*conseil de salubrité*). By these, all persons are forbidden to sleep, or to allow grooms to sleep, in a stable in which there is a horse, even suspected to be glanderous. The like prohibition extends to sleeping in the stables used as infirmaries for sick horses, or in any place used for lodging sick animals of any kind. Those who are allowed to take charge of glandered horses, or of horses supposed to have the disease, or who have horse infirmaries, and who are desirous of watching their animals during the night, are enjoined so to contrive it that the room of the stable-keeper or groom shall not communicate with the stable, but that the supervision shall be made through a glass window."

In the symptoms of eruption in glanders and farcy, there is no uniformity. It is chiefly pustular, and of carbuncles resembling anthracion. I shall conclude by introducing a few cases of this terrible disease.

Cases related by Dr. Graves (*op. cit.*, pp. 314-19):

I. Communicated by Dr. McDonnell to Dr. Graves.—"Patrick Wallace, a healthy muscular man, aged twenty, was admitted into the Richmond Surgical Hospital on the 6th October, 1836. It was stated that he had been in care of a glandered horse—driving, cleaning, &c.—and that he had been in the habit of drinking out of the vessel from which the horse drank. It appeared, also, that he had had an abrasion on one of his ears. On admission he had much of the appearance of a person labouring under cynanche tonsillar; he could only open his mouth to the extent of half an inch; this was the only uneasiness complained of. The left tonsil was very much enlarged, red, hard, and projecting towards the middle line; no fluctuation could be felt; there was a general fulness about the angle of the jaw, extending upwards nearly as far as the zygoma. The submaxillary gland on the same side was also enlarged and indurated. These symptoms had been ushered in by feverishness, a few days previous to admission. He was ordered to have eight leeches to the throat, to be followed by a poultice, and a bolus composed of calomel and jalap.

"Next day the external swelling was found to be increased; greater difficulty of opening the mouth; the tonsil still hard and swollen. Twelve leeches were applied to the fauces, and the patient took the tartar emetic mixture of the hospital, with sulphate of magnesia.

"On the 15th of October the disease is reported to be on the increase. Tonsil still hard, but no fluctuation; left side of the face greatly swollen; eye of the same side nearly closed, from tumefaction of the lids; general inflammatory appearance over the cheeks, and great hardness of the tissues about the angle of the jaw of the

same side, extending towards the chin; several circumscribed spots of redness, varying in extent from the size of a sixpence to that of a halfpenny, with irregular margins, scattered over different parts of the body; two pustules observable on the left leg.

"16th.—A vesicle, containing a yellowish serum, observable on the left tonsil; the same inability of opening the mouth continues; increase of swelling over the left side of the face; a small abscess has formed on the posterior part of the left forearm; some delirium during the night; three evacuations from the bowels. The tonsil to be brushed over with a solution of nitrate of silver; a blister to the fauces; the tartar emetic mixture to be continued.

"17th.—Some sleep during the night, interrupted by delirium of a low muttering character. Patient appears willing to answer questions, but cannot, from obstruction in the mouth. This, however, lasts but for a moment, and he then lapses into a state of incoherency. Mouth open to the extent of half an inch; left eye closed; considerable swelling of the left side of the face, which is indurated, hot, tense, and shining; all the glands on both sides of the jaw, but particularly on the left, are swollen and hard; same state of tonsil; nares dilated; breathing stertorous, somewhat hurried, about 28 in the minute, and interrupted by frequent sighs. Pulse very small, rapid, intermitted, and cannot be counted; skin hot, tongue furred, teeth covered with sordes. He complains of great thirst, but says he feels no pain; it is evident, however, that he feels great uneasiness in the joints and limbs when moved. There is, however, no swelling or redness of the joints; there is no discharge from the nostrils, nor is there any perceptible ulceration of the mucous membrane of the nose. No apparent affection of the absorbent glands in any other part of the body.

"During this period, vesicles and pustules of various sizes, and at various stages of growth, had made their appearance on different parts of the body, particularly on the back. They varied in size, from the head of a pin to the section of an almond. In the first stage they resembled very minute vesicles, scarcely surrounded by any inflammatory border, and containing a limpid serum. In the second stage the serum was replaced by pus; there was a considerable blush of redness around each pustule, which, at this period, became greatly increased in size. When one of the vesicles was punctured the serum appeared to come from a single cavity under the cuticle: this operation did not produce any subsidence of the tumour, a considerable hardness still remaining in the cutis or beneath it, with a cavity in the centre in which the serum was contained. A number of *achores* existed in various parts, congregated together, and not much larger than the head of a pin. These clusters were surrounded by *white raised margins*, having much the appearance of wheals, and about a line and a half or two lines in breadth; between these margins and the *achores* there existed a line of redness. The whole taken together are rather of an oval shape. There also existed numerous inflammatory spots on the right shoulder, left arm, and other parts of the body. These were of a dark brown, approaching to a livid colour; when pressure is made on them the colour disappears, but returns immediately when it is removed. On running the finger over them, a small hard tumour was felt in the centre; the margins of these spots were irregular.

"On the 17th the character of the disease became more plainly developed; at three o'clock, P. M., pus, in considerable quantity, was observed to issue from both nostrils. The patient was ordered to take the solution of chlorate of soda internally, in drachm doses, three times a day; and also a mixture composed of carbonate of ammonia, liquor ætheris oleosus, and camphor mixture. At five o'clock, P. M., he was found half out of bed, his head resting on the pillow; still able to express his wants; pulse not to be counted; legs and feet cold; breathing stertorous; numerous stigmata scattered over the surface of the body. The purulent discharge from the nostrils had ceased, but there is a discharge of mucus from the mouth, with considerable fetor of breath.

"8 o'clock, P. M.—A copious perspiration has broken out over the body; face red, tense, shining, and very much swelled; swelling has now extended to the right side of the face; right eye nearly closed; can open the left better; a few pustules have made their appearance at the inner canthus of the eye. Pulse, tongue, and skin, as in last report; delirium and muttering continue.

"Died at 4 o'clock, A. M., October 18th.

"On examining the body ten hours after death, the redness was found to have disappeared from the face; the glands about the left angle of the lower jaw as before mentioned; they were found matted to the surrounding parts. The cellular tissue covering the submaxillary and parotid glands was infiltrated with serum, and indurated; numerous depositions of pus were found in the tissue of the submaxillary and parotid glands. The brain was firm, but its ventricles contained a considerable quantity of fluid; the arachnoid membrane was opaque in many places; several patches of vascularity were observed on the pia mater. The lungs presented a congested appearance; numerous pustules were scattered over their surface—some separate, yellow in the centre, and surrounded by an ecchymosed border; others existing in clusters. They resembled, in every respect, those found on the surface of the body. The lining membrane of the larynx was very much inflamed, especially about its upper part and about the epiglottis. The inflamed parts, in this situation, were of a livid hue. There was some appearance of vesicles in the trachea, but this could not be satisfactorily ascertained. The bronchial tubes were filled with mucus. The stomach contained a quantity of yellowish-green mucus; its lining membrane presented an ecchymosed and inflamed appearance. The liver was somewhat enlarged, and adhered, by its inferior margin, to a few folds of intestine. The periosteum did not exhibit any appreciable deviation from the normal state.

"One of the chief things to be noticed in the foregoing case is the variety of inflammatory affections observed in the skin as the result of the introduction of an animal poison into the system. There was, in the first place, the general diffused redness of the face, then superficial inflammatory spots on the shoulders and arms, resembling erythema nodosum; in the next place, scattered pustules, of various sizes, commencing in the form of a vesicle, which afterwards became a pustule surrounded by an inflammatory zone; and, lastly, *achores* congregated together, and surrounded by an elevated white margin, within which there existed an inflammatory ring of a red colour. Another point worthy of notice, is the state of the lungs and bronchial mucous membrane. The lining membrane of the larynx, particularly in the vicinity of the epiglottis, was inflamed, and of a livid colour, and there was an indistinct appearance of vesicles in the trachea. But what was particularly deserving of note in the lungs, was the existence of pustules on their surface, bearing the closest resemblance to those found on the surface of the body. It is not stated whether there was any appearance of vesicles or pustules in the nose, pharynx, or œsophagus, but we are told that the stomach was ecchymosed and inflamed.

"II. The following case, says Dr. Graves, was witnessed by myself and Dr. Halahan, and seems more nearly allied to the variety of glanders termed button farcy. I regret that want of time has prevented me from arranging its details in a form more worthy of your attention; and were not the disease one of comparatively rare occurrence, I should not have ventured to lay the case before you in its present imperfect state.

"The subject of this case was a gentleman residing at Rathmines, an extensive proprietor of horses, and who, having originally graduated as a surgeon, exhibited much skill in the veterinary art. About the time of his illness he had had some horses in his establishment labouring under glanders and button farcy, to which he paid particular attention. After having laboured for some days under considerable lassitude and derangement of the stomach and bowels, he was attacked, on the 8th of July, with rigors, followed by great thirst, excessive heat of skin, and pains in his limbs. The moment he felt himself attacked in this way, he said he was sure that he had got some dangerous infection from the horses, and would never recover. He took some blue pill and colocynth, which produced a few dark and very fetid evacuations. On the 9th, his pulse was 94, his urine very high coloured, his thirst and feverish symptoms rather increased, and he suffered greatly from constant nausea and vomiting. A tumour now began to appear about three inches above the inner ankle of the right foot. He applied a poultice over it, but was obliged to remove it in a short time, in consequence of the pain occasioned by its weight. The tumour was about the size of half a walnut, of a dull red colour, tense, shining, and exquisitely painful. Its external aspect was peculiar, and might be compared to something intermediate between a boil and a spot of erythema nodosum. On the 10th, another tumour of the same cha-

acter appeared near the outer ankle of the same leg; and in this way the disease went on, tumour after tumour appearing on different parts of the body, with an increase of the feverish symptoms, until the 20th of July, when he was first seen by Dr. Halahan. At this time several tumours had appeared on different parts of his body; there was one of an extremely painful character on his head, and he complained of great tenderness and pain along the right clavicle. His thirst was still urgent, his restlessness excessive; the slightest motion gave him exquisite pain, and sleep had completely abandoned him. He had endeavoured to regulate his bowels by purgative medicines, and had applied leeches to the tumours and to the clavicle at various times, but without any decided benefit. There were eight or nine tumours on different parts of the body, of the character before mentioned, without any tendency to suppuration, and so exquisitely painful that he could only bear a single sheet over him. The inflammation about the clavicle, which was of a diffuse character, had extended up the neck and over the right shoulder; there was not much swelling, except about the clavicle; the colour of the affected parts was a peculiar dusty red. Immediately over the clavicle two vesicles were observable, filled with a transparent fluid. Three dozen leeches were ordered to be applied over the clavicle and shoulder, and the patient was directed to use chicken-broth, beef-tea, and other light nutritious articles.

"On the 21st all symptoms are stated to be on the increase. His fever, thirst, and sleeplessness are undiminished; his tongue furred and dry; his teeth covered with sordes; his pulse small, weak, and rapid; his nausea and vomiting not so troublesome. He had received no benefit from the application of the leeches; the swelling and stiffness of his neck were increased, and he had now some difficulty of swallowing. The erysipelatous surface of the neck, clavicle, and shoulder, were lightly brushed over with lunar caustic, which gave the patient an agreeable sensation, and from which he stated that he derived much relief. This was repeated the next day at his own request, and with equal benefit; the difficulty of deglutition diminished, and for two days he went on pretty well. On the 25th there was an evident increase of fever; the tumours over the body and limbs were increasing in size and number; and his anxiety, restlessness, and sufferings unabated. He had taken alternative doses of calomel and James's powder, and his bowels had been regulated by mild aperients and enemata. I saw him for the first time on the 28th. His pulse was then 98, small, and easily compressed; his thirst excessive; his restlessness and agony such as would strongly excite the pity of persons most conversant with scenes of human suffering. He had several tumours over different parts of his body, all exquisitely painful, and in their aspect something between boil and erythema nodosum. Some of them were hard to the touch; others, which appeared more advanced, were softer, and had a boggy feel. There was, however, no appearance of anything like suppuration. He was ordered sulphate of quinine, chicken-broth, ale, and other light nourishment, and an opiate at night. On the 31st, a tumour appeared on the right side of his forehead, larger and more painful than any of the rest. Another of a similar character showed itself on the right clavicle, which had been previously affected. Shortly after their appearance vesicles were observable on their surfaces, such as generally precede mortification in cases of anthrax and malignant carbuncle. Next day he was evidently worse; his pulse was 108; his fever, pain, and restlessness, unabated; and a miliary eruption began to make its appearance over his chest and abdomen. The vesicles now began to increase on the surface of the tumour; his fever and restlessness were aggravated; and his mind, which had been hitherto collected, began to wander. His restlessness was so excessive that he could not remain for a moment in the same position; and being a person of much mechanical ingenuity, he had a set of pulleys constructed and fastened to his bedstead, so that he could move himself in various directions. His medicines and diet, with the addition of claret, and opiates at night, were continued as before.

"On the 6th of August he was still worse; the tumour on the head continued to enlarge, and decided sloughing had taken place. The tumour on the clavicle presented the same aggravation in appearance and character, and a fresh tumour had appeared on the back of his head. A pustular eruption now began to make its appearance over his body, chiefly over the abdomen and limbs; his symptoms became

aggravated in every respect; the delirium and watchfulness increased; and he died on the 10th of August, about thirty-three days from the commencement of the disease. He attributed his illness to attending horses, four of which had died of button fever; and what is also curious, his nephew, who had been also engaged about the diseased animals, had fever of a typhoid character, with petechiæ of a larger sort than usual, but ultimately recovered."

*Case showing the transmission of the glanderous poison from man to the horse*—related by M. Nonat. (*Med. Chir. Rev.*, 1840.)

"In February, 1839, a young man, 21 years of age, was admitted into the Hôtel Dieu, under the care of M. Nonat. He was in a state of great prostration of strength, and highly feverish; his breathing was rapid and oppressed; the skin was hot, the face flushed, the eyelids swollen, and the eyes themselves glazed. The right side of the forehead was red, painful and puffy; further back there was a swelling on the scalp, which, when pressed upon, conveyed to the finger a sense of fluctuation. Other two abscesses existed; one on the right thigh, and the other on the left leg. Next day several pustules made their appearance on several parts of the body; and now, when the nostrils were compressed, a sanguineous frothy fluid exuded out. This pressure caused pain; and at the root of the nose the integuments began to exhibit a red and swollen appearance. During the night a purging came on, and the patient was excessively restless and uneasy.

"On the following morning there was a drowsiness, which was speedily followed by a state of complete coma; different portions of the scalp and face had become of a livid aspect; other abscesses had made their appearance in various parts of the body, and there were fresh pustules on the arms, legs, and chest; a thick yellowish-white discharge also oozed from both nostrils. All these symptoms continued to increase until next day, when death took place.

"*Dissection.*—The body was covered with pustules, which were depressed on the surface (*affaissées*), without any redness at their base, and of a dull white aspect: some were ulcerated.

"The alterations of the lymphatic system were in strict relation with the pustular eruption on the surface. The ganglia, which were the most diseased, were those in the armpits and groins.

"In addition to the abscesses noticed above, there were found many others in various states of maturity; some having the appearance of diffused purulent collections, but the greater number being very similar to what are well known under the name of metastatic abscesses. The veins of the dura mater and the cells of the diploe presented many traces of marked inflammation.

"The mucous membrane on the septum narium was swollen and highly injected with blood: here and there dark patches of ulceration, and several pustules, also, were observed. On the floor of the nostrils the mucous membrane was found thickened, very much softened, and covered with a gray-coloured *detritus*: the maxillary sinus was full of a yellowish viscid mucus.

"On the surface of the lungs there were numerous ecchymosed spots; and imbedded within their parenchyma were several abscesses—under the form of circumscribed pulmonary hæmorrhages, having a purulent infiltration in their centre. The largest of these were of the size of a walnut, the smallest of that of a hazelnut.

"*Remark.*—It was with the matter taken from one of the abscesses of this patient that M. Boulay inoculated two horses: it was inserted at the margin of the nasal passages.

"In one of them the acute form of the disease very quickly showed itself, and the animal died on the eighteenth day, after having exhibited all the usual symptoms of decided glanders.

"The other horse lived for twenty-eight days, and then died very suddenly; the immediate cause of death being certainly a rupture of the aorta; although many of the symptoms of acute glanders had been manifested during life, and also some of the most pathognomonic traces of this disease also were discovered on dissection.

"To add further weight to this conclusion—that the glanderous principle may be communicated from man to the horse, we may state that MM. Nonat and Bouley inserted some matter taken from one of the horses, which had been inoculated from their patient, into another horse, and that this last animal quickly sickened, and eventually died with all the symptoms of the genuine disease."—*Revue Médicale*.

Cases exhibiting varieties assumed by the disease (*Edinb. Month. Journ.*, June, 1841).

"CASE 1.—*Report of a case, by J. B. Tytler, Esq.*—Charles Higgs, a stout young cab-driver, was admitted into the Westminster Hospital on the 16th June, having been ill for five weeks, with severe rheumatism, pains of the legs and arms, increased at night, but without redness or swelling of the joints; the tongue furred in the centre; pulse very frequent; bowels rather confined. About three weeks ago he was bled and blistered, and felt some relief. He had three several abscesses in the lower extremities. He was treated by warm bathing, diaphoretics, and regulation of the bowels, and appeared to be making some progress toward recovery, until 23d June, when he complained of severe pain in the left leg, and swelling of the knee, with muscular pains of the chest unaccompanied by any marked constitutional symptoms. Relief was obtained from mustard cataplasms to the knee, and he continued under the former treatment, without marked alteration, till the 29th. He complains of violent pain in the head, and has had a rigor, followed by heat and fever. Ordered eight leeches to the nape of the neck, and saline purgatives, with antimony, every six hours.

"July 2d. He has again experienced some relief: the head has been shaved, and is easier; some patches of inflammation appear on the scalp. Ordered to continue the saline purgatives.

"4th. An extensive but very flat carbuncle has formed on the vertex, and having been freely incised, is dressed with resinous ointment, and poulticed. There is considerable fever.

"5th. Another carbuncle has formed on the left eyebrow. The right eyelid and cheek are much swollen and cracked in several places, discharging an extremely fetid sanies. The scalp looks erysipelatous, and is dusted with flour, and covered with cotton wool. The pulse is quick and weak; and the breathing hurried. He complains of sore throat. He takes wine and cinchona.

"6th. The throat is now extremely sore: the tongue, which had been usually pretty moist, is parched and red; breath fetid; some offensive discharge from the right nostril; pulse very rapid and small. On examining the throat, many irregular yellow ulcerated patches are seen. Wine and bark continued.

"7th. A number of pustules have appeared on the arms and legs; the throat is more ulcerated, and the right eye closed by the swelling; the sanious discharge continues. He has fallen into a low muttering delirium.

"8th. All the symptoms are aggravated; and his occupation having given rise to suspicions of glanders, which were confirmed by persons who had seen the disease in the human subject, his friends were minutely examined, and now acknowledged that not only had he been working about a glandered horse, but that a fellow-servant had died recently from the disease, by infection from the same animal. The horse also died. The patient himself died at 3 A. M. On examination ten hours after death, the fauces were found coated with sanious matter, which had collected about the angle of the jaws, and flowed into the trachea and gullet. The palate and fauces, with the posterior nares, were sloughy; a small ulcerated patch existed in the lining membrane of the trachea, just opposite the cricoid cartilage, and the larynx was generally much inflamed. The thoracic and abdominal viscera were healthy; the brain was not examined.

"This case seems to have lasted long, and, for forty-eight days, the symptoms were very ill defined.

"CASE 2.—*Report of a case of glanders in the human subject, by Alexander Graham, Esq.*—J. S., a carter, aged seventeen, consulted me on the 2d February, 1840, about a pain he had felt for some days previous in the index finger of the right hand, which was swelled, and slightly inflamed. The skin covering the first phalanx was of a livid colour, and there was fluctuation underneath. He had a considerable degree of febrile irritation. On opening the finger, a very small quantity of thin grayish-coloured fluid escaped, without affording any relief from pain. The soft parts appeared dead, but no line of separation was observable, nor indeed for many days after were there any symptoms of impending danger. He continued in nearly the same state till the evening of the fifth day from the time I first saw him, when the soft parts covering the first phalanx came off during the dressing, leaving the bone exposed. On removing the bone, which was easily done, without causing the least pain to the patient, the part presented the appearance of a very healthy-looking sore, and the red-

ness and swelling of the hand and finger entirely disappeared. On the following day, however, a new and more alarming train of phenomena presented themselves. During the preceding night, he experienced a great tendency to rigors; there was increased pyrexia, and he complained of a pain over the spine of the left tibia, near its distal extremity. At this place there was a small circumscribed tumour, which was very painful to the touch. The integuments were slightly inflamed, and an obscure fluctuation was also observed. On interrogating him and his friends closely regarding the sore on his finger, it was discovered that he had been driving a glandered horse, and that it was possible it might have been produced by his finger, which was scratched, coming into contact with the diseased animal.

"On the eighth day the tumour over the spine of the tibia had nearly disappeared, but he experienced severe and constant pain from the site of the swelling along the inside of his leg, as far as the middle of the thigh, which was tense and swelled. He showed much restlessness and anxiety; his stools were of a darkish-green colour, thin, and fetid; his tongue was loaded, and he had great thirst. The pulse was quick and small.

"On the following day (the ninth) his finger appeared to be healing; but he informed me that he had passed a very restless night, without sleep, and that the pain of his leg was more severe. The absorbents now became red and hard, and their course could be traced distinctly as far as the knee joint. The leg and thigh were more swelled, and the tumour was hardly perceptible. The pulse was 120, and small, the skin hot and dry, and the tongue very foul.

"Next day I found the leg and thigh more swelled, and found it necessary to make several incisions on the inside of the leg. They did not bleed much, but nevertheless afforded the patient some relief. His bowels were open, and the stools were fetid. From this time he became gradually worse; and on the evening of the day before that on which he died, (the twelfth,) when I visited him in company with a professional friend, we found a general tumefaction of the whole body, but mostly of the left side. His head and face were much enlarged, and, in addition to this increased swelling, there were all over his body and face several distinct and prominent pustules, resembling variola, none of which were visible the preceding day. The inside of the leg and thigh was also covered with a great number of gangrenous spots, of irregular size and shape, ranging from the bulk of a split pea to that of a shilling, but without vesication, or the least appearance of separation. These gradually increased in size and number until he died, on the 13th February.

"During the whole course of his disease, and even up to the very close of it, there was not the least manifestation of any disturbance in the sensorial functions."

Case of acute glanders following a bite from a horse, and where new symptoms were seen, by M. Landouzy (*Med. Gaz.*, 816).—"A vine-grower, fifteen days after buying a horse, in July, 1843, perceived that it was labouring under glanders. The disease was communicated to an ass living in the same stable. In order to make the horse take the drinks, the proprietor used to open his jaws with the help of a rope. One day the rope broke, and the jaws closing suddenly, he received a bite on his cheek. On the 20th of December, being two days after this, symptoms of acute glanders manifested themselves. A pustular eruption, abundant discharge from the nares, dyspnoea, diminution of the respiratory murmur, abscesses, &c.; and in addition to these symptoms, there appeared one that has not yet been described—opacity of the cornea.

"The man died on the 2d of January. At the autopsy an abundant eruption was found on the thorax and the abdomen: the bronchi were covered by a miliary eruption; the lung was filled with abscesses; the liver and spleen were evidently increased in size; in the intestines there was a miliary eruption above and below the cæcum, and in the cæcum seven ulcerations, a lesion that has not yet been mentioned. The principal features of interest which the case presents are, its inoculation by a bite, the opacity of the cornea, and the ulcerations of the cæcum.

"M. Barthelemy remarked, that the horse had been five months ill, and that, consequently, as the case was one of acute glanders, communicated by a bite from an animal chronically diseased, the distinction which some persons had attempted to establish between acute and chronic glanders was not warranted."—*Veterinarian*, Sept. 1844.

# FORMULARY.

## BATHS.

Baths ought to be prepared with soft or river water. A bath is generally taken at about blood heat, 97 of Fahrenheit; but it may be prescribed at a lower or a higher temperature according to the indications to be fulfilled. The time of remaining in a bath extends from half an hour to an hour or several hours.

### Acid Bath.

Water		
Hydrochloric or sulphuric acid	galls. xxx.	℥ii to ℥iv.

### Alkaline Bath.

Water		
Subcarbonate of potash	galls. xxx.	℥iv.

### Bath of Bran Water.

Water		
Bran	galls. xxx.	℔s. iv.

Boil the bran in ten or twelve quarts of water for half an hour, pass the decoction through a hair sieve with squeezing, and add it to the bath.

### Emollient Bath.

Emollient herbs, (althea, marshmallow, elder flowers, parietaria, &c.)		℔s. iv.
Linseed		℔ss.

Tie the linseed and herbs loosely in a cloth; boil them in 30 ℔s. of water, express, and add the decoction to a tepid bath.

### Gelatinous Bath.

Purified gelatine		℔i.
Dissolve in 10℔s. of water, by boiling, and add the solution to a bath.		

### Iodurated Baths, (Lugol.)

Water		galls. xxx.
Add to this for baths of increasing strength.		

No.	Iodine.	Ioduret of potassium.
1.	℥ii.	℥iv.
2.	℥iiss.	℥v.
3.	℥iii.	℥vi.
4.	℥iv.	℥viii.

### Sublimate or Bichloride of Mercury Bath.

Water		galls. xxx.
Bichloride of mercury		℥ii to ℥i.
This bath should be taken in a wooden bathing tub.		

### Soap Bath.

Water		galls. xxx.
Soap		℔i.

### Sulphureous Water Bath.

Water		galls. xxx.
Sulphuret of potash		℥iv.
With the addition of a pound of gelatine the gelatino-sulphureous bath, in such frequent use, is prepared. (a.)		

## CATAPLASMS.

Cataplasms are generally applied warm; cool or cold they are sometimes more effectual in relieving pruritus and subduing heat of skin.

(a) See recipes for sulphureous washes, at p. 138. Also, imitation of Barèges water for bathing, at p. 57.

### Soothing Catapasm.

Crum of bread		℥iv.
Milk		℔i.

Bring to the boiling point over a slow fire, stirring the mixture.

[The poultice made by pouring boiling water over a sufficient quantity of crum of bread, letting it stand for a few minutes, and then draining off the superfluous moisture, is generally a much better application than the poultice of bread and milk.]

### Narcotic Emollient Catapasm.

Linseed		℥iv.
Boiling decoction of poppyheads a sufficient quantity;		
add of Extract of Hyoseyamus		℥i.

## CAUSTICS.

Caustics or escharotics are in familiar use for the destruction of the skin and subcutaneous tissues when affected with disease, or for the purpose of changing the mode, the form, or the nature of an inflammatory affection of the integuments.

### Burned Alum.

Burned or desiccated alum is used in powder to a variety of ulcers of the skin; the quantity employed varies with the extent of surface to be stimulated. It is either sprinkled upon the parts with the fingers, or dusted over them with a dossil of lint.

### Nitrate of Silver.

The nitrate of silver melted and run into moulds is one of the caustics most frequently employed of all. The point of the caustic is dipped into water and applied to the part affected, during a longer or shorter space of time, according to the effect intended to be produced. If the application have been lengthened, a thin grayish and superficial eschar is produced. When minute points of the skin only require to be touched with the caustic, the stick may be shaped into a black-lead pencil.

### Potassa Fusa.

A piece of potassa fusa or of potassa cum calce, weighing a grain, and about a line and a half in diameter, applied to the skin, will, in the course of from three to four hours, occasion a grayish eschar of about half an inch in diameter, implicating the whole substance of the skin.

### Muriate or Butter of Antimony.

This caustic from being fluid has the advantage of penetrating readily into all the windings and inequalities of the sores or diseased surfaces to which it is applied. It causes eschars that are drier and better defined than those that result from the application of the potassa fusa.

### Acids.

The concentrated mineral acids, the sulphuric, nitric and hydrochloric, are all used in the same manner. Applied pure, they occasion deep eschars; diluted with water, they may be used to stimulate certain chronic inflammations. The concentrated mineral acids are frequently employed to cauterize malignant pustule in its early stages, warts, tubercles, &c.

### Acid Nitrate of Mercury.

Nitric acid		℥i.
Proto-nitrate of mercury		℥i.

This caustic is frequently and beneficially used in the treatment of certain ulcers. A piece of lint is dipped in the solution and applied to the affected surface, either continuously for as long a time as may be deemed necessary, or is simply dabbed repeatedly upon the part. If the object be to produce a deep eschar, a quantity of scraped lint is spread upon the part, and being then imbibed with the caustic solution, is kept in its place by means of a bandage. A single application of any caustic may suffice in some cases, several may be found necessary in others.

*Arsenical Paste, and Chloruret of Zinc.*  
(For these caustics vide sub. POWDERS.)

## CERATES.

*Cerate of the Subacetate of Lead.*

Simple cerate . . . . . 3i.

[White wax one part, oil of sweet almonds four parts;  
melt with a gentle heat, and as they are cooling stir  
in three parts of rose water.]

Solution of subacetate of lead (Extract. Saturni) . . . 3i.

Mix in a marble mortar. The quantity of the mineral solution may be variously increased, an ounce being in some cases not too much.

*Cerate of the Acetate of Morphia.*

Cerate . . . . . 3i.

Acetate of morphia . . . . . gr. iv.

Dissolve the acetate in a little alcohol, and mix it well with the cerate.

*Sulphur Cerate.*

Cerate (without the addition of water) . . . . . 3ii.

Sublimed sulphur . . . . . 3iv.

## DOUCHES.

Douches, to their action of simple lotions, add percussion to a greater or less degree of the parts against which they are directed. The jet is either made to ascend or to descend. It is administered during ten, fifteen or twenty minutes. After the douche, patients are often directed to take a bath for half an hour.

## FOMENTATIONS.

All the compounds employed as baths and douches may be used as fomentations.

Cool or cold fomentations are usefully employed in several of the acute and chronic inflammations of the skin.

*Of the Subacetate of Lead.*

Water . . . . . lbj.

Solut. of subacetate of lead, from . . . . . 3ii to 3i.

## FUMIGATIONS.

Fumigations or fumigating baths are prepared with substances susceptible of being converted into vapour, which, by means of a suitable apparatus, is applied to the whole or to a portion only of the body.

*Of Calomel.*

Proto-chloride of mercury (calomel) . . . . . 3ii.

*Of Cinabar.*

Red sulphuret of mercury . . . . . 3ss to 3iii.

Local fumigations of this substance are readily applied by means of a hot tile and a funnel.

*Of Sulphur.*

Sulphur . . . . . 3iv to 3i.

## LINIMENTS.

*Mercurial.*

Olive oil . . . . . 3i.

Liquor of ammonia . . . . . 3i.

Strong mercurial ointment . . . . . 3ii.

Useful in the treatment of the syphilitic eruptions.

*Chlorine.*

Water saturated with chlorine . . . . . 3i.

Oil of sweet almonds . . . . . 5i.

Used to disperse the dark stains consecutive on syphilitic pustules, tubercles, &c.

*Hydrochloric Acid.*

Balsam of Fioravanti . . . . . 3iv.

[Alcohol distilled over a host of aromatics; cloves, cinnamon, nutmeg, styrax balsam, Venice turpentine, &c., &c. Eau de Cologne or proof spirit with a drop or two of any essential oil, may be substituted for it.]

Hydrochloric (muriatic) acid . . . . . gtts. xxxii.

Useful in recent and unexcoriated chilblains. The parts affected are rubbed night and morning with a little of the mixture.

## LOTIONS.

As lotions, plain water, and decoctions or infusions of various emollient, narcotic and astringent vegetables are employed. Cool or cold they are very useful in a great variety of acute and chronic inflammations of the integuments.

*Spirituos Mercurial.*

Rose water . . . . . lbj.

Eau de Cologne . . . . . 3i.

Bichloride of mercury (corrosive sublimate) . . . . . grs. viii.

Very useful in old cases of rosacea. The quantity of bichloride may be increased till it amounts to 3ss.

*Mercurial.*

Almond emulsion . . . . . lbj.

Bichloride of mercury . . . . . grs. xii.

Eau de Cologne . . . . . 3i.

This is similar to but not so active as the Gowland's lotion.

*Phagedenic Mercurial.*

Bichloride of mercury . . . . . grs. xxx.

Lime water . . . . . lbj.

The corrosive sublimate is decomposed, a chlorate of lime or chloride of calcium, and an oxide of mercury being formed; it should always be well shaken before being used.

*Mercurial.*

Rose water . . . . . 3iiss.

Mercurial water of the *codex*, [a compound of the liquor

of subacetate of lead, alum, corrosive sublimate, sal

ammoniac, and water] . . . . . 3ss.

Used to destroy pediculi pubis.

*Sulphate of Copper.*

Sulphate of copper . . . . . 3ss to 3i.

Distilled water . . . . . lbj.

*Hydrocyanic.*

Distilled water of the lettuce . . . . . 1bssii.

Medicinal prussic acid . . . . . 3ii to 3iv.

Used in impetigo and ulcerated cancer.

## PILLS.

*Asiatic, (Arsenical.)*

Arsenious acid . . . . . English. French.

Powdered black pepper . . . . . 55 grs. troy 66 grs.

Gum Arabic . . . . . 9 drachms 9 drs. (gros.)

Water . . . . . q. s. 2 drs.

Water . . . . . q. s. q. s.

The arsenious acid and black pepper powder are triturated for a long time together in an iron mortar. The gum Arabic is then added, and in a marble mortar, water is added in sufficient quantity to make a mass which is divided into 800 pills.

These pills contain nearly 1-14th of a grain English, of arsenious acid in each.

*Arsenical.*

Arsenious acid . . . . . 1 gr.

Gum Arabic and mucilage, q. s. to make 12 pills.

The dose is one a day for adults.

*Plummer's Pills, (Mercurial.)*

Protochloride of mercury, (calomel) } . . . . . aa 3i.

Golden sulphuret of antimony } . . . . . q. s.

Mucilage . . . . . q. s.

Make pills of 3 grs. each.

The recipes for these pills vary.

*Of Dulcamara and Sulphuret of Antimony.*

Extract of dulcamara . . . . . 1bss.

Sulphuret of antimony . . . . . 3ii.

Powder of dulcamara . . . . . q. s.

To form a mass to be divided into pills weighing 4 grs. each.

These pills are the same as those denominated *Kunkel's*, in all but the addition of the powder of dulcamara. They vary in their effects with the sulphuret of antimony with which they are prepared, and the quantity of arsenic it contains.

*Of Dulcamara and Arsenic.*

Extract of dulcamara . . . . . 3i.

Arsenious acid . . . . . gr. i.

Mix and make eighteen pills.

Dose, one daily.

*Of Protochloride of Mercury, (Calomel.)*

Protochloride of mercury, (calomel) . . . . . 3i.

Gum guaiacum . . . . . 3ii.

Syrup of buckthorn . . . . . q. s.

Make into seventy pills.

Two for a dose, night and morning, drinking a glass of infusion of hops after each dose, and taking a purgative draught occasionally.

*Of Protoioduret of Mercury.*

Protoioduret of mercury . . . . . gr. ii.

Gum guaiacum . . . . . gr. xii.

Starch and mucilage . . . . . q. s.

To make six pills.

Dose, one a day.

*Of Sedillot, (Mercurial.)*

Strong mercurial ointment . . . . .	℥i.
Spanish soap . . . . .	℥ii.
Althea root and mucilage . . . . .	q. s.
To make 36 pills, weighing 4 grs. each.	
Dose, two or three a day.	

*Of Mercurial Ointment and Opium.*

Mercurial ointment . . . . .	℥ii.
Extract of opium . . . . .	℥ss.
Powder of althea root . . . . .	℥iij.
Syrup . . . . .	q. s.
To make 72 pills, each containing a grain of mercury, and half a grain of watery extract of opium.	
Dose, same as Sedillot's pills, and may be substituted for these advantageously in the syphilides which are accompanied with nocturnal pains in the bones and joints.	

## UNGUENTS.

*Alkaline.*

Slaked quick lime } . . . . .	āā ℥i. (a)
Subcarbonate of soda } . . . . .	
Watery extract of opium . . . . .	gr. xv.
Lard . . . . .	℥ii.
Essence of bergamot . . . . .	gtts. x.
Prescribed in prurigo.	

*Strong Mercurial.*

Lard . . . . .	} equal parts by weight.
Mercury . . . . .	
Rub till the mercury is extinguished.	

*Of the Protochloride of Mercury, (Calomel.)*

Calomel . . . . .	℥i.
Lard . . . . .	℥i.
Used in various pustular and squamous inflammations of the skin.	

*Of the Ammoniacal Protochloride of Mercury.*

Ammon. pr. chlor. of merc. . . . .	℥i.
Lard . . . . .	℥ii.
Prescribed in Rosacea and Sycosis, when the inflammation is no longer acute.	

*Of the Proto-chloride of Mercury and Sulphur.*

Lard . . . . .	℥i.
Calomel . . . . .	℥i.
Sublimed sulphur . . . . .	℥iss.
Essence of bergamot . . . . .	gtts. x.

*Of the Cyanuret of Mercury.*

Cyanuret of mercury . . . . .	℥ss.
Lard . . . . .	℥i.
Ess. of bergam. . . . .	gtts. x.
Used in chronic lichen and eczema in quantities of half a drachm, gradually increased.	

*Of the Protoioduret of Mercury.*

Protoiod. of merc. . . . .	gr. xx.
Lard . . . . .	℥i.
Ess. of bergam. . . . .	gtts. x.
This salve expedites the cicatrization of cutaneous syphilitic sores. The quantity of the protoioduret should be increased or diminished, according to its effects, and as the parts are inflamed in a greater or less degree.	

*Of the Deutoioduret of Mercury.*

Deuto-iod. of merc. . . . .	gr. vi to xii.
Lard . . . . .	℥i.
For the discussion of tubercles and syphilitic ulcers.	

*Of the Ioduret of Sulphur.*

Ioduret of sulphur . . . . .	gr. iii.
Lard . . . . .	℥i.
Dose, a scruple by way of friction.	

*Of the Nitrate of Mercury.*

Nitrate of mercury . . . . .	℥i.
Spermaceti ointment . . . . .	℥i.
Used in prurigo, sycosis, &c. (b)	

*Of the Sub-deutosulphate of Mercury.*

Sub-deutosulph. of merc. (turpeth mineral) . . . . .	grs. xxx.
Lard . . . . .	℥i.
Ess. of bergamot . . . . .	gtts. x.
Useful in inveterate psoriasis.	

(a) Of anthrokokali, and of fuligokali, see pp. 301-2.

(b) See formulæ of various anti-pruriginous ointments in note to p. 231.

*Of the Red Oxide of Mercury.*

Fresh butter . . . . .	℥iii.
White wax melted . . . . .	℥iii.
Red ox. of merc. (red precipitate) } . . . . .	āā ℥iss.
Camphor . . . . .	
Used in Rosacea.	

*Of the Bichloride of Mercury.*

Lard . . . . .	℥i.
Bichlor. of mercury (corrosive sublimate) . . . . .	℥i.
Rub them well together in a glass mortar for six hours: and during the last hour add of hydrochlorate of ammonia . . . . .	
Used in the way of friction, in doses of a drachm, to the soles of the feet.	

*Of Pitch or Tar.*

Pitch melted by means of heat } . . . . .	āā ℥i.
Lard, also melted } . . . . .	
Mix and pass through a piece of fine rag. (a)	

*Of the Subacetate of Lead.*

Liquor of the subacetate of lead . . . . .	℥ii.
Olive oil . . . . .	℥ii.
Yellow wax . . . . .	℥ss.
Camphor . . . . .	gr. x.

*Of the Subcarbonate of Potash and Sulphur, (Helmerich's ointment.)*

Lard . . . . .	℥i.
Sublimed sulphur . . . . .	℥ii.
Sub-carbonate of potash . . . . .	℥i.
Use. In scabies, in the dose of an ounce in friction daily. (b)	

*Of Spermaceti.*

Olive oil . . . . .	℥iv.
White wax . . . . .	℥i.
Spermaceti . . . . .	℥ii.
Used in chaps of the lips, &c.	

*Of White Hellebore.*

Powder of white hellebore . . . . .	℥i.
Hydrochlorate of ammonia . . . . .	℥i.
Lard . . . . .	℥i.
Used as a stimulant in various chronic diseases of the skin, such as inveterate psoriasis, lepra, &c. (c)	

*Of Cacao Butter.*

Cacao butter . . . . .	℥ss.
Oil of sweet almonds . . . . .	℥ii.
Mucilage of quince seeds . . . . .	℥ii.
Used in chapping of the nipples, &c.	

*Of Oxide of Zinc.*

Oxide of zinc . . . . .	℥i.
Lard . . . . .	℥vi. (d)

*Depilatory.*

Lard . . . . .	℥ii.
Sub-carb. of Soda of commerce . . . . .	℥iii.
Slaked quick lime . . . . .	℥ii.
Used in favus.	

## POWDERS.

*Of the Sulphuret of Antimony.*

Sulphuret of antimony } . . . . .	āā grs. xii.
Sugar } . . . . .	
To be divided into twelve doses. The effects of the medicine vary according as the sulphuret of antimony contains a larger or smaller proportion of arsenic.	

*Of Calomel and Arsenious Acid.*

Calomel prepared by sublimation . . . . .	199 parts.
Arsenious acid . . . . .	1 part.
Use. In ulcerated lupus and cancer.	

(a) In note to p. 237, see formula for naphthaline ointment.

(b) See also note to p. 138.

(c) The following is advantageously used to stimulate sebaceous secretion:

Elderflower ointment . . . . .	℥i.
White of egg . . . . .	℥i.
Croton oil . . . . .	℥x.

To be used night and morning.

*(d) Sulphuret of Copper and Zinc.*

Elder flower ointment . . . . .	℥i.
Sulphate of copper or zinc . . . . .	℥i.
To be used twice or thrice in the day.	

Useful in sebaceous flux.

*Of Sulphuret of Lime. (Of Pyhorel.)*

Sulphuret of lime . . . . . ℥ii.

Use. Rubbed on the palms of the hands with a little oil, in scabies.  
The sulphurets of potash and soda may be used in the same manner.*Depilatory.*Lime . . . . . ℥i.  
Sub-carb. of potash of commerce . . . . . ℥ii.  
Charcoal powder . . . . . ℥i.

Used in favus.

*Depilatory of Plenck, of the Sulphuret of Arsenic.*Quicklime . . . . . ℥iss.  
Starch . . . . . ℥x.  
Sulphuret of Arsenic . . . . . ℥i.

It is made into a soft paste with water, and applied to the parts to be denuded.

*Of the Hydrochlorate of Gold.*Hydro-chlor. of gold and soda . . . . . gr. i.  
Powder of lycopodium . . . . . gr. ii.

To be divided into fifteen parts, and one used daily, being rubbed on the tongue and gums in syphilis. The dose to be gradually increased. The preparation exposed to the air is rapidly decomposed. It is also given in the shape of pills, each containing 1-15th of a grain.

*Of Sulphuret of Mercury and White Oxide of Arsenic (of Rousselot).*Sulphuret of Mercury . . . . . ℥i.  
White oxide of Arsenic . . . . . ℥ss.  
Dragon's blood . . . . . ℥ss.*Arsenical of Dubois.*White oxide of arsenic . . . . . ℥ss.  
Dutch vermilion . . . . . ℥i.  
Dragon's blood . . . . . ℥iv.

A little of this powder is made into a thick paste with water or mucilage, and applied to the surface of open cancers, freed from incrustations.

*Arsenical of Frère Come.*Arsenious acid . . . . . gr. x.  
Cinnabar . . . . . ℥ii.  
Charcoal of an old shoe . . . . . a pinch.

Applied in the same way as the last. It must be used very cautiously, and only to limited portions of the ulcerated surface at the time.

*Of Chloride of Zinc.*Chloride of Zinc . . . . . 1 part.  
Flour . . . . . 3 parts.

Use. Same as the arsenical powders. It must be very slightly moistened, and left to attract moisture from the atmosphere for some time before it is applied.

## SYRUPS.

*Compound of Sarsaparilla (of Larrey).*Sarsaparilla . . . . . lbj.  
Dried elder berries . . . . . lbss.  
Guaiacum . . . . . ℥iv.  
China-china } . . . . . āā ℥ii.  
Sassafras }  
Senna leaves } . . . . . āā ℥ss.  
Boragae }  
Sugar . . . . . lbvi.  
Water . . . . . q. s.

Mix and add to each pound of syrup.

Watery extract of opium }  
Bichloride of mercury } . . . . . āā grs. v.  
Hydrochlorate of ammonia }

Used in syphilis. Dose, one or two tablespoonfuls daily.

The following is the formula used in the Hospitals of Paris:

Bichloride of mercury } . . . . . āā grs. xx.  
Hydrochl. of ammon }  
Extract of opium }  
Hoffman's anodyne liquor . . . . . ℥ii.  
Syrup of sarsaparilla . . . . . lbiv.*Of Mercurial Ether.*Simple syrup . . . . . lbj.  
Mercurial ether (sulphur. ether, ℥i. Corros. sublim. grs. xvi.) . . . . . ℥i.

Used in syphilis. Dose, from one to four drops daily.

*Antisyphilitic of Laffecteur.*Sarsaparilla . . . . . lbj.  
Guaiacum . . . . .  
China-china } . . . . . āā lb. vi.  
Sassafras }  
Yellow cinchona bark . . . . . lbiii.  
Boragae flowers . . . . . lbj.  
Anise seeds . . . . . ℥iv.  
Purified molasses . . . . . lbs. xxx.

A simple compound decoction is first to be made with a sufficient quantity of water, after maceration for forty-eight hours. Add the molasses at last, and bring the decoction to the consistence of syrup. (a)

*Of Fumitory.*Expressed juice of fumitory, depurated by heat . . . . . lbii.  
White sugar . . . . . lbii.  
Make a syrup.*Of wild Pansy.*Expressed juice of the leaves, depurated . . . . . lbii.  
White sugar . . . . . lbii.  
Make a syrup.

## SOLUTIONS.

*Of Arsenite of Potash (Fowler's Solution).*Protoxide of arsenic, in powder } . . . . . āā 32 grs.  
Subcarbonate of potash }  
Distilled water . . . . . ℥iv.

Digest in a sand bath in a flask, till the oxide is dissolved. When cold, add two drachms of the compound spirit of lavender, and a sufficiency of water to bring the whole to a pound. A very active medicine, to be used with great discretion; five or six drops gradually increased to twenty.

*Of Arseniate of Soda (Pearson's solution).*Arsen. of soda . . . . . gr. iv.  
Distilled water . . . . . ℥iv.  
Dose, twenty drops to half a drachm, daily.  
Used in chronic eczema, lichen agrius, &c.*Of Arseniate of Ammonia.*Arseniate of ammonia . . . . . gr. vi.  
Distilled water . . . . . lbss.

Used in chronic eczema with discharge, but little inflammation. Dose, same as last formula.

*Of the Bichloride of Mercury (of Van Swieten).*Bichl. of mercury . . . . . gr. viii.  
Alcohol . . . . . ℥i.  
Distilled water . . . . . lbj.

Dose, a tablespoonful daily in a glass of water, or of milk, or of decoction of sarsaparilla.

*Of Subcarbonate of Potash.*Subcarb. of potash . . . . . grs. xxiv.  
Decoction of dogs-tooth grass . . . . . lbii.

The dose of subcarb. of potash may be carried the length of half a drachm.

## TINCTURES.

*Of Camphorated Cantharides.*Tinct. of cantharides . . . . . ℥iv.  
Camphor . . . . . ℥i.

Dose, 4, 6, 8, 10, 15, 20, and 30 drops gradually increased. This acts less powerfully on the urinary organs than the common tincture.

## TISANS.

*Of Daphne Mezereum and Sarsaparilla.*Sarsaparilla root . . . . . ℥ii.  
Bark of the mezereon root . . . . . ℥i to ℥ii.  
Boil in three quarts of water till a third is wasted; add near the end,  
Coriander seeds } . . . . . āā ℥i.  
Liquorice root. }*Of Ormus Pyramidalis.*Bark of ormus pyram. . . . . ℥i.  
Water . . . . . lbiss.

Reduce to lbii. by boiling.

*Of Muriatic Acid.*Water . . . . . lbii.  
Simple syrup . . . . . ℥ii.

Muriatic acid q. s. to make the liquor pleasantly acid.

*Of Sulphuric Acid.*Water . . . . . lbii.  
Sulphuric acid . . . . . ℥ss.  
White sugar . . . . . ℥ii.  
Essential oil of lemon peel . . . . . gtts. ii.

The mixture is more energetic without the sugar.

(a) M. Gibert has lately directed the attention of the Academy of Medicine to a formula which he terms syrup of ioduretted deutioduret of mercury (*sirup de deuto-iodure-ioduré*). The formula for this syrup is the following:—Deutoioduret of mercury . . . . . 1 part  
Ioduret of potassium . . . . . 50 parts.  
Water . . . . . 50 "  
Dissolve, filter, and add of simple syrup . . . . . 2400 "

The average dose is from four to six drachms.

*Of Sarsaparilla.*

Sarsaparilla root . . . . . ℥ii.  
 Macerate for twelve hours in  
 water . . . . . ℥iiss.  
 Which are reduced to ℥ss. by boiling.

*Of Sarsaparilla and Sulphuret of Antimony (Tisan de Feltz).*

Root of sarsaparilla . . . . . ℥i.  
 Sulphuret of antimony (tied up in a bag) . . . . . ℥i.  
 Isinglass . . . . . ℥iv.  
 Boil the sarsaparilla and sulphuret of antimony in a pint and a half of water;  
 add the isinglass already dissolved in a little water; reduce to a pint by boiling,  
 which the patient will take during the course of the day.

*Of Sarsaparilla and Arsenious Acid.*

Tisan of sarsaparilla . . . . . ℥ii.  
 Arsenious acid . . . . . gr. 1-16th.  
 Used in the same way as the last.

*Compound of Sarsaparilla (Tis. de Vinache).*

Sulphuret of antimony . . . . . ℥ii.  
 Sarsaparilla . . . . . }  
 China-china . . . . . } āā ℥iiss.  
 Guaiacum . . . . . }  
 Sassafras . . . . . } āā ℥ss.  
 Senna leaves . . . . . }

Tie up the sulphuret of antimony in a bag; boil with the three first articles in  
 three quarts of water. When reduced to a third, add the senna and sassafras,  
 which are only to be infused. When cold, decant and allow to settle.

*Of Walnut husks, Sarsaparilla, &c., (of Pollini).*

Green walnut husks . . . . . }  
 Sarsaparilla . . . . . } āā ℥ss.  
 China-china . . . . . }  
 Pumice stone pulverized . . . . . }  
 Sulphuret of antimony . . . . . }  
 Boil in two quarts of water till reduced to one half.  
 Dose, a spoonful every hour.

*Of Sarsaparilla, Alum, Senna, &c. (Decoction of Zittman.)*

[A purgative compound decoction of sarsaparilla, which has been vaunted in  
 syphilitic complaints].

• *Zittman's Decoction modified.*

No. 1.  
 Sarsaparilla . . . . . ℥xii.  
 Liquorice root . . . . . ℥ss.  
 Senna leaves . . . . . ℥iii.  
 Anise seeds . . . . . ℥ss.  
 Sulphate of alumina . . . . . ℥ss.  
 Calomel . . . . . ℥ss.

Boiled in a sufficient quantity of water to fill sixteen bottles after the decoction  
 is complete.

No. 2. Residue of the above.  
 Sarsaparilla . . . . . ℥vi.  
 Liquorice root . . . . . ℥vi.  
 Cinnamon . . . . . ℥iii.  
 Lemon-peel . . . . . ℥iii.  
 Cardamom seeds . . . . . ℥iii.

After decoction, fill sixteen bottles. (a)

(a) For an enumeration of remedies in chronic cutaneous diseases, see "Pre-  
 liminary Considerations" by the author from p. 32 to 65, and "outlines &c.," by  
 the editor, p. 56 to 58.

# EXANTHEMATA.

---

THE exanthemata are characterized, when at their height, by red spots or surfaces, which disappear for a short time under the pressure of the finger. There are seven of them, viz :—measles, scarlet rash, scarlet fever, erysipelas, erythema, urticaria and the syphilitic exantheme.

## FIRST GROUP.

This comprises the febrile exanthemata—*rubeola*, *roseola*, *scarlatina* and *erysipelas*.

*RUBEOLA* (or *measles*) is characterized by blotches, sometimes slightly elevated, developed on the skin, leaving the interspaces of a natural colour, or presenting a faint blush. The form of these blotches is occasionally irregularly lunated. The eyes are generally red and filled with tears.

IN *ROSEOLA* (or *scarlet rash*) there is less fever; the spots are large and round or oval, and there is no injection of the conjunctivæ.

*SCARLATINA* presents a scarlet-red or strawberry-coloured eruption, diffused and consisting of small dots close together. The tongue, towards the last, sheds its epithelium, and is of a vivid red. Sore throat most frequently attends, but the eyes are not injected.

*ERYSIPELAS* shows itself on various parts of the body by a violet or yellowish-red, in patches slightly swelled. It is often confined to one side. There is neither sore throat nor redness of the eyes.

## PLATE I.

*Fig. 1.*—*Roseola*, or scarlet rash, developed on the face and body of an infant.

*Fig. 2.*—*Rubeola*, or measles, in its ordinary form.

*Fig. 3.*—Measles, attended with extravasation of blood in the cutis, called *rubeola hemorrhagica*. This appearance is observed under two circumstances :—1st, in severe cases of common measles attended with congestion; 2d, in malignant cases, attended with hemorrhage from the mucous membranes.

*Fig. 4.*—Appearance presented by the decline of hemorrhagic *rubeola*, in which the petechiæ are left, (tenth day.)

*Fig. 5.*—Eruption of *scarlatina*, with small white points on the neck.

*Fig. 6.*—Sanguineous effusion into the skin in scarlet fever, constituting *scarlatina hemorrhagica*.

*Fig. 7.*—The appearance presented by the tongue in scarlet fever.

# EXANTHEMATA.

---

## PLATE II.

*Fig. 1.—Erysipelas* of the face, with œdema of the eyelids in an old subject. The diffuse redness of erysipelas is easily distinguished from the spotted appearance of other eruptions.

*Fig. 2.—Bullæ* and *vesicles* developed on an erysipelatous surface. They are seldom numerous.

## SECOND GROUP.

The second group comprises the exanthemata which are seldom preceded or accompanied by a febrile movement. It is composed of ERYTHEMA and URTICARIA.

*Fig. 3.—Rheumatic erythema.* This variety is sometimes preceded by fever, and has been described as *rheumatic roseola* and *eruptive rheumatic fever*.

*Fig. 4.—Erythema nodosum.* A very painful variety involving the cellular tissue.

*Fig. 5.—Erythema papulosa.* This variety resembles *lichen urticatus*, but is distinguished by the colour and the absence of itching.

*Fig. 6.—Erythema annulata.* This may be confounded with *lepra* with the scales rubbed off; but, besides other distinguishing traits, this disappears in a week or two.

ROSIOLA — RUBEOLA — SCARLATINA

1. Roseola.

2. Rubella (Measles).

6. Tongue of Scarlatina.

4. Rubella.

3 & 4  
Rubella (Scarlatina).

7. Scarlatina  
haemorrhagica.

5. Scarlatina.

3. Rubella.

ERYSIPELAS — ERYTHEMA.

1. Erysipelas.

3. Rheumatic Erythema.

2. Vesicles of  
Erysipelas.

4. Erythema nodosum.

5. Erythema papulosa.

6. Erythema annulata.

# EXANTHEMATA.

---

## PLATE III.

*Fig. 1.—Erythema iris.* A rare variety resembling *herpes iris*, but wanting the vesicles.

*Fig. 2.—Chronic erythema.* Distinguished by red spots, superficial, irregular at the margins and destitute of heat or itching.

*Fig. 3.—Urticaria* (nettle rash). On the face.

*Fig. 4.—Urticaria alba* (porcelaine). White prominent wheals, like the cuts of a whip.

## BULLÆ.

Bullæ are large elevations of the cuticle distended by a serous, or sero-purulent fluid.

The *First Group* of Bullæ comprises PEMPHIGUS, RUPIA and BULLAR SYPHILIS.

*Fig. 5.—Pemphigus.* The bullæ discreet and scattered irregularly. This is the most frequent variety. Observe the bullæ but slightly inflamed and the lamellated crusts which take their places when they are broken.

*Fig. 6.—Pemphigus* in groups, forming a sort of transition or intermediate link between it and *herpes*.

*Fig. 7.—A large bulla.* Occasionally seen distended with a milky fluid; the skin is much inflamed.

## BULLÆ.

---

### PLATE IV.

- Fig. 1.—Pemphigus pruriginosus.* A rare variety, distinguished by small bullæ, mixed with the papulæ of prurigo.
- Fig. 2.—Pemphigus infantilis.* Often attended with white ulcerations, and forming a link between *pemphigus* and *rupia*.
- Fig. 3.—Scabs of pemphigus,* left after the breaking of the bullæ.
- Fig. 4.—Rupia simplex.* Ulcerations and scabs surrounded by a kind of ring formed of the detached epidermis.
- Fig. 5.—Rupia prominens.* Elevated conical scabs, surrounded with pus.
- Fig. 6.—Rupia cachectica.* Bullæ sanguinolent, scabs black, and shaped like a shell.
- Fig. 7.—Rupia gangrenosa.* A deep slough with a livid tint of the surrounding skin.

PEMPHIGUS. — RUPIA

1. Pemphigus pruriginosus.

4. Rupia simplex

2. Pemphigus infantilis.

Baths & excoriations.

3. Crusta of Pemphigus.

5. Rupia prominens.

6. Rupia Cachectica.

7. Rupia Gangrenosa.

1. Herpes Zoster on face

2. Herpes Zoster (*Shingles*)

5. H. Zoster in the mouth.

4. — H. Zoster. — 3.

7. Herpes Iris.

6. H. Zoster or Zona.

## VESICULÆ.

---

VESICLES are small elevations of the cuticle, filled with serosity, at first transparent, afterwards becoming muddy or sero-purulent previous to desiccation; and they comprise, HERPES, MILIARIA, SUDAMINA, ITCH, ECZEMA, MERCURIAL ECZEMA and VESICULAR SYPHILIS.

The vesicles of *Herpes* are developed in groups on a red ground, and terminate in little scales or crusts.

The vesicles of *Sudamina* are minute, and resemble drops of water.

The vesicles of *Miliaria* are red or white, minute and mixed with papulæ, accompanied by fever and profuse sweating.

## PLATE V.

Fig. 1.—*Herpes zoster*, on the *face*; this variety almost always extends upon the scalp.

Fig. 2.—*Herpes zoster*, on the *body* (shingles), at the commencement.

Fig. 3 and 4.—Consecutive ulcerations, and 4th, cicatrices following *zona*, fig. 6.

Fig. 5.—*Herpes zoster*, extending from the face into the mouth.

Fig. 6.—*Zona. Herpes zoster* of the trunk, presenting irregular bullæ and crusts.

# VESICULÆ.

---

## PLATE VI.

- Fig. 1.*—*Herpes phlyctenodes*. Scattered groups of vesicles without symmetry, on various parts of the body.
- Fig. 2.*—*Herpes circinatus* (ring-worm). Commencing in a point and spreading in an irregular circle; as the old vesicles disappear, new ones arise outside of them.
- Fig. 3.*—*Herpes præputialis*, on the prepuce.
- Fig. 4.*—*Herpes labialis*, on the lips, often seen after fevers.
- Fig. 5.*—*Herpes digitorum*, whitish on its palmar aspect.
- Fig. 6.*—*Sudamina*.
- Fig. 7.*—*Miliaria*.
- Fig. 8.*—*Mercurial* eruption resembling *eczema*.

## PLATE VII.

*Fig. 1.*—*Scabies* or *itch* of long standing.

*Fig. 2.*—*Scabies purulenta*, with the burrows running out from them.

*Fig. 3.*—*Scabies* on the foot of an infant.

*Fig. 4.*—Conoidal form of the vesicles seen through a magnifier.

*Fig. 5.*—*Acarus scabei* or itch-insect magnified. (Ventral aspect.)

*Fig. 6.*—Do. dorsal aspect.

*Fig. 7.*—*Eczema simplex* in the vesicular stage.

*Fig. 8.*—*Eczema impetiginodes*. Large, moist, yellowish, flattened scales, covering a great portion of the body.

# ECZEMA.

---

## PLATE VIII.

*Fig. 1.*—*Eczema* of the scalp, and of the ear, which after being chronic has suddenly assumed an acute character.

*Fig. 2.*—*Eczema* of the face in the acute form, presenting here and there whitish pellicles like false membranes.

*Fig. 3.*—Curious appearance of the leg of an old woman suffering from chronic eczema.

*Fig. 4.*—Affection of the nails accompanying general eczema.

*Fig. 5.*—*Chronic eczema* of the penis attended with redness and swelling of the prepuce.

*Fig. 6.*—*Inveterate chronic eczema* complicated with varices in an old man. The skin is ulcerated in many places during an exacerbation.

1. Eczema of scalp.

2. E. of face

3. Eczematous fissures

6. Chronic eczema with excoriations.

5. E. of the penis

4. E. of the nails

1. Eczema impetiginodes.

2. Eczema inveterata.

3. Eczema furfuracea.

4. Eczema rubrum.

5. Eczema of the nipple.

6. Eczema of the lips.

7. Eczema of the navel.

# ECZEMA.

---

## PLATE IX.

- Fig. 1.*—*Chronic eczema impetiginodes* presenting a mixture of scabs and epidermoid scales.  
*Fig. 2.*—Remarkable state of the face after a long continued *eczema impetiginodes*.  
*Fig. 3.*—Scaly condition following a chronic *eczema* of the scalp.  
*Fig. 4.*—*Eczema rubrum* of the bend of the arm. The cuticle is abraded in several points.  
*Fig. 5.*—*Chronic eczema* of the nipple in the scaly stage.  
*Fig. 6.*—A rare variety of *eczema impetiginodes* on the lips.  
*Fig. 7.*—Moist *eczema* of the navel in an acute stage.

# ECZEMA.

---

## PLATE X.

Fig. 1.—*Chronic eczema* affecting the toe-nails.

Fig. 2.—*Inveterate eczema* of the anus with fissures and abraded cuticle in patches.

## PUSTULES.

Pustules are little deposits of pus in the skin, which is deeply inflamed. Pustular diseases are ten in number, viz:—VARIOLA, VARICELLA, VACCINE, VACCINELLA, FAVUS, IMPETIGO, ACNE, ROSACEA, ECTHYMA and PUSTULAR SYPHILIS.

They are divided into three groups:—

The first group comprises *variola*, *varicella*, *vaccine*, and *vaccinella*.

The second group comprises *favus* and *impetigo*.

The third group contains *acne*, *rosacea*, *sycosis*, and other follicular diseases. *Ecthyma* forms the transition between pustular diseases and furunculous inflammations.

## VARIOLA, (SMALL-POX.)

Fig. 3.—*Discrete small-pox*, commencing stage.

## S Q U A M Æ .

---

THE scaly diseases are recognized by scales or plates of altered cuticle, dry, of a dead-white colour, which are rapidly reproduced. The subjacent skin is always more or less inflamed. The Squamæ are preceded by red spots or papular elevations surmounted by a minute scale.

They comprise PSORIASIS, LEPRO, PITYRIASIS and SCALY SYPHILIS.

TUBERCLES are solid elevations, developed in the thickness of the skin, of which the size varies from that of a small bean to an olive and which almost always terminate in suppuration or ulceration.

The Tuberculæ are six in number, viz:—LUPUS, SCROFULA ELEPHANTIASIS, FRAMBÆSIA, CANCER and SYPHILITIC TUBERCLES.

# SYPHILIS.

THE appearances presented by primary syphilis are very various. They are BLENNORRHAGIA, BALANITIS, and COMMON, INDURATED, PHAGEDENIC, and GANGRENOUS CHANCER. All these symptoms are produced by a *morbid virus*, capable of being inoculated, and when inoculated, of being followed by general or secondary syphilitic diseases.

These secondary affections comprise many affections of the skin, and may be made to include, VEGETATIONS, ONYXIS and ALOPECIA.

Fig. 6.—*Yellow blotches* of a uniform tint of colour.

Fig. 7.—A *yellowish scaly band* filled with fissures.

Fig. 8.—*Lenticular copper-coloured blotches* scattered over the palm of the hand.

Fig. 9.—*Confluent blotches* on the sole of the foot detaching the cuticle.

Fig. 10.—*Blotches* with a scab in the centre.

# SYPHILIS.

---

## PLATE XXXII.

- Fig. 1.*—Small yellowish syphilitic papulæ on the back.  
*Fig. 2.*—Small groups of yellowish-brown papulæ.  
*Fig. 3.*—Large papulæ looking almost like tubercles.  
*Fig. 4.*—Syphilitic lichen circumscriptus.  
*Fig. 5.*—Papulæ and yellowish tubercles on the breast.  
*Fig. 6.*—A papulous arc surrounding a cicatrix.  
*Fig. 7.*—A portion of the skin of the shoulder exhibiting groups of papulæ.  
*Fig. 8.*—An eruption of vesicles on the back of the forearm of a man affected with syphilis.  
*Fig. 9.*—Ordinary appearance of a syphilitic psyrdraceous eruption.  
*Fig. 10.*—Phlyzaceous pustular syphilis.  
*Fig. 11.*—Large conoidal pustules on the breast and face.

1. Tubercles in groups

2. Large tubercles.

3. Tubercles in rings

4. Flattened tubercles.

5. Tubercles  
*flat & scaly*

6. Tubercles  
*flat & moist*

7. Sub-cutaneous tubercles.

8. Ulcerated tubercles.

9. Tubercles in arcs.

# SYPHILIS.

---

## PLATE XXXIII.

*Fig. 1.*—A group of *agglomerated tubercles*, of a copper-red colour, near the ala of the nose.

*Fig. 2.*—Large projecting *tubercles* on the skin of the thigh.

*Fig. 3.*—A part of the skin of the back showing *chaplets of tubercles*.

*Fig. 4.*—*Flattened tubercles* presenting fissures in the direction of the folds of the anus.

*Fig. 5.*—*Tubercles* above and at the corners of the mouth.

*Fig. 6.*—*Flat moist tubercles* on the scrotum; the upper part of the raphe is swelled and hardened.

*Fig. 7.*—*Tubercles* on the thigh without any change in the colour of the skin.

*Fig. 8.*—*Ulcerated tubercles* on the nipple of an infected nurse.

*Fig. 9.*—An *arc of ulcerated tubercles* on the nose of a syphilitic patient.

# SYPHILIS.

## PLATE XXXIV.

- Fig. 1.*—An eruption of *flat tubercles* on the thighs and genitals.  
*Fig. 2.*—*Tubercles* on the back of the neck.  
*Fig. 3.*—Groups of little ulcers with subcutaneous indurations.  
*Fig. 4.*—Small masses of *vegetations*, traversed by hairs, cut from the verge of the anus.  
*Fig. 5.*—Same *vegetations* seen in section.  
*Fig. 6.*—*Flat scaly tubercles* in the axilla.  
*Fig. 7.*—Red indolent *tubercles* accompanying syphilitic ozæna.  
*Fig. 8.*—*Vegetating tubercles* on the thighs and vulva.  
*Fig. 9.*—An *arc of tubercles* surmounted by triangular ulcerations.

1. Blackish tubercles

2. Tubercles  
*Fig. 1. ulcerated*

3. Ulcerated tubercles.

8. Vegetating tubercles.

4. Vegetations.

6. Scaly tubercles.

7. Indolent tubercles.

5. Vegetations.

9. Small ulcerated tubercles.

1. Bullae.

2. Syphilis bullae.

3. Primaries.

6. Vegetations.

5. Vegetations in the larynx.

8. Ovary.

7. Vegetations.

9. Tumor.

12. Alopecia.

11. Condylar pustules.

10. Tumor.

# SYPHILIS.

---

## PLATE XXXV.

- Fig. 1.*—A *bullar syphilitic eruption* on the back of the forearm.  
*Fig. 2.*—A similar eruption on the palm of the hand.  
*Fig. 3.*—A large *bullula* ulcerated and covered by a black adherent crust in the palm of the hand.  
*Fig. 4.*—Upper lip elevated to show a deep ulcerated fissure, and a small grayish tubercle.  
*Fig. 5.*—Obstruction of the larynx by a voluminous vegetation.  
*Fig. 6.*—Vegetations on the *corona glandis*.  
*Fig. 7.*—Vegetation in the form of a horn on the *corona glandis*.  
*Fig. 8.*—*Syphilitic onyxia* on two of the toes and a grayish tubercle in their commissure.  
*Fig. 9.*—Section of a tumour from the forehead of a syphilitic patient.  
*Fig. 10.*—A large *tubercle* or tumour on the cheek.  
*Fig. 11.*—*Confluent syphilitic pustules* on the end of the nose.  
*Fig. 12.*—*Syphilitic alopecia*.

# SYPHILIS.

---

## PLATE XXXVI.

*Fig. 1.*—*Reddish-brown blotches* on a new-born child affected with *gonorrhœal ophthalmia*.

*Fig. 2.*—An eruption of tubercles on the thighs of a new-born child.

## VASCULAR ALTERATIONS.

These are produced by the morbid alterations of the capillaries of the skin, and are characterized by permanent red spots, without morbid heat, and disappear for the moment under the pressure of the finger. They are divided into CUTANEOUS and SUBCUTANEOUS.

*Fig. 3.*—A *varicose tumour* on the thumb.

*Fig. 4.*—A small *vascular nævus* commonly called a strawberry.

*Fig. 5.*—Small *vascular papular vegetations*, around the mouth and on the nose.

*Fig. 6.*—Small *petechiæ*, scattered over the face of a child of 12 years affected with *purpura*.

1. Congenital Syphilis.

2. Congenital Syphilis.

3. Varicose tumor.

4. Varicose tumor.

5. Vascular regurgitation.

6. Purpura petechialis.

6. Vascular nævus.

4. Ecchymosis  
(intestinal)

1. Purpura urticans.

7. Spotted vascular  
nævus.

5. Ecchymosis  
(pulmonary)

3. Purpura.

2. Purpura & Rupia.

8. Ulcerated vascular nævus.

9. Vascular nævus.

# VASCULAR ALTERATIONS.

---

## PLATE XXXVII.

- Fig. 1.—*Purpura urticans*; an eruption of rose-red, itching, lenticular spots, slightly prominent, disappearing partially under pressure, mixed with yellowish or brownish blotches, which bear pressure without altering.
- Fig. 2.—The lower part of the leg of an adult covered with *purpura* and *rupia* mingled.
- Fig. 3.—*Purpura*; large ecchymoses, such as are produced by a blow.
- Fig. 4.—A small portion of intestine presenting *ecchymoses*.
- Fig. 5.—A portion of the right lung, presenting *sub-pleural petechiæ* and an ecchymosis in the substance of the lung.
- Fig. 6.—A congenital *vascular* tumour. (*Nævus*.)
- Fig. 8.—A *vascular nævus* which has taken on the ulcerative process.
- Fig. 9.—A portion of a *vascular nævus* which has no distinct *arborizations*.

# DISEASES OF THE CORNEOUS TISSUES.

## PLATE XXXVIII.

- Fig. 1.—*Onychia* of the root of the nail consequent upon a bruise.  
Fig. 2.—*Lateral onyxis*, or the nail growing into the flesh.  
Fig. 3.—A deformed, blackened nail, following onyxis.  
Fig. 4.—Deformed nail, following a chronic onyxis.  
Fig. 5.—A wart under the nail elevating the edge.  
Fig. 6.—Alteration of the nails in *plica-polonica*.  
Fig. 7.—A horn developed on a large wart in an old woman.  
Fig. 8.—A horn on the scrotum.  
Fig. 9.—Toe-nail altered and elongated.  
Fig. 10.—A hand totally deformed by horny excrescences.  
Fig. 11.—Spots of *lentigo* or *nævus pilaris*.  
Fig. 12.—*Warty vegetations* on the wrist.  
Fig. 13.—*Warts* on the finger.  
Fig. 14.—*Hordeolum* or styne, followed by a wart.  
Fig. 15.—Excessive development of the papillæ of the skin.  
Fig. 16.—Do. of the tongue.

1. Onyxis  
of the root of the nail.

2. Lateral  
Onyxis.

3. Chronic  
Onyxis

4. Chronic  
Onyxis

5. Deformity  
of the nail.

6. Trichomatous  
Onyxis

7. Horn.

8. Horn  
from the Scutum.

9. Nail  
in the form of a horn

10. Horny transformation  
of the hand.

11. Lentigo.

12. Warty Vegetations.

16.

15 & 16. Hypertrophy  
of the Papillæ

( of the skin )

14. Hordeolum.

13. Warts

( of the tongue )

1. Corn

2. Corn.

3. Corn.

4. Corn  
(Section)

7. Corneous Ichthyosis.

6. Ichthyosis.

5. Simple Ichthyosis.

9. Chloasma.

8. Alopecia.

10. Trichoma  
(plica polonica)

11.

# ALTERATIONS OF THE EPIDERMIS, &c.

---

## PLATE XXXIX.

- Fig. 1.*—*Corn* on the little toe.  
*Fig. 2.*—*Corn* which had been a long time freed from pressure.  
*Fig. 3.*—Internal face of *fig. 2.*  
*Fig. 4.*—Section of a *corn*.  
*Fig. 5.*—*Simple ichthyosis* on the elbow.  
*Fig. 6.*—Bend of the knee covered with *brown mosaic* plates of *ichthyosis*.  
*Fig. 7.*—Appearance of the thumb of one of the brothers by the name of *Lambert*, who were called *porcupines*, accompanied by two magnified views of the spines.  
*Fig. 8.*—Dead white spots deprived of their hair. (*Alopecia*.)  
*Fig. 9.*—Spots of *chloasma*, some small, others large and irregular.  
*Fig. 10.*—*Plica-polonica*, or *trichoma*. (From *Lafontaine*.)  
*Fig. 11.*—*Chloasma* in the form of little blotches.

# ALTERATIONS OF THE PIGMENT.

---

## PLATE XL.

- Fig. 1.*—Dark discoloration of the skin, which followed articular rheumatism. (*Melasma*.)  
*Fig. 2.*—*Melasma* in an individual affected with *pellagra*.  
*Fig. 3.*—Same affection on the hand.  
*Fig. 4.*—Small white blotches on the upper eyelid. (*Canities*.)  
*Fig. 5.*—An old woman with bunches of white hair growing on the face.  
*Fig. 6.*—*Albinism* in a negro.  
*Fig. 7.*—Partial *albinism*; congenital.  
*Fig. 8.*—Partial *leucopathia* or *albinism*.  
*Fig. 9.*—*Nigrities*; a part of the shoulder, which became as dark as that of a mulatto.  
*Fig. 10.*—Tint of the skin produced by the internal use of nitrate of silver.  
*Fig. 11.*—Black spots on the tongue.  
*Fig. 12.*—Yellow spots symmetrically disposed on the eyelids.

1. Melasma.

2. Pellagrous melasma.

3. Pellagrous melasma.

6. Albinism.

5. Canities.

4. Canities.

(a bearded woman.)

7. Partial Albinism

8. Leucopathia.

9. Nigritia.

10. Purple tint  
from Atrial of Silver.

11. Spot on the tongue.

12. Yellow spots on the eyelids.

# INDEX AND VOCABULARY.

- ACARUS SCABIEI, 136-7 and append. 397.  
 Achor, 195.  
 ACNE, 180.  
 Acne Rosacea v. Rosacea.  
 — Syphilitica, see syphilida, psyraceous pustules.  
 ACRODYNIA, 424.  
 Albaras, Baras, Lepra. q. v.  
 ALBINISM, 337.  
 Albohak, Lepra. q. v.  
 Aleppo pustule, 411.  
 ALOPECIA or Baldness, 379; porrigo decalvans, 380; tinea tonsans, 380.  
 Alphos, Lepra. q. v.  
 AMBOYNA PUSTULE or POX, 416.  
 AMBUSTIO or Burn, 318; erythematous, 318; vesicated or bullous, 318; gangrenous, 318.  
 AMPULLÆ, 100.  
 ANEMIA, 322.  
 ANÆSTHESIA, 335.  
 ANDRUM, a form of Arabian Elephantiasis, 410.  
 ANGIECTASIA, 356.  
 ANIMALS, PARASITIC, infesting the body of man, 393.  
 Anomalous rosy Eruption v. Roseola.  
 ANTHRACION seu PUSTULA MALIGNA, 214.  
 ANTHRAX, 212.  
 Aphthæ præputii v. Herpes præputialis.  
 APPENDIX, 393.  
 Area, Alopecia. q. v.  
 Aspreto, Aspretudo, Urticaria. q. v.  
 Atheromatous tumours, 375.  
 Atonic Ulcers, consequences of Rupia. q. v.  
 Bacchia v. Rosacea.  
 Baker's Itch, Psoriasis of the hand v. Psoriasis.  
 Baldness v. Alopecia.  
 Baras v. Elephantiasis Græcorum.  
 Barbadoes Leg, 410.  
 Blactiæ v. Rubeola.  
 Blanching, Endemic, of the Skin, 425; Carate, 425; Pinta, 425.  
 — of the Hair v. Canities.  
 Blebs v. Bullæ.  
 Boil v. FURUNCULUS.  
 Bricklayer's Itch, impetiginous Eczema and Impetigo of the hands v. Eczema and Impetigo.  
 BRUNNO-GALLICUS Morbus (syphiloid), 416.  
 BULLÆ, 91.  
 — accidental, ampullæ, blisters, 100.  
 Bulla, Pemphigus, q. v.  
 Burn, 318.  
 Calculi of the sebaceous follicles, 376.  
 CANCER, 265; vulgaris, 265; melanic, 266; leucoid, 267; globose, 267; mollusciform, 267; chimney sweepers, 268; local varieties, 268.  
 Cancroid v. Cheloid formation.  
 CANITIES, 378.  
 CARATE, 425.  
 CARBO or malignant pustule, 434.  
 Carbuncle v. Anthracion and Anthrax.  
 CHEILOLACE, 410.  
 CHELOID FORMATION, 360.  
 Chicken-pox, 148, 163 v. Varicella.  
 Chilblain v. Pernio.  
 Chin-welk v. Sycosis.  
 CHLOASMA, 342.  
 Cingulum. Herpes zoster.  
 CLASSIFICATION of Diseases of the Skin, 21, 47.  
 Cnesmos. Prurigo.  
 COLOUR of the Skin, alterations of the, 337; Albinism, 337; Nigrities, 339; Ephelis, 341; Lentigo, 342; Chloasma, 342; Melasma, 343; Pigmentary nævi, 344; Blue colour, 345; Yellow colour, 345; Slate colour from use of Nit. Argenti, 346; Artificial Staining v. Skin, 347.  
 COLOUR, SLATE, of the Skin from using Nitras Argenti internally, 346.  
 COLOUR, (yellow,) 345.  
 CORION, hypertrophy of the, 363.  
 CORN v. Tylosis.  
 Crusted-tetter v. Impetigo.  
 Cow-pox v. Vaccinia, 172, 430.  
 Crusta lactea, Eczema and Impetigo of the face v. Eczema and Impetigo.  
 Crystalli, Vaccinia.  
 Crystallina, Herpes præputialis.  
 Cuticle v. Epidermis.  
 Dandruff v. Pityriasis.  
 DEGENERATIONES, 364; fibrous 364; Melanosis, 365; Tubercular matter, 366.  
 DERMIS, diseases of the, 51.  
 — suppurative inflammation of, 147.  
 — depositive inflammation of, 218.  
 — disordered chromatogenous functions of, 337.  
 Diffuse cellular inflammations, see Gangrenæ.  
 DIPHTHERITIS of the Skin, 427.  
 DISCOLORATIONS of the SKIN, artificial or accidental, 346.  
 Djuzam v. Elephantiasis Græcorum.  
 Diseases which have disappeared, 428; of Animals susceptible of communication to the human subject; Cow-pox, 430; Grease, 434; Carbuncle or malignant pustule, 434; Scabies, 435; Glanders, 435.  
 Dracunculus v. Filaria.  
 Dry-scall, Psoriasis.  
 Dysodia, impeded perspiration.  
 ECTHYMA, 205; acutum, 205; chronicum, 205; cachecticum, 207.  
 ECZEMA, 114; Simplex, 114; rubrum, 115; impetiginodes, 115, 190; Chronic Eczema, various local forms of, on the scalp, face, ear, &c., 116; et sequent complications, 118; diagnosis, 118; treatment, 121.  
 Eczema mercuriale v. Hydrargyria.  
 Efflorescence. Erythema.  
 ELEPHANTIASIS ARABICA, 401; generally attacks lower extremities, 404; of the scrotum, 405; geographical distribution of, 407.  
 ELEPHANTIASIS Brazilian, 406.  
 — Græcorum, 273.  
 ELEPHANTOID affections, modifications of tubercular or Greek elephantiasis, 412.  
 EPHELIS, 341.  
 EPIDROSIS, 334.  
 EPIDERMIS, structure of, 46.  
 — morbid secretions of the, 333.  
 EPINYCTIS, 420.  
 Epinyctis pruriginosa v. Urticaria.  
 ERUPTIONS, Endemic acute, 425; Lichen tropicus, 426; Itch of the Illinois, 426.  
 ERUPTIVE FEVERS, are general diseases, 13.  
 — variety of character of, in different epidemics, 14.

- ERUPTIVE FEVERS, writers on, 14.  
 ERYSIPELAS, 65; causes of, 65; simplex, 65; symptoms of, 65; miliaris, 66; phlyctenodes, vel bullosa, 66; erratica, 66; metastatica, 66; phlegmonous, 66; gangrenous, 66; ædematous, 66; Erysipelas of the face, 66; scalp, 67; mamma and umbilicus, 67; groin, scrotum, prepuce, and extremities, 67; General Erysipelas, 67; diagnosis, prognosis and treatment, 68; history and cases, 70.  
 Erysipelas zoster, Herpes zoster.  
 Erysipelatous efflorescence v. Roseola.  
 ERYTHEMA, 60; intertrigo, 60; paratrimma, 60; a punctura, 60; papulatum, 60; tuberculatum, 60; nodosum, 60; marginatum, 60; circinatum, 60; fugax, 60; Chronic, of the feet, 60; lips, nipple, abdomen, anus, prepuce, and vulva, 60; fiery spots of the face, 60; diagnosis, 61; prognosis, 62; treatment, 62; cases of, 63.  
 Essera v. Urticaria.  
 Exanthema labiale v. Herpes labialis.  
 EXANTHEMATA, progress of, 58.  
 ——— associated with internal disease, 59.  
 ——— changes of skin in, 59.  
 ——— artificial, 90.  
 EXCRESCENCES, syphilitic.  
 EXCRESCENCES, vascular, 357.  
 FACIALDINE, (syphiloid), 416.  
 False measles, Roseola.  
 FARCY, 438.  
 ——— chronic, 440.  
 FAVUS, 195 dispersus (*Porrigo lupinosa*, Wil.) 196; confertus (*Porr. scutulata*, Wil.) 197; organic nature of, 196; probably a modification of tubercle, 199.  
 Febris bullosa v. Pemphigus.  
 Febris pemphigoides v. Pemphigus.  
 Febris urticata v. Urticaria.  
 Fiery spots of the face—Erythema, 61.  
 FILIARIA Medinensis or Guinea-worm, 398.  
 Fish-skin disease, Ichthyosis.  
 Fleas v. Pulices.  
 FOLLICLES SEBACEOUS, diseases of the, 367.  
 Follicular grubs or worms, 370; elevations, 371; tumours, 375; calculi, 376.  
 Formica. Herpes phlyctenodes.  
 Formica corrosiva. Lupus.  
 FRAMBÆSIA, Yaws, or pian, 417.  
 ——— diagnosis between, and sибbens, 418.  
 Freckle. Ephelis.  
 FURUNCULI, 210.  
 FURUNCULUS or Boil, 210.  
 GANGRENÆ, 214; simple of the skin, 387.  
 GANGRENOUS DISEASES, epidemic or endemic, 426; Nome, 426; Ignis sacer of the middle ages, 426.  
 GLANDERS, 435; acute, 439; chronic, 440; connection between Glanders and Farcy, 437; transmission from man to horse, 443.  
 Glandular disease of Barbadoes. Elephantiasis Arabum.  
 Grease of the horse, 434.  
 Grutum vultus, Acne.  
 Grocer's Itch. Impetigo of the hands, Psoriasis of the hands.  
 Guinea-worm v. Filaria Medinensis.  
 Gum v. Strophulus.  
 Gutta rosea v. Rosacea.  
 Hæmacelinosi v. Purpura.  
 Hemorrhagica, 323.  
 Hæmorrhæa petechiale v. Purpura.  
 Hair v. sub Piliferous follicles.  
 Herpes Esthiomenes. Lupus.  
 HERPES, 103; Herpes zoster, 104; of the trunk, face and mouth, 104; is generally complicated, 105; causes, diagnosis, and prognosis, 106; treatment, 107; phlyctenodes, 109; circinatus, 110; labialis, 111; præputialis, 112; vulgaris, auricularis, palpebralis, 113; iris, 113.  
 Herpetic affections depend on constitutional causes, 13.  
 Hives, Globular variety of Varicella.  
 HORDEOLUM or STY, 211.  
 Horn-pox v. Varicella.  
 HORNS or horny productions, 354.  
 Hydati. Pemphigus.  
 Hydræa febrile. Herpes labialis, 410.  
 HYDROCELE, ENDEMIC, a form of Elephantiasis Arabum.  
 HYDRARGYRIA mitis, 130, febrilis, 130; maligna, 131.  
 HYPERÆSTHESIA, 336.  
 HYPERTROPHY, 348.  
 HYPERTROPHY OF THE CORION, 363; of the nose, 363.  
 ——— of the Papillæ and Epidermic layers of the skin, 318.  
 ——— of the subcutaneous cellular and adipose tissues, 363.  
 ——— of the vascular elements of the skin, 356; Phlebectasia, 356; capillary angiectasia, 356; Nævus araneus, 356; flammeus, 356; vascular excrescences, 357; Cutaneous vascular nævus, 357; subcutaneous vascular nævus, 357; congenital cutaneous and subcutaneous vascular nævus, 358; of erectile tissue, 358; of dilated veins, 359.  
 ICHTHYOSIS, 348; simplex, cornea, spuria, 368.  
 ——— sebacea, 367, 370.  
 Ignis Persica v. Anthracion.  
 Ignis sacer v. Erysipelas.  
 ——— v. Herpes zoster.  
 IGNI SACER of the middle ages, 426.  
 ILLINOIS ITCH, 426.  
 IMPETIGO figurata, 189; Sparsa, 190; of the scalp, (tinca granulata), 190; eczematosa, 190.  
 INFLAMMATORY AFFECTIONS of the Skin, 22. Effects of these: ulcers 23; crusts, 23; local symptoms, 23; general symptoms, 23; complications, 24; etiology, 26; diagnosis, 29; prognosis, 29; influence of on the general health, 30; treatment, 31; of the acute forms, 31; of the chronic, 32; effects of various therapeutic agents and means—medicines, baths, etc., 33, 45, 56.  
 INFLAMMATORY AFFECTIONS of the Skin, having a single elementary form, 58.  
 Intertrigo—Erythema intertrigo, q. v.  
 INTUMESCENTIÆ, diseases at first foreign to the Skin, but implicating it at length, 401.  
 Ionthos v. Acne.  
 Itch v. Scabies.  
 ——— Insect v. Acarus scabiei.  
 ——— Bakers'—Grocers' v. Psoriasis; psor. palmaris.  
 JEWISH Leprosy, 413.  
 LABRI-SULCI Hiberniæ, 410.  
 LENTIGO, 342.  
 Lepra medii ævi v. Elephantiasis Græcorum.  
 LEPROA of Holstein, (Spedalsked), 413.  
 ——— Taurica, (Lep. Crimeæ), 413.  
 ——— Judaica, 413.  
 ——— anæsthesiaca Indorum, 413. All these Lepras are varieties of tubercular Elephantiasis.  
 LEPROA, (scaly lepra), 233; (vulgaris), 234; its frequency in England, 234.  
 Leuce Lepra.  
 LEUCOPATHIA seu Albinismus, 337; general, 337; partial or accidental, 337.  
 Leontiasis. Elephantiasis Græcorum.  
 LICHEN simplex, 220; pilaris, 221; circumscriptus, 221; agrius, 221; urticatus, 221; lividus, 221; tropicus, 221; local varieties, 222.  
 Liver-spot v. Chloasma.  
 LUPUS exedens, 253; non exedens, 255.  
 Lymphatic system, disease of in Arabian Elephantiasis, 404.  
 Maculæ volaticæ. Erythema.  
 ——— hepaticæ. Chloasma.  
 MAL ROUGE de Cayenne, 412.  
 MAL DE ROSA, 423.  
 MALUM MORTUUM, 414.  
 Measles v. Rubeola.  
 Melada, disease of, 424.  
 MELANOSIS, 365; in grains, in mass, of the forehead, cancerous of the heart, of the liver, cancerous of the muscles, cancerous of the lung. See plates.  
 Melas v. Lepra.  
 MELASMA, 343; (acrodynia; pellagra).  
 Mentagra v. Sycosis.  
 MENTAGRA of the Latins, 430.  
 Mentagrophyte, 186.  
 Metastasis of cutaneous diseases, 14.  
 MILIARIS SUDATORIA, 139; Cases of, 143.  
 Miliun, Acne.  
 Mole, Nævus, Spilus.  
 Molluscum contagiosum, 371; structure of, 372-4.  
 Morbilli v. Rubæola.  
 Morbilli confluentes v. Scarlatina.  
 Morbus maculosus hemorrhagicus. Purpura.  
 Mother marks. Nævi of different kinds.  
 Mouth Canker, 410.  
 MUCCOUS MEMBRANES, diseases of Skin in contrast with those of the, 359.  
 ——— morbid states of the, in cutaneous diseases, 29, 55.  
 NÆVUS araneus, 356. Nævus flammeus, 356.  
 ———, varieties of, 358.

- NÆVUS**, mollusciform piliferous.  
 — pilaris.  
 — cutaneo-vascular, 357; subcutaneo-vascular, 358; congenital-cutaneo and subcutaneo-vascular, 358; of erectile tissue, 358; of dilated veins, 359; ulcerated nævus.  
**NÆVUS**, pigmentary, 344.  
 — verrucous, 353.  
 — structure of, 358.  
 Nails, faulty conformation of, 385; excessive growth of, 386; anomalous situation, 386; *fungus unguium*, 386; anomalous form, 386; *defœdatio unguium*, 386; Reproduction, 387. Vide **SUBUNGUAL MATRICES**, and **ONYCHIA**.  
 Nails in the form of horns, 386.  
 Nettle rash v. *Urticaria*.  
**NEUROSES** of the Skin, 335.  
**NIGRITIES**, 339.  
**NITRATE OF SILVER**, effect of, on the Skin, 345.  
 Noli me tangere v. Cancer.  
 Noli me tangere v. Lupus.  
**NOME**, of Sweden, 426.  
**ŒSTRUS**, 400; a supposed cause of cancerous fungus of the uterus, 401.  
**ONYCHIA** from an outward cause, 382; *from the nail growing into the flesh*, (lateral onychia,) 383; from an internal cause, 383; chronic; of the root of the nail; *Eczematosa*, 383; *Squamosa*; *Scrofulosa*; *Syphilitica*, 384; *maligna*, 384.  
**PAPILLÆ**, Hypertrophy of the, 348.  
 — OF THE TONGUE, hypertrophy of the, 348.  
**PAPULÆ**, 219.  
 — artificial, 232.  
 Parasitic vegetable structure, cause of certain cutaneous diseases, 393.  
**PEDARTHORACE**, a name for Arabian Elephantiasis, 401.  
**PEDICULI**, 394; *pediculus capitis*, 394; *corporis*, 394; *pubis*, 395.  
**PELLAGRA**, 419.  
**PELLAGROUS DISEASES**, 419; (*melasma*) *mania*, 420; *Mal de Rosa*, 420; *Acrodynia*, 424; disease of *Melada*, 424.  
**Pelliosis rheumatica** v. *Roseola rheumatica*.  
**PEMPHIGUS acutus**, (*febris bullosa*, *feb. synocha c. vesiculis*, *feb. pemphigoides*, *pompholyx solitarius*), 91; *chronicus*, (*pompholyx diutinus*), 92; associated with inflammation of mucous membranes, 92; with herpes and prurigo, 92; treatment, 93; of pemphigoid inflammation of mucous membranes, 94.  
 Pemphigoid fever. Acute pemphigus.  
**PERICAL**, a form of Elephantiasis Arabum, 410.  
**PERNIO** orchilblain, 321; erythematous, 321; bullous, 321; gangrenous, 321.  
**PERSPIRATION**, morbidly increased, 334.  
*Petechiæ*, *Petechiæ sine fibre*. Purpura.  
**PHLEBECTASIA**, 356.  
**Phlyctena**. Bulla.  
**Phlyzacia**, 144, 195, 205.  
 — v. *Ecthyma*.  
**Phyma**. Furunculus.  
**Pian**, *frambæsia*. q. v.  
**Pian de nerac**, (syphiloid,) 417.  
**Pigment**, diminution of, 337.  
**Pigmentary nævus**, 344.  
**Piliferous follicles**, special diseases of the, 376; Atrophy, 376; congenital deficiency of the hair, 376; tufts of hair, 376; unusual growth of the hair, 376; felting of the hair, 377; changes of colour of the hair, 378; Canities, 378; accidental, 378; of the beard, 379; Alopecia, 379; (*porrigo decalvans*, Wil. 380, *tinea tonsans*;) partial alopecia of the beard, 380; Syphilitic, 380; general, 381; summary of treatment, 381.  
**Pimple**. Pustula, Papula.  
**PINTA**, 425.  
**PITYRIASIS**, 217; general, 217; *capitis*, 248; *palpebrarum*, 248; *labrum*, 249; *palmaris et plantaris*, 249; *oris*, 249; *præputii*, &c., 249.  
**Pityriasis versicolor**. Chloasma.  
 — *nigra*. Chloasma.  
**PLICA**, 427.  
**Pompholyx** v. *Pemphigus*.  
**Porcelana** v. *Urticaria*.  
**Porcupine men** v. *Ichthyosis*.  
**Porrigo decalvans** v. *Alopecia*.  
 — v. *Favus* and *Impetigo*.  
 — *favosa* v. *Impetigo*.  
 — *scutulata* v. *Favus confertus*.  
 — *lupinosa* v. *Favus dispersus*.  
**Prickly-heat** v. *Lichen tropicus*.  
**PRURIGO**, 227; *mitis*, 227; *formicans*, 228; *senilis*, 228; *podicis*, 228; *scroti*, 228; *plantaris*, 229.  
 Pseudo-membranous affections of the Skin, 427; *Diphtheritis*, 427.  
**Psora** v. *Scabies*.  
**PSORIASIS**, 240; *discreta*, (*guttata*), 240; *confluens*, (*diffusa*), 241; *inveterata*, 242; *gyrata*, 242; of the scalp, 242; of the face, 242; of the trunk, scrotum, and prepuce, 242; *palmaris*, 242; *palmaris centrifuga*, 242.  
**PSYDRACIA**, 146, 195.  
**Psychracia** v. *Impetigo*.  
**Pulices**, 396; varieties of, 396.  
**Purpura**, 323; *sine fibre*, 323; *simplex*, 323; *urticans*, 324; *hemorrhagica*, 324; *febrilis*, 326; *senilis*, 326.  
**Purpura** v. *Scarlatina*.  
**Purpura urticata** v. *Urticaria*.  
**Pustula maligna** v. *Anthraxion*.  
**PUSTULÆ**, 146, varieties of, 195.  
**PUSTULES**, artificial, 209.  
**RADESYGGE**, 412.  
**Rash** v. *Roseola*.  
**Red gum** v. *Strophulus*.  
**Retro-vaccination**, 431.  
**Ringworm**, vesicular. *Herpes circinatus*.  
**Ringworm**. *Porrigo scutulata*, *Herpes circinatus*, and *Impetigo figurata* are so denominated.  
**ROSA**, *mal de*, 423.  
**ROSACEA**, 182.  
**Rosa volatica** v. *Roseola*, *Erysipelas*.  
**Rossalia** v. *Rossania*. *Scarlatina*.  
**Rose**. *Erysipelas*, *Roseola*.  
**ROSEOLA**, 84; *æstiva*, 84; *autumnalis*, 84; *annulata*, 84; *infantilis*, 84; *variola*, 84; *vaccina*, 85; *miliaris*, 85; *febrilis*, 85; *rheumatica*, 85; *Cholericæ*, 86; Cases, 86.  
**RUBEOLA VULGARIS**, MEASLES, 71; *sine catarrho*, 71; *nigra seu hæmorrhagica*, 72; *sine efflorescentia* (*febris morbillosa*) 72; Anomalous, 72; Consecutive diseases, 72; causes, diagnosis, 73; Prognosis, treatment, 74; Historical Notices and Cases, 76.  
**Running Tetter**, *Impetigo*, *Eczema*.  
**RUPIA simplex**, 98; *prominens*, 98; *escharotica seu gangrenosa*, 99.  
**St. Anthony's Fire**. *Erysipelas*.  
**SANGUINEOUS CONGESTIONS** of the skin, 323.  
**SCABIES**, 135. Causes, 135; experiments with *acarus scabiei*, 137.  
**Scabies** of animals, 435.  
**Scabies sicca**. *Psoriasis*.  
**Scall** v. *Psoriasis*.  
**SCARLATINA simplex**, 77; *anginosa*, 78; *maligna*, 78; *sine exanthemata*, 77; Secondary diseases, 79; Treatment, 81; prophylaxis, 82.  
**Scarlatina urticata** v. *Urticaria*.  
**Scarlet fever**. *Scarlatina*.  
**Scalped-head**. *Favus* and *Impetigo* of the scalp.  
**Scaly Tetter**. *Psoriasis*.  
**SCHERLIEVO**, (syphiloid,) 415.  
**SCROFULA**, 261.  
**SEBACEOUS FOLLICLES**, diseases of the, 367; increased secretion, 367; worms or grubs, 370; follicular elevations, 371; tumours, 375; containing hair, 375; *calculi*, 376.  
**SECRETING FUNCTIONS OF THE SKIN**, morbid states of the, 333.  
**SENKI**, a Japanese word for a variety of Elephantiasis Arabica, 410.  
**Serpedo** and *Serpigo*-*Psoriasis*.  
**Shingles** v. *Herpes zoster*.  
**SIBBENS**, (syphiloid,) 417.  
**Skin**, anatomy of the, 25, 45.  
 — morbid secretions of, 333.  
 — neuroses of, 335.  
 — alterations in the colour of, 337.  
 — blue colour of, 345.  
 — yellow colour of, 345.  
 — artificial discolorations of, 346.  
 — artificial staining of, 347.  
 — hypertrophy of vascular elements of, 356.  
 — vascular growths of, 357.  
 — increase of morbid secretion of, 367.  
 — gangrene of, 387.  
 — cicatrices of, 388.  
 — endemic blanching and discoloration of, 425.  
 — anomalous formation of the, 388; congenital deficiency of the, 388; remarkable extension of portions of the, 389.  
**SKIN**, outlines of pathology of, contrasted with that of the mucous membranes, 389.  
 — classification of diseases of the, 21, 47, 54.

- SKIN Diseases, symptoms of, 23.  
 ——— complications, 24.  
 ——— anatomical lesions, 25.  
 ——— etiology of, 26, 47.  
 ——— hereditariness of, 28.  
 ——— diagnosis, 29.  
 ——— prognosis, 29.  
 ——— treatment of, 31, 47.
- Small-pox v. Variola.
- SPEDALSKED, or Lepra of Holstein, 413.
- Spilus. Nevus pilaris.
- SQUAMÆ, 233.
- SQUAMOUS INFLAMMATIONS, artificial, 253.
- STATES, unusual, of the elements of the skin, 336.
- STEARRICA, 367.
- STROPHULUS, 226; intertinctus, 226; albidus, 226; candidus, 226; confertus, 226.
- STRUCTURE, faulty, of the skin.
- Struma v. Scrofula.
- Sty v. Hordeolum.
- Sycosis seu Mentagra, 185; with excrescences, 186; contagiosum, 186.
- SYPHILIDA, Syphilides or Syphilitic eruptions, 282, 296. Primary symptoms of Syphilis: Gonorrhœa, 283; Chancre and its varieties, 283; Syphilitic ulcers, 285; Bubo, 288; Secondary symptoms, 290; Syphilitic eruptions, 290; exanthematous, 291; maculæ syphiliticæ, 292; bullous, 292; vesicular, 292; psyracious pustular, 293; phlyzacious pustular, 293; Rupia syphilitica, 294; papular, 295; squamous, 295; subcutaneous gummy tubercles (gummata) 997; serpiginous syphilide, 299. Ulcers. Ulcers of the mucous membranes, 300; Syphilitic excrescences, 301; S. alopecia, 302; S. onychia, 302.
- SYPHILIS, 282.
- SYPHILOID DISEASES,—various epidemic or endemic varieties of syphilis, 414; of Chavanne-Lure, 414; of the Bay of St. Paul, 415; of Fiume, or scherlievo, 415; Facaldine, 416; morbus Brunno-Gallicus, 416; tophi Amboinenses, 416; sibbens, 416; pian de Nerac, 417; Frambœsia, 416.
- SUDAMINA, 144.
- SUDOR ANGLICUS, 428.
- Sweating-sickness, 428.
- Swine-pox, conoidal varicella, 169.
- Tara of Siberia, 412.
- Tetter v. Herpes. Impetigo. Eczema.
- Tetter, humid, Impetigo; scaly Psoriasis.
- Tinea annularis v. Impetigo figurata.
- Tinea. Species referred to Favus, Impetigo, or Eczema of the scalp.
- Tinea favosa v. Impetigo.
- Tinea tonsans v. Alopecia.
- Tooth rash v. Strophulus.
- TRICHOMATOIS AFFECTIÖNS, 427; Plica, 427.
- TUMOUR, vascular, 253.
- Tumours, endemic, 411.
- TUBERCULA, 253.  
 ——— artificially produced, 281.
- TYLOSIS or CORN, 355.
- Ulcuscula præputii v. Herpes præputialis.
- UNGUAL matrices, special diseases of the, and alterations of the nails, 382; onychia, 382; v. onychia. Subungual ecchymosis, 385; faulty conformations and texture of the nails, 385.
- Urticaria, 87; acuta: vulgaris ab ingestis, 87; sine causa, 88; perstans, 88; chronica, 88; evanida, 88; subcutanea, 88; tuberosa, 88; with intermittent fevers and rheumatism, 88.
- Uredo v. Urticaria.
- VACCINIA, (Cow-pox,) 172; Progress of the pustule, 173, 431; Modified vaccina, 174, 434; Vac. spuria, 175; origin of, 175, 431; from small-pox, 432.
- VACCINELLA, (horn-pox,) 178.
- VARICELLÆ, (variola spuria,) 148, 163; umbilicated pustular (varioloid) 164; conoidal pustular, 169; globose pustular, 169; papular, 170; vesicular, (chicken pox,) 170; sine varicellis, 172.
- VARIOLÆ, 147; two series of, 147; affinity of, 147; periods of variola, confluentes, 150; discretæ, 152; corymbosæ, 152; cohærentes, 152; progress of variola, 151; inoculated variola, 152; anomalies of, 153; diagnosis of, prognosis, 155; treatment, 156; epidemic mortality from, 163; per insitionem, (inoculated,) 152.
- Variolæ spuria v. Varicellæ.
- Varioloid v. Varicellæ.
- Varus v. Acne.
- Vegetations, a cause of favus, &c., 393.
- VERRUCA, WART, 352.
- VERRUCOUS NEVUS, 353.
- VESICULÆ, or VESICULAR INFLAMMATIONS, 103.
- VESICULAR ERUPTIONS, artificial or accidental, 145.
- Vitiligo, partial Leucopathia, also Greek Elephantiasis.
- WAREN of Westphalia, 430.
- WART v. Verruca.
- Whelk v. Acne.
- Zona v. Herpes zoster.

# VALUABLE MEDICAL WORKS PUBLISHED BY CAREY & HART.

## MEDICAL LIBRARY.

CAREY & HART have recently published the following valuable Medical and Surgical works, superbly illustrated—to which they beg leave to call the attention of the profession. This splendid series now forms FOUR ROYAL QUARTO VOLUMES, containing THREE HUNDRED AND NINETY 4to. PLATES, beautifully executed; and the price at which they are offered is infinitely less than any similar works have heretofore been published.

QUAIN'S ANATOMICAL PLATES, | MOREAU'S MIDWIFERY, and  
PANCOAST'S SURGERY, | GODDARD ON THE TEETH.

## A SERIES OF ANATOMICAL PLATES,

With References and Physiological Comments, illustrating the structure of the different parts of the Human Body.

EDITED BY

JONES QUAIN, M. D., and W. J. ERASMUS WILSON.

With Notes and Additions by JOSEPH PANCOAST, M. D., Professor of Anatomy in the Jefferson Medical College of Philadelphia.

The Plates are accompanied by letterpress, containing detailed references to the various objects delineated. But with a view to render them intelligible to a greater number of persons, a running commentary on each plate is given, stating in general terms and divested, as far as can be, of all technicality, the uses and purposes which the different objects serve in the animal economy.

THE WORK CONSISTS OF THE FOLLOWING DIVISIONS:

THE MUSCLES OF THE HUMAN BODY, *Fifty-one Plates.*

THE VESSELS OF THE HUMAN BODY, *Fifty Plates.*

THE NERVES OF THE HUMAN BODY, *Thirty-eight Plates.*

THE VISCERA OF THE HUMAN BODY, including the Organs of Digestion, Respiration, Secretion and Excretion, *Thirty-two Plates.*

THE BONES AND LIGAMENTS, *Thirty Plates.*

*Complete in One Royal 4to. Volume of nearly 500 pages, and 200 plates, comprising nearly 700 separate illustrations.*

*Being the only complete system of Anatomical Plates, on a large scale, ever published in America.*

Third American Edition. Price only \$15. Cloth Gilt.

PANCOAST'S OPERATIVE SURGERY, \$10.

## OPERATIVE SURGERY;

OR,

A DESCRIPTION AND DEMONSTRATION OF THE VARIOUS PROCESSES OF THE ART; INCLUDING ALL THE NEW OPERATIONS, AND EXHIBITING THE STATE OF SURGICAL SCIENCE IN ITS PRESENT ADVANCED CONDITION.

BY JOSEPH PANCOAST, M. D.,

Professor of General, Descriptive and Surgical Anatomy in Jefferson Medical College, Philadelphia.

*Complete in One Royal 4to. Volume of 380 pages of letterpress description and Eighty Large 4to. Plates, comprising 485 Illustrations, and being the only complete work on the subject in the English Language. Price, full bound in cloth, only \$10.*

"This excellent work is constructed on the model of the French Surgical Works by Velpeau and Malgaigne; and, so far as the English language is concerned we are proud as an American to say that, OF ITS KIND IT HAS NO SUPERIOR."—*New York Journal of Medicine.*

"For this beautiful volume, the student and practitioner of Surgery will feel grateful to the ability and industry of Prof. Pancoast. The drawing and execution of the plates are splendid examples of American art, and do credit to Messrs. Cichowski and Duval, while the description is no less creditable to the author. We have examined the book with care, and feel great pleasure in declaring that in our opinion, it is a most valuable addition to the surgical literature of the United States. It was a happy idea to illustrate this department of surgery, as it renders perfectly clear what the very best verbal description often leaves obscure, and is, to some extent, a substitute for witnessing operations. To those practitioners especially, who are called upon occasionally, only, to perform operations, we are not acquainted with any volume better calculated for reference prior to using the knife. There are similar works published in Europe, but they are much more expensive, without being superior in point of usefulness to the very cheap volume before us.

"All the modern operations for the cure of squinting, club foot, and the replacing lost parts and repairing deformities from partial destruction of the nose, &c., are very clearly explained and prettily illustrated. It is questionable whether any thing on this subject can be better adapted to its purpose, than Pancoast's Operative Surgery."—*Saturday Courier.*

## GODDARD ON THE TEETH.

THE

## ANATOMY, PHYSIOLOGY, AND DISEASES

OF THE

## TEETH AND GUMS.

WITH THE MOST APPROVED METHODS OF TREATMENT, INCLUDING OPERATIONS, AND A GENERAL ACCOUNT OF THE METHOD OF MAKING AND SETTING

## ARTIFICIAL TEETH.

BY PAUL BECK GODDARD, M. D.,

Demonstrator of Anatomy in the University of Pennsylvania.

In One 4to. Volume, illustrated by 30 beautifully executed Plates, each containing Numerous Figures, handsomely bound in Cloth Gilt. Price \$6.

*Uniform with "Quain's Anatomy," "Pancoast's Surgery" and "Moreau's Midwifery."*

"We do not possess a modern work on Dental Surgery, written by a British author, which equals that of Dr. Goddard. One reason for this may arise from the circumstance, that the learned author is a practical anatomist, whose knowledge is on a level with the modern discoveries, and who has himself authenticated the latest researches into the minute anatomy of the dental structure. It is quite apparent that such knowledge must prove of immense value in enabling any one to arrive at just conclusions relative to the diseases of the teeth; and it is chiefly to be attributed to the want of such knowledge that most writers on Dental Surgery have erred so much relative to the causes and nature of these diseases.—This work may confidently be recommended, as containing the *best and most approved methods of performing all the operations connected with Dental Surgery.*

"We cannot close our remarks without adverting to the thirty very beautiful lithographs which illustrate the text. They render it quite impossible to misunderstand the author, and afford a very favourable example of the advanced state of the Art on the American Continent."—*Edinburgh Medical and Surgical Journal*, 1844.

## MOREAU'S GREAT WORK ON MIDWIFERY.

## A PRACTICAL TREATISE ON MIDWIFERY:

EXHIBITING

THE PRESENT ADVANCED STATE OF THE SCIENCE.

By F. G. MOREAU.

Translated from the French by T. FORREST BETTON, M. D., and Edited by PAUL BECK GODDARD, M. D.

THE WHOLE ILLUSTRATED BY

EIGHTY SPLENDID QUARTO PLATES,

WHICH ARE EITHER

THE SIZE OF LIFE

OR

EXACTLY HALF THE SIZE.

Upon which the first artists have been employed, and which are fully equal, if not superior, to the original, and the publishers can safely pronounce it

THE MOST SPLENDID WORK ON MIDWIFERY

EVER PUBLISHED.

*Now complete in one large 4to. volume, of the size of "Quain's Anatomy," "Pancoast's Surgery," and "Goddard on the Teeth."*

Price TEN DOLLARS, full bound in cloth.

"The work of Professor Moreau is a treasure of Obstetrical science and practice, and the American edition of it an elegant specimen of the arts."—*Medical Examiner*, August, 1844.

"A splendid 4to., containing eighty lithographic plates, true to the life, has been some weeks before us—but we are groping our way through a mass of new works, with a full expectation of soon doing justice to the merits of this elaborate and truly beautiful work."—*Boston Med. and Surg. Journal.*

"Moreau's treatise is another valuable work upon the science of Midwifery, with eighty of the most splendid lithographic plates we have ever seen. THESE ILLUSTRATIONS ARE ENGRAVED WITH SO MUCH BEAUTY AND ACCURACY AND UPON SO LARGE A SCALE, that they cannot fail to present to the eye the precise relation of the fetus and of the parts engaged in labour, under every condition and circumstance, from the commencement of the state of natural parturition, to the most difficult and complicated labour. The profession are greatly indebted to French industry in pathological and special anatomy for the continued advance in the science of Obstetrics; and the work before us may be regarded as the completion of all that has accumulated in this department of medical science, greatly enhanced in value by many valuable original suggestions, to the proper arrangement of which the author has devoted a great amount of labour. The translation is faithfully and elegantly done and the work will be a valuable addition to the medical literature of our country."—*The New York Journal of Medicine.*

# PRINCIPLES AND PRACTICE OF MEDICINE.

BY

JOHN ELLIOTSON, M. D., F. R. S.

COMPLETE IN ONE VOLUME.

WITH NOTES AND ADDITIONS ADAPTING IT TO THE UNITED STATES.

BY

THOMAS STEWARDSON, M. D.,

PHYSICIAN TO THE PENNSYLVANIA HOSPITAL.

Among other additions, the American Editor has introduced entirely new articles upon

## REMITTENT FEVER AND YELLOW FEVER,

AS WELL AS CONSIDERABLE ADDITIONS TO THE ARTICLE ON

CONTINUED FEVER.

"Under such circumstances, we cannot but congratulate the profession in this country that it has now been placed within their reach, under the auspices of an editor whose ample experience and especial study of fevers have enabled him to add several chapters and notes, which materially enhance the usefulness of this treatise. We refer, in particular, to Dr. Stewardson's chapter on Remittent and Yellow Fevers, diseases so prevalent in many sections of this country, and which had received but very cursory notices in the original work. Dr. Stewardson has given an account of Cholera Infantum, a disease peculiar to this country, and which, therefore, rarely attracts the attention of European writers."—*American Medical Journal*, January, 1844.

A

## PRACTICAL TREATISE

ON THE

## DISEASES OF THE TESTIS,

AND OF THE

## SPERMATIC CORD AND SCROTUM.

BY

J. B. CURLING.

EDITED BY

P. B. GODDARD, M. D.

"We have another instance of it in the work of Mr. Curling, a diligent labourer, who has carefully collected every fact within his reach, relative to the diseases of the testis and spermatic cord, producing a VOLUME THAT MAY FOR MANY YEARS BE THE STANDARD WORK ON THOSE DISEASES. We shall conclude our notice with an extract relative to a new and promising method of treating varicose veins, and take leave of the volume by warmly recommending that it be added to the library of every surgeon."—*London Lancet*, August, 1843.

"A work on these diseases, not only superior to any yet published, but which, we imagine, is not likely to be soon superseded by a better."—*British and Foreign Medical Review*.

"Goddard's Curling.—Messrs. Carey & Hart, Philadelphia, have unquestionably the credit of publishing the most beautifully executed Surgical work that has yet appeared on this side of the Atlantic. The printer, Mr. Sherman, has proved that wood engravings may be as well printed here as in Europe.

"This faithful reprint of Curling's admirable volume supplies a desideratum to the surgical literature of the day, having been carefully revised and enriched by several judicious notes by Dr. Goddard. All surgeons and practitioners who have occasion to treat patients suffering from hydrocele, orchitis, or other diseases of the same locality, will be glad to possess this volume, being filled as it is, with practical instruction for the management of some of the most afflicting diseases man is heir to.

"This intimation of the existence of a valuable and beautiful surgical book ought to be sufficient to induce practitioners, as well as students, to seek for, and examine it themselves."—*North American*.

# ENCYCLOPEDIA OF CHEMISTRY.

Now Ready, Parts 1 to 9, Price 25 Cents.

THE

## ENCYCLOPEDIA OF CHEMISTRY, THEORETICAL AND PRACTICAL.

Presenting a complete and extended view of the present state of Chemical Science, with its numerous and important applications to Medical Science, Agriculture, the Arts, and Manufactures; based upon the plan of the Dictionary of Chemistry, by Dr. Ure, and the Dictionary of Theoretical and Practical Chemistry, now publishing by Liebig, Poggendorf, Woehler, &c.

BY JAMES C. BOOTH,

Member of the American Philosophical Society, and of the Academy of Natural Sciences, Professor of Technical Chemistry in the Franklin Institute, and of Elementary Chemistry in the Philadelphia High School.

The facility for easy reference offered by the Dictionary, (rendering that form preferable to any other for works on science and the arts,) has induced the author to adopt it in the publication of an

### ENCYCLOPEDIA OF PRACTICAL AND THEORETICAL CHEMISTRY,

which, while it will embrace all the latest discoveries in the pure science of chemistry, shall at the same time exhibit the manifold applications of chemical principles and theories to every department of the useful arts.

The rapid advancement of chemical science in the path of discovery within a few years, has created a demand for treatises upon this subject which has not been fully answered by the several elementary works lately issued from the English press.

While these works must be mentioned with unqualified praise as text-books for the student of chemistry, it must at the same time be acknowledged that since they offer little more than an outline of the science, they cannot satisfy the thirst for more extended treatises, which may be employed as valuable works of reference by the advanced scholar, while their practical tendency shall enable the uninitiated to enter actively into the vast field of research.

The *ENCYCLOPEDIA OF CHEMISTRY* is designed to meet the varied wants of the student of science, the physician, the agriculturist, and the manufacturer. The first and second will find the whole theory of chemistry fully developed, as contained in the original essays of all the great and leading chemists, among whom we place Berzelius, Liebig, Woehler, Rose, Mitscherlich, Zeisse, &c., Dumas, Pelouze, Fremy, &c., Graham, Kane, Hare, and many others in Europe, and in our own country. They will find all the important recent discoveries in organic and inorganic chemistry, and practical treatises on the several branches of analysis.

The sciences of Mineralogy and Geology will receive their full share of attention, more especially in their chemical relations, and where they admit of such application.

It will be seen from the hasty sketch of the design of the work presented above, that it is intended as a complete *Encyclopedia of Chemistry* both in theory and practice, and that while the pure theoretic nomenclature will be adopted in the one part, the second shall be so developed as to bring it within the reach of those not fully conversant with chemical principles.

### TERMS OF PUBLICATION.

This work will appear in semi-monthly numbers, and in addition to numerous wood cuts, will contain many beautifully engraved plates, and will be completed in Twenty Numbers, at 25 cents each.

CAREY & HART, Publishers.

Extract from the *Edinburgh New Philosophical Journal*, October, 1844.

"The Encyclopedia of Chemistry, Theoretical and Practical; presenting a complete and extended view of the present state of Chemical Science. By James C. Booth, Member of the Am. Phil. Society, &c.; and Martin H. Boyé, Member of the Am. Phil. Society. Carey & Hart, Philadelphia. Six Nos. of this work have reached us. Judging from the industry, research, and accuracy of the authors, we anticipate that when finished it will contribute to the advancement of CHEMICAL SCIENCE, AND FIND A PLACE IN EVERY CHEMICAL LABORATORY AND LIBRARY. The style too, in which it is got up is very creditable to the American publishers."

IN PRESS,

## A WORK ON SURGICAL DISEASES.

With about seventy finely engraved Plates, illustrative of the Pathology, and various methods of Treatment.

IN ONE QUARTO VOLUME.
